A TELEGRAM has been received from Prof. Hull, F.R.S., the chief of the Geological Expedition to the Holy Land, announcing the safe arrival of himself and his party at Gaza, where they are at present detained in quarantine. A letter, dated December 2, was also received from him a few days ago, which has been brought by camel post *viâ* Naklhl from Akabah, where the party arrived on November 27. In this letter Prof. Hull writes:—"We had every reason to be satisfied with the conduct of our Towârah Arabs. We spent three days in the neighbourhood of Jebel Musa, and made the ascent of the mountain, from the top of which Major Kitchener took angles to several prominent points; while on the same day Mr. Hart ascended Mount Catharina, a feat hitherto unperformed in one day, and was rewarded by finding several plants—representatives of colder climates. From Jebel Musa to Akabah we took the upper route, partially explored by Palmer. This has enabled us to add considerably to the accuracy of the geology and topography of the district; we have also taken a considerable number of photographs. On Saturday week we traversed a magnificent gorge cut through granite cliffs and extending for several miles, which, we believe, has not hitherto been described. It commences at the head of the Wady el Ain. We found the escarpment of the Tih much more broken and indeterminate than is represented in the maps, owing to the existence of several large faults or dislocations of the strata which traverse that district in a generally northerly and southerly direction, and we have finally determined the position of the leading line of fracture to which, at least, this portion of the Wady el Arabah owes its existence. Our course through to the Dead Sea by the valley is barred, owing to a blood feud between two tribes. We have, however, contracted with one of the tribes to be escorted as far as the Wady Musa and Petra, after which we shall strike off west across Tih Plateau to Gaza. This will enable us to do the greater part of the work in the Wady Arabah which we proposed. We are all in good health, and have made excellent collections to illustrate the botany, geology, and zoology of the district."

THE budget of the Ministry of Public Instruction in France reaches the unprecedented sum of six millions sterling. Half of this sum is absorbed by the primary and infant schools. The dotation for astronomy and meteorology is 40,000*l*., exclusive of municipal credits voted by Marseilles, Toulouse, Bordeaux, Lyons, for their astronomical observatories; Besançon, Clermont, Paris, and Toulouse, for Besançon, Puy de Dôme, Montsouris, and Pic du Midi meteorological establishments. The National Library of Paris receives 30,000*l*., and other public libraries in Paris, 11,000*l*; National Archives, 8000*l*. The pecuniary grants given to learned men amount to 8000*l*.; voyages and missions, 11,000*l*.; Collège de France, 20,000*l*.; Superior Normal School, 20,000*l*.; National Institute, 28,800*l*.; Academy of Medicine, 3000*l*.; School of Hautes-Études, 19,000*l*.; Faculté d'État (Universities), 400,000*l*.; Grammar Schools (Lycées), 319,000*l*.; Museum (Jardin des Plantes), about 40,000*l*.

THE following arrangements have been made for the meetings of the Society of Arts. The papers to be read at the ordinary meetings will be:—Electric Launches, by A. Reckenzaun; Science Teaching in Elementary Schools, by William Lant Carpenter; Coal Gas as a Labour-Saving Agent in Mechanical Trades, by Thomas Fletcher; Sanitary Progress, by B. W. Richardson, F.R.S.; The Progress of Electric Lighting, by W. H. Preece, F.R.S.; Forest Administration in India, by Dr. Brandis, F.R.S.; Reclamation of Land on the North-Western Coast of England, by Hyde Clarke; Water Regulation in England, by General Rundall; Telpherage, by Prof. Fleeming Jenkin, F.R.S.; New Process of Permanent Mural Painting (invented by Adolph Keim, Munich), by Rev. J. A. Rivington; Slate Quarrying, by W. A. Darbishire. At the meetings of the Sections the following papers will be read:—Foreign and Colonial Section—Canada as it will appear to the British Association in 1884, by Joseph G. Colmer, Secretary to the High Commissioner for Canada; The Portuguese Colonies of West Africa, by H. H. Johnston; Reflections on Chinese History, with reference to the present situation of affairs, by Demetrius G. Boulger; Borneo and its Products, by B. Francis Cobb; The Rivers Congo and Niger as Entrances to Mid-Africa, by R. Capper. Applied Chemistry and Physics Section—Manufacture of Gas from Limed Coal, by Prof. Wanklyn and W. J. Cooper; The Upper Thames as a Source of Water Supply, by Dr. Percy F. Frankland; Cupro-Ammonium Solution and its Use in Waterproofing Paper and Vegetable Tissues, by C. R. Alder Wright, F.R.S.; Economic Applications of Seaweed, by Edward C. Stanford. Indian Section—State Monopoly of Railways in India, by J. M. Maclean; The New Bengal Rent Bill, by W. Seton-Karr; Trade Routes in Afghanistan, by Griffin W. Vyse; The Existing Law of Landlord and Tenant in India, by W. G. Pedder. The courses of Cantor lectures will be on Recent Improvements in Photo-Mechanical Printing Methods, by Thomas Bolas; The Building of London Houses, by Robert W. Edis, F.S.A.; The Alloys used for Coinage, by Prof. W. Chandler Roberts, F.R.S., Chemist of the Royal Mint; Some New Optical Instruments and Arrangements, by J. Norman Lockyer, F.R.S.; Fermentation and Distillation, by Prof. W. Noel Hartley.

THE Portuguese explorers, Senhores Capello and Ivens, have just sailed for West Africa. They proceed first to Loanda, thence northward to Zaire. It is expected that they will be absent for about two years.

M. ACHARD's continuous electric brake has been worked successfully in competition with the Westinghouse and other systems. The electricity is obtained by a dynamo worked by the train itself, and can give light for signals and other purposes, when worked by the engine. The sliding valve of locomotives for admitting steam has been replaced by a piston, which renders similar service. A large diminution of friction and wear results from this improvement. The economy in coals is stated to have been 5 per cent.

DR. NACHTIGAL, the well-known African traveller, who is now German Consul-General at Tunis, has received the gold medal for Art and Sciences from the Grand Duke of Mecklenburg-Schwerin.

THE members of the International Polar Commission will meet in Vienna early in May next, where preparations for this meeting are already being made.

THE death is announced of Dr. Wilhelm Gintl, an eminent telegraph engineer, and formerly director of all Austrian telegraphs. He died at Prague on December 22, 1883, aged eighty years.

LIEUT. WOHLGEMUTH, the leader of the Austrian Polar Expedition, has read a paper on the results of the Expedition at the last meeting of the Viennna Geographical Society; 124 auroræ were observed, amongst which about ten were crown-shaped. Amongst the old lava streams and in the crevices of the numerous craters of the island of Jan Mayen, Lieut. Wohlgemuth found traces of a still progressing volcanic activity, and three times observed well-marked subterranean shocks.

A SERIES of ornithological observatories has been established throughout Austria-Hungary at the instance of Crown Prince Rudolf, with a view of paying special attention to the migrations of birds, as well as to their breeding habits. The work done by these stations is satisfactory enough; yet it has been found that a complete insight into the periodical movements of birds cannot be obtained so long as similar stations are not spread over the whole globe. The subject is to form one of the principal topics for discussion at the approaching Ornithological Congress, which will be held under the auspices of the Crown Prince at Vienna on April 16 next and the following days.

AT Cobern, near Coblenz, a Franconian burial-ground has been discovered, containing many objects of interest, such as ornaments, weapons, glass and clay vases, stones with inscriptions, &c.

THE Turin Academy of Sciences has given a prize (480*l.*) to Mr. Hormuzd Rassam for his discoveries in the domain of Assyrian and Babylonian antiquities.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♀) from India, presented by Madame Kettner; two Rhesus Monkeys (*Macacus rhesus* ♂ ♀) from India, presented by Mr. G. Glyn Petre, F.Z.S.; a White-throated Capuchin (*Cebus albifrons* ♀), a Crab-eating Opossum (*Didelphys cancrivora*) from the West Indies, presented by Lady Brassey, F.Z.S.; a Common Genet (*Genetta vulgaris*) from West Africa, presented by Capt. A. North Daniel; a Canadian Porcupine (*Erithizon dorsatus*) from North America, presented by Mr. A. Glidden; a Kinkajou (*Cercoleptes caudivolvulus*) from Brazil, presented by Dr. Byres Moir; a Ring-hals Snake (*Sepedon hæmachates*), a Robben Island Snake (*Coronella phocarum*), an Egyptian Cobra (*Naia haje*), a Rhomb-marked Snake (*Psammophylax rhombeatus*), a Many-spotted Snake (*Coronella multimaculata*), a Hissing Sand Snake (*Psammophis sibilans*), a Smooth-bellied Snake (*Homalosoma lutrix*), a Spotted Slow-worm (*Acontias meleagris*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; two Gold Pheasants (*Thaumalea picta* ♂ ♀) from China, two Common Peafowls (*Pavo cristatus* ♂ ♀) from India, deposited; five Knots (*Tringa canutus*), a Common Guillemot (*Lomvia troile*), British, purchased.

OUR ASTRONOMICAL COLUMN

THE SOLAR MOTION IN SPACE.—The recently published volume of the *Memoirs of the Royal Astronomical Society* contains a paper by Mr. W. E. Plummer, of the Oxford University Observatory, on the Motion of the Solar System. The data on which the author has founded his discussion are the proper motions of the stars in the southern hemisphere, as determined by Mr. Stone in the Cape Catalogue. The work is therefore a repetition and extension of the inquiry conducted by the late Mr. Galloway, and it would appear that the necessity of a rediscussion was suggested to Mr. Plummer by the discordances between the values of the proper motions there employed and those given by Mr. Stone. To illustrate the uncertainty in the result, particularly when based upon an insufficient number of stars, the position of the apex of the solar system is first derived from the same list of stars as that used by Mr. Galloway, but with improved values of the proper motion. The more trustworthy result from these restricted data places the apex in the constellation Ophiuchus some thirty degrees south of the generally received position.

Incorporating, however, all the southern stars whose known proper motions exceed one-tenth of a second (which raises the number of stars employed to 274), a more accordant result is obtained. If the apparent magnitude be adopted as a criterion of distance, and the irregularities of proper motion be supposed due to the peculiar motions of the stars themselves, the co-ordinates of the apex are $\alpha = 270^\circ\ 8'$, $\delta = +\ 20^\circ\ 20'$, and the annual motion of the sun, viewed from the mean distance of the first magnitude stars, subtends an arc of $1''\cdot690$. Unfortunately, if the corrections computed on this supposition be applied to the individual proper motions, the sum of the squares of the residuals is slightly larger than the sum of the squares of the original motions.

Selecting as a second hypothesis the suggestion that the distances of the stars vary inversely as their proper motions, the position of the apex is given in $\alpha = 276^\circ\ 8'$ and $\delta = +\ 26^\circ\ 31'$, and the annual motion of the sun seen from the distance of stars whose annual proper motion is about $1''\cdot5$ seconds of arc, is $0''\cdot926$. Introducing the necessary corrections, the sum of the squares of the proper motion in R.A. is reduced from $124''\cdot9$ to $70''\cdot4$, and in declination from $54''\cdot6$ to $39''\cdot3$, a result that tends to support the reality of the second hypothesis.

THE LATE M. YVON VILLARCEAU.—Antoine-François-Joseph-Yvon Villarceau was born at Vendôme on January 15, 1813. He first studied in the local college, and subsequently went through the course of instruction at the Conservatoire in Paris, where, in 1833, he gained a first prize. In the same year he proceeded to Egypt with Felicien David, and joined the mission under Enfantin: in this way his attention was directed to engineering. Returning to France in 1837 he was admitted to the École Centrale, which he left in 1840, being then first in the Mechanical Section. Already possessed of an independent fortune, in the years immediately following he was chiefly occupied with mathematical studies, with the view to qualify himself for the higher branches of mechanics and astronomy. In 1845 his first memoir upon comets, which was judged worthy of insertion in the "Recueil des Savants Etrangers," brought him under the notice of Arago, who, impressed with the originality of his ideas, offered him, in 1846, a place at the Observatory of Paris, to which establishment he was attached until the close of his life, at first as assistant, and since 1854 as titular astronomer. Villarceau was the author of a large number of memoirs upon mechanical and geodetical subjects, amongst others, on the stability of locomotives in motion, and on the theory of arches, accompanied by extensive tables and numerous practical applications, on the theory of the gyroscope of Foucault, and the compensation of chronometers; he made geodetical determinations in France between 1861 and 1865, which led to several important deductions. Amongst his earlier astronomical work was the development and application of a new method of investigating the orbits of the revolving double-stars, which he applied to η Coronæ Borealis and other binaries; this was followed by a memoir on the determination of the orbit of a planet, founded on the method of Laplace. In 1851, on the discovery by D'Arrest of the short-period comet which bears his name, Villarceau determined the orbit rigorously, and by means of his predicted places the comet was again observed, in 1857, by Maclear at the Cape of Good Hope. It was upon his plans that, while Leverrier was in direction of the Observatory of Paris, the great equatorial in the west tower, which constituted a notable advance in the construction of such astronomical instruments, was erected. Villarceau died on December 23. At the funeral discourses were delivered by Col. Perrier in the name of the Academy of Sciences (of which Villarceau had been a member, in the Section of Hydrography and Navigation, since 1867); by M. Faye in the name of the Bureau des Longitudes; and by M. Tisserand in that of the Paris Observatory.

THE ENGLISH CIRCUMPOLAR EXPEDITION[1]

On April 14, 1882, I was informed that I was appointed to the command of the Circumpolar Expedition. I at once proceeded to London, and was occupied until the day of sailing in practice with the magnetic instruments at the Kew Observatory, and the purchase of stores, &c., for the expedition.

On May 1 Sergeant F. W. Cooksley, Royal Horse Artillery, and Gunner C. S. Wedenby, Royal Artillery, and on May 6 Sergeant Instructor of Gunnery J. English, R.H.A., reported themselves to me, and commenced attendance at Kew for instruction.

Journey to Fort Rae.—We sailed from Liverpool on May 11, and arrived at Quebec on the 23rd. Here I spent some days, finding that the steamer for the north did not leave Winnipeg till June 10, and my party was very kindly afforded quarters in the citadel by Lieut.-Col. Cotton, commanding the Canadian Artillery at that place.

Having obtained a free pass for our baggage on the Grand Trunk Railway, I started at once for Winnipeg, proceeding by the lakes, that being the cheaper route, and the one which, on the whole, exposed the instruments to the least knocking about.

We reached Winnipeg on June 9, and left on the following day by the *Saskatchewan* steamer. On June 26 we reached Carlton, where it was necessary to engage carts to take our baggage to Green Lake, a distance of 140 miles.

On the 29th the carts were taken across the river, and on the 30th we started for Green Lake, which we reached on July 9, having been delayed by the extreme badness of the road. The heat of the weather also rendered a long halt necessary in the middle of the day, and the flies prevented our animals from feeding properly, incapacitating them for long marches or fast work, and on one occasion forcing us to halt for a whole day, the oxen being so worried by them as to be unable to march.

At Green Lake we entered upon the system of water communication that forms the only roadway in the north, and by way of Portage la Loche, and the Clearwater and Athabasca Rivers, we reached Fort Chipewyan on July 30. Here we had to await the Mackenzie River boats, there being no other means of reaching Fort Rae, and it was not until August 17 that we were able to start on this last stage of our journey. We reached Great Slave Lake on the 22nd, on the evening of which day a gale arose which stove in and sunk our boat, damaging most of our provisions. Fortunately we were able to repair the boat, but it was not until the 25th that the weather allowed us to proceed, and on the 27th we were again detained by a fresh storm, so that it was not until 10 p.m., on August 30, that we arrived at Fort Rae.

Fort Rae.—Fort Rae is situated in lat. 62° 38′ 52″ N., and long. 115° 43′ 50″ W., at the south-west extremity of a peninsula that juts out from the north-east shore of a long gulf running in a north-westerly direction for more than 100 miles from the northern shore of the Great Slave Lake. It is almost entirely surrounded by water, as shown in the annexed plan. The formation is limestone. The land rises to a height of some 200 feet, and it is covered in part with moss, in part with pines and scanty brushwood. A few vegetables are grown in the summer in the garden attached to the Roman Catholic Mission, but for food the inhabitants chiefly depend upon the produce of the nets, and on deer, which are brought in by the Indian hunters attached to the post.

On arrival it was found that the magnetic instruments required a good deal of setting to rights, their boxes being filled with water and the fittings loosened, so that not a single instrument was quite in working order. There was, moreover, no building ready for their reception, so that it was not possible to keep August 31—September 1, as a term day, but we succeeded in getting the meteorological instruments in position so as to commence observations with them at midnight on the 31st.

We were fortunate in finding a building that admitted of conversion into a magnetic observatory, it only requiring a floor, fireplace, door, and windows to be habitable. This work was at once commenced, and on September 3 the declinometer, on the 4th the bifilar, and on the 6th the vertical force magnetometer were mounted in their places. This observatory was finished on September 10, and another one commenced for astronomical and absolute magnetic observations, the continual wind rendering out-door observations unsatisfactory.

The men of my party were accommodated in the house of one of the sub-officers of the fort, and I had a room in the house of the Hudson's Bay Company's officer in charge.

The instruments, on the whole, suffered but little from the journey. One barometer and one thermometer were broken, and the object glasses of the telescopes of most of the magnetic instruments were nearly opaque, the cement joining the two lenses having, from some cause or other, melted on the journey. Our provisions were more damaged, 190 lbs. of sugar, 30 lbs. of tea, all our rice, and most of our baking powder having been destroyed.

The observations were then carried on without interruption until August 31, 1883.

Magnetic Observations.—The balance magnetometer was the only magnetic instrument whose performance was not satisfactory, as not only did it frequently get out of adjustment, but in times of magnetic disturbance it often vibrated through so large an arc that exact reading was impossible. The other instruments were remarkably free from vibration, and there was never any difficulty in reading them, but it was found necessary to extend the scale of the bifilar on the side of decreasing force, owing to the great movements of this instrument.

The greatest magnetic disturbance was on November 17, 18, and 19, 1882, when all the instruments moved at times beyond the limits of their scales. On the first of these days the difference between the extreme easterly and westerly positions of the declinometer magnet exceeded 10°.

Aurora.—Aurora was observed on almost every clear night, and was usually attended by more or less magnetic disturbance. It did not appear to me, however, that the two phenomena stood in the relation of cause and effect, but rather that they were both due to a common cause. The most marked instance of connection between the two phenomena consisted in a rapid decrease in both vertical and horizontal magnetic forces which attended a sudden outburst of aurora in the zenith. This was observed on several occasions. The bifilar almost always showed a reduction of horizontal force during a display of aurora. I also think that the declinometer magnet tended to point towards the brightest part of the aurora, but that (*sic*) I have not yet had time to make that careful comparison of the auroral and magnetic observations which will be required to decide this point. It was found impossible to obtain photographs either of the aurora or of its spectrum—the latter invariably presented the characteristic yellowish green line, and occasionally, but rarely, several other bright lines were visible for a few moments towards the violet end of the spectrum, and once a bright band was seen in the red.

I was also unsuccessful in my attempts to measure the height of the aurora, chiefly from the want of a well defined point to measure to, also from the fact that some hours were required to prepare for this observation, whereas the appearance of a suitable aurora could not be predicted, and was, in fact, not of frequent occurrence, and then often only lasting a few seconds. For this observation two stations some miles apart should be connected by telegraph and occupied for many days, or even weeks, in succession.

Although I paid attention to the point, I never heard any sound from the aurora save on the occasion mentioned in a former memorandum, but I made many inquiries on the subject from residents in the country, both English and French, and their statements agree so well, both with one another and with what I myself heard, that I am forced to conclude that the aurora is at times audible, and that on these occasions it appears to be, and probably is, very near the earth.

Meteorological Observations.—With regard to the meteorological observations, the station was somewhat unfavourably placed for observations of wind, on account of the hill to the north-east, but as winds from this quarter were rare, the effect on the results will not be great, especially as one of the anemometers was on an island in the lake, in an entirely open situation.

The anemometers did not work quite satisfactorily, being at times choked by ice; but I hope by the comparison of the two satisfactory results may be attained.

The wind was usually either south-east or north-west; and when it blew from the former quarter, the motion of the upper clouds often showed the existence of a north-westerly current.

The hair hygrometers were found to be useless out of doors in cold weather, on account of the formation of ice on the hair.

The earth thermometers were read every alternate day: the observations were interrupted by a carcajou, or other animal, which extracted the thermometers from their tube for the sake of the fur in which it has been found necessary to envelop them, and broke them all; other thermometers were, however, substituted, and the observations continued. It was found impossible to obtain the temperature of the soil at a greater depth than four feet, on account of the rocky nature of the ground.

---

[1] "Report on the Circumpolar Expedition to Fort Rae," by Capt. H. P. Dawson, R.A. Communicated to the Royal Society by Prof. G. G. Stokes, Sec.R.S.

A series of observations of terrestrial radiation was made by means of a thermometer placed on the surface of the snow, but the almost continual wind detracts much from the value of these readings.

I was told by the residents of the country that the year was an unusually dry one, and certainly the rainfall is remarkably small; they also said that the winter was particularly mild and free from storms, which, from all accounts, and from the journals kept at the fort, seem to be both frequent and severe; as it was, we only experienced one, in February.

Astronomical Observations.—My first determination of the longitude was made by means of lunar distances, and time was found by the method of equal altitudes, but after the observatory was finished both these points were determined by transits, and the first value of the longitude found to be more than a minute in error. The latitude was determined by transit observations in the prime vertical, and is probably within a few seconds of the truth. The longitude may be ten seconds in error. The time was generally correct to within three or four seconds.

A more solidly constructed transit instrument would have been desirable, as it was found that in the cold weather it required so much force to move the telescope of the transit theodolite on its axis that there was great risk of disturbing the adjustments of this instrument, composed as it is of so many parts.

Food, &c.—Our supply of provisions proved quite sufficient. I had brought enough flour to admit of my issuing the usual ration of $\frac{3}{4}$ lb. per diem, and tobacco 1 lb. per month to each man. We also had a supply of Chollet's preserved vegetables, and a reserve stock of bacon, besides tea and sugar. Of the latter we were somewhat short, owing to the loss sustained on the journey up. We usually had fresh meat throughout the winter; in the summer we were occasionally reduced to dried meat. During the journey there and back we chiefly lived on pemmican. The Rev. Père Roure, of the Roman Catholic Mission, most kindly furnished us with fresh vegetables and potatoes throughout the summer.

The conduct of the men under my command was everything that could be desired. They took great interest in the observations, and did their best to carry them out with accuracy and punctuality, and were always contented and cheerful, in spite of the inevitable discomforts of their winter quarters and the occasional hardships of the journey.

Return Journey.—We were running great risks of being overtaken by the winter, and therefore lost no time in our departure.

The last hourly observation was made at midnight on August 31, 1883, after which the instruments were dismounted and packed, their cases having been previously arranged in readiness outside the observatory. The remainder of the baggage was already in the boat, so that by 2.30 a.m. on September 1 we were *en route*, and reached Fort Chipewyan on September 17, and Portage la Loche on October 4, having experienced some delay in surmounting the rapids of the Clearwater, the hard frosts having frozen all the small tributary streams, thus considerably lowering the water in the river.

The boat awaiting us on the south side of the portage was frozen in, but fortunately the wind changed and the ice broke up before our arrival. Had it been otherwise, we must have waited until the rivers were thoroughly frozen and travelling with dog-trains possible. In that case we should have been compelled to abandon our instruments and baggage.

On the 21st we reached Carlton on the Saskatchewan, where we were detained a day, the man engaged to transport our baggage across the prairie having refused to proceed. Another man was engaged, and on October 31 we reached the railway at Qu'Appelle, arriving at Winnipeg the following day. We were fortunate in crossing the prairie with so little difficulty, as at the same time last year it was covered with three feet of snow.

At Winnipeg I remained a couple of days to adjust accounts with the Hudson's Bay Company, and on November 4 we started for Quebec, going by rail *via* Chicago. We reached Quebec on the 8th, and Liverpool on November 20.

In conclusion, I have to acknowledge the assistance received from the officers of the Hudson's Bay Company, who spared no trouble in carrying out my wishes, especially Chief Commissioner Grahame at Winnipeg, Chief Factors MacFarlane and Camsell in charge of the Athabasca and Mackenzie River Districts respectively, and Mr. King in charge at Fort Rae. To their hearty co-operation the success of the expedition is in great part due.

Results of Expedition.—The following is a list of the observations taken at Fort Rae, the result of our year's work there, which I have now the honour to lay before the Royal Society:—

Magnetic

Hourly—

Declination	from September	3,	1882, to August	31, 1883.
Hor. Force	,,	4,	,,	,,
Vert. Force	,,	6,	,,	,,

Term Day—

In accordance with programme laid down by St. Petersburg Conference—from September 15, 1882, to August 15, 1883.

Occasional—

Absolute observations of Hor. Force Dip and Declination.

Meteorological

Hourly—

Barometer	from Sept. 1,	1882, to	Aug. 31, 1883.
Dry and Wet Bulb Therms.	,,	,,	,,
Anemometer	,,	,,	,,
Wind, Clouds, and Weather	,,	,,	,,
Aurora (when visible)	,,	,,	,,

Hair Hygrometer (when in working order).
Terrestrial Radn. (occasionally in clear weather).

Daily—

Max. and Min. Solar and Terrest. Radn. Therms.
Rain Gauge.

Earth Thermometers every two days.

THE EVIDENCE FOR EVOLUTION IN THE HISTORY OF THE EXTINCT MAMMALIA[1]

II.

COMING to the vertebræ as a part of the osseous system, I will mention the zygapophyses, or antero-posterior direct processes, of which the posterior looks down and the anterior looks up. They move on each other, and the vertebral column bends from side to side. In the lower forms of mammals they are always flat, and in the hoofed mammals of the Puerco period they are all flat. In the Wasatch period we get a single group in which the articulation, instead of being perfectly flat, comes to be rounded; in the later periods we get them very much rounded; and finally, in the latest forms, we get the double curve and the locking process in the vertebral column, which, as in the limb, secures the greatest strength with the greatest mobility. In the first stages of the growth of the spinal cord it is a notochord or a cylinder of cartilage or softer material. In later stages the bony deposit is made in its sheath until it is perfectly segmented.

Now all the Permian land animals, reptiles, and batrachians retain this notochord with the beginnings of osseous vertebræ in a greater or less degree of complexity. There are some in South Africa, I believe, in which the ossification has come clear through the notochord, but they are few. This characteristic of the Permian appears almost alone—perhaps absolutely alone as regards land animals. There is something to be said as to the condition of that column from a mechanical standpoint, and it is this: that the cord exists, its osseous elements disposed about it; and in the batrachians related to the salamanders and the frogs, these osseous elements are arranged under the sheath in the skin of the cord, and they are in the form of regular concave segments, very much like such segments as you will take from the skin of an orange—parts of spheres, and having greater or less dimensions according to the group or species. Now the point of divergence of these segments is on the side of the column. They are placed on the side of the column where the segments separate—the upper segments rising and the lower segments coming downward. To the upper segments are attached the arches and their articulations; and the lower segments are like

---

[1] A lecture by Prof. E. D. Cope of Philadelphia, given in genera session before the American Association for Advancement of Science at Minneapolis, August 20, 1883. Stenographically reported for *Science*. Continued from p. 230.

the segments of a sphere. If you take a flexible cylinder and cover it with a more or less inflexible skin or sheath, and bend that cylinder sidewise, you of course will find that the fractures of that part of the surface will take place along the line of the shortest curve, which is on the side; and, as a matter of fact, you have breaks of very much the character of the segments of the Permian batrachia. It may not be so symmetrical as in the actual animal, for organic growth is symmetrical so far as not interfered with; for, when we have two forces, the one of growth and the other of change or alteration, and they contend, you will find in the organic being a quite symmetrical result. That is the universal rule. In the cylinder bending in this way, of course the shortest line of curve is right at the centre of the side of that cylinder, and the longest curve is of course at the summit and base, and the shortest curve will be the point of fracture. And that is exactly what I presume has happened in the case of the construction of the segments of the sheath of the vertebral column in the lateral motion of the animal swimming always on one side, and which at least has been the actual cause of the disposition of the osseous material in its form. I have gone beyond the state of the discussion in calling attention to one of the forces which have probably produced this kind of result. That is the state of the vertebral column of many of the vertebrata of the Permian period.

I go back to the mammalia, and call attention to the teeth. The ordinary tooth of the higher type of the mammalia, whether hoofed or not, with some exceptions, is complex with crests or cusps. In cutting the complex grinding surfaces we find they have been derived by the unfolding extensions of four original cusps or tubercles. They have been flattened, have been rendered oblique, have run together, have folded up, have become spiked, have descended deeply or have lifted themselves, so that we have teeth of all sorts and kinds, oftentimes very elegant, and sometimes very effective in mechanism. In many primary ungulates, the primitive condition of four conical tubercles is found. In passing to older periods we find the mammalia of the Puerco period, which never have more than three tubercles, with the exception of three or four species. In the succeeding periods, however, they get the fourth tubercle on the posterior side. Finally, you get a complicated series of grinding or cutting apparatus, as the case may be.

Last, but not least, we take the series of the brain. No doubt the generalisation is true, that the primitive forms of mammalia had small brains with smooth hemispheres; later ones had larger brains with complex hemispheres. In general, the carnivora have retained a more simple form of brain, while herbivorous animals have retained a most complicated type of brain. The lowest forms of mammalia display the additional peculiarity of having the middle brain exposed, and the hemispheres or large lobes of the brain, which are supposed to be the seat of the mental phenomena, are so reduced in size at the back end that you see the middle brain distinctly, though it is smaller than in reptiles and fishes. It is beyond the possibility of controversy that these series have existed, and that they have originated in simplicity, and have resulted in complication; and the further deduction must be drawn, that the process of succession has always been towards greater effectiveness of mechanical work. There are cases of degradation, as in the growing deficiency in dentition in man. There is no doubt that a large number of people are now losing their wisdom-teeth in both jaws.

We are now brought to the question of the relations which mind bears to these principles. The question as to the nature of mind is not so complex as it might seem. There is a great deal of it, to be sure; but on examination it resolves itself into a few ultimate forms. An analysis reduces it to a few principal types or departments—the departments of intelligence and of emotions (with their modified smaller forms, likes and dislikes), and the will, if such there be. Those three groups, proposed by Kant, are well known, and adopted by many metaphysicians; and they stand the scrutiny of modern science perfectly well in both men and the lower animals. But the question of the material of the mind, the original raw stuff out of which mind was made, is one which is claiming attention now from biologists, as it always has done from physiologists proper and physicians. This is sensibility, mere simple sensibility, unmodified sensibility, or consciousness. Sensibility, in connection with memory, is sufficient for the accomplishment of wonderful results. It is only necessary to impress the sensibility with the stimuli which this world affords, whether from the outside or the inside, to have the record made, and to have the record kept. Among wonderful things this is perhaps the most wonderful: that any given form of matter should be able to retain a record of events, a record which is made during a state of sensibility for the most part, a greater or less degree of sensibility, which is retained in a state of insensibility, and is finally returned to the sensibility by some curious process of adhesion, and the results of impresses which are found on the material tissue concerned.

And these simple elements of mind are found in animals. No zoologist who has perception or honesty, nor any farmer or breeder, nor any person who has charge of animals in any way, can deny sensibility to all the lower animals at times. The great stumbling-block in the way of the thinker in all this field is the great evanescence of this sensibility: the great ease with which we dissipate it, the readiness with which we can deprive a fellow-being of his sense, is a stumbling-block in more ways than one. While it is a question of the greatest difficulty, nevertheless, like other departments of nature, doubtless it will ultimately be explained by the researches of physiologists. I only need to call attention to the fact as an important factor in evolution.

Of course, if these structures are suggested, affecting the mechanical apparatus, the question arises whether they were made ready to hand, whether the animal, as soon as he got it, undertook to use it, and whether he undertook to use the organism under the dire stimuli of necessity, or amended through ages these modifications in his own structure. We are told by some of our friends that law implies a Lawgiver, that evolution implies an Evolver; the only question is, Where is the Lawgiver? where is the Evolver? where are they located? I may say, it is distinctly proven in some directions, that the constant applications of force or motion in the form of strains, in the form of impacts and blows, upon any given part of the animal organism, do not fail to produce results in change of structure. I believe the changes in the ungulates to which I have called your attention are the result of strains and impacts, precisely as I have shown you the manner of the fracture of the vertebral column of the primitive vertebrates of the Permian period. This would require long discussion to render clear; nevertheless I venture to make the assertion that this series of structures is the result of definite and distinct organic forces, directed to special ends. We have yet to get at the conflicting forces which have produced the results we see. Mechanical evolution will give us a good deal to do for some time to come. Of course, if motion has had an effect in modifying structure, it behoves us to investigate those forces which give origin to motion in animals. First in order come the sensibilities of the animal, which we have traced to simple consciousness; stimuli, upon notice of which he immediately begins to move. The primary stimulus of all kinds of motion is necessarily touch. If a stone falls upon the tail of some animal which has a tail, he immediately gets out of that vicinity. If a jellyfish with a stinging apparatus runs across an eel which has no scales, the eel promptly removes. External applications of unpleasant bodies will always cause an animal to change his location. Then he is constantly assaulted by the dire enemy of beasts, hunger, which is an instinct which is evidently universal, to judge from the actions of animals. This seems to have fashioned, in large part, all forms of life, from the least to the greatest, from the most unorganised to the most complex. Each exercised itself for the purpose of filling its stomach with protoplasm. Then come the stimuli, which should be included under the class of touch, changes of temperature. No animals like to be cold or too hot; and when the temperature is disagreeable the tendency is to go away from that locality. Among primary instincts must be included that of reproduction. After that comes the sensation of resistance, or, carried to a high degree, of anger: when an animal's interests are interfered with, its movements resisted, it prompts to the most energetic displays. So you see it is a matter of necessity that mental phenomena lie at the back of evolution, always provided that the connecting link of the argument—that motion has ever affected structure—be true. That is a point which of course admits of much discussion. I have placed myself on the affirmative side of that question; and, if I live long enough, I expect to see it absolutely demonstrated.

Of course the development of mind becomes possible under such circumstances. It is not like a man lifting himself up by his boots, which it would be if he had no such thing as memory. But with that memory which accumulates, which formulates first habits, and then structures, especially in the soft, delicate nervous tissue, the development of the mind as well as the machinery of the mind becomes perfectly possible. We develop our intellect through the accumulation of exact facts, through the collation of pure facts, no matter whether it be a humble kind of a truth—as the knowledge of the changes of the seasons, which induces some animals to lay up the winter's store—whether it be knowledge of the fact that the sting of the bee is very unpleasant, or knowledge of the fact (of which the ox, no doubt, is thoroughly aware) that the teeth of the wolf are not pleasant to come in contact with, or whether it be the complex knowledge of man. When the cerebral matter has become larger and more complex, it receives and retains a much greater number of impressions, and the animal becomes a more highly educated being.

As regards the department of emotions or passions, it is also much stimulated by the environment. Animals which live in a state of constant strife naturally have their antagonistic passions much developed, while amiable, sympathetic sentiments are better and more largely produced by peace-loving animals. Thus it is that the various departments of the mind have the beautiful results which we now find in the human species.

There are some departments of the mind which some of our friends decline to admit having had such an origin. The moral faculty, for instance, is excepted by many from this series. But the reasons why they object to its production in this way are, to my mind, not valid. The development of the moral faculty, which is essentially the sense of justice, appears to them not to fall within the scope of a theory of descent or of evolution. It consists of two parts. First is the sentiment of benevolence, or of sympathy with mankind, which gives us the desire to treat them as they should be treated. It is not sufficient for justice that it is unmixed mercy, or benevolence, which is sometimes very injurious, and very often misplaced. It requires, in the second place, the criticism of the judgment, of the mature intellect, of the rational faculty, to enable the possessor to dispose of his sentiments in the proper manner. The combination of rational discrimination and true judgment with benevolence constitutes the sense of justice, which has been derived, no doubt, as a summary of the development of those two departments of the mind, the emotions and the intellect.

It is said that a sense of justice could not be derived from the sense of no justice; that it could not have been derived from the state of things which we find in the animals, because no animal is known to exhibit real justice: and that objection is valid as far as it goes. I suspect that no animal has been observed to show a true sense of justice. That they show sympathy and kindness there is no question; but when it comes to real justice they do not display it. But do all men display justice? Do all men *understand* justice? I am very sure not. There are a good many men in civilised communities, and there are many tribes, who do not know what justice is. It does not exist as a part of every mental constitution. I never lived among the Bushmen, and do not know exactly what their mental constitution is; but in a general way the justice of savages is restricted to the very smallest possible circle—that of their tribe or of their own family. There is a class of people who do not understand justice. I do not refer to people who know what right is, and do not do it; but to the primitive state of moral character, in which, as in children, a sense of justice is unknown. I call attention to the fact because some of our friends have been very much afraid that the demonstration of the law of evolution, physical and metaphysical, would result in danger to society. I suspect not. The mode in which I understand this question appears to me to be beneficial to society, rather than injurious; and I therefore take the liberty of appending this part of the subject to its more material aspect.

To refer to another topic, and that is to the origin of life, the physical basis of life. The word "life" is so complex that it is necessary to define it, and so to define it away that really the word "life" does not retain its usual definition. Many phenomena of life are chemical, physical, mechanical. We have to remove all these from consideration, because they come within the ordinary laws of mechanical forces; but we have a few things left which are of a different character. One is the law of growth, which is displayed in the processes of embryonic succession; secondly, the wonderful phenomena of sensibility. Those two things we have not yet reduced to any identity with the ordinary laws of force. In the phenomena of embryology the phenomena of evolution are repeated, only concentrated in the early stages through which animals have to pass. So whatever explains the general phenomena of evolution explains the phenomena of embryology.

What is the nature of physical sensibility? In this planet it is found residing only in one form of matter which has a slightly varied chemical constitution, namely, protoplasm; so called from a physical standpoint. Now this world, as you all know, has passed through many changes of temperature. Its early periods, it is probable, were so very hot that protoplasm had a very poor chance. The earth has passed through a great many changes of temperature, many of which would not permit the existence of protoplasm. Again, can we assume for a moment that this little speck in the great universe is the only seat of life? I suppose scarcely any scientific man will venture to do so. If, therefore, life exists in other parts of this great universe, does it necessarily occupy bodies of protoplasm in those different, remote spheres? It would be a great assumption. It is altogether improbable. The certainty is that in those planets which are in proximity to the sun's heat there could be no protoplasm. Protoplasm in the remote planets would be a hard mineral, and near the sun it would be dissipated into its component gases. So that, if life be found in other parts of this universe, it must reside in some different kind of material. It is extremely probable that the physical conditions that reside in protoplasm might be found in other kinds of matter. It is in its chemical inertness and in its physical constitution that its adaptation to life resides; and the physical constitution necessary for the sustentation of life may be well supposed to exist in matter in other parts of the universe. I only say the door is open and not closed: any one who asserts that life cannot exist in any other material basis than protoplasm is assuming more than the world of science will permit him to assume. And that it is confined to this single planet, and not in the great systems of the universe,—that assumption will not for a moment be allowed. Therefore the subject is one which allows us a free field for future investigation: it is by no means closed in the most important laws which it presents to the rational thinker. I hope, therefore, if the evidence in favour of this hypothesis of the creation of living forms be regarded as true, that no one will find in it any ground for any very serious modification of existing ideas on the great questions of right and wrong, which have long since been known by men as a result of ordinary experience, and without any scientific demonstration whatsoever.

THE REMARKABLE SUNSETS

WE have received the following further communications on this subject:—

REFERRING to Mr. Meldola's letter in your last number (p. 224), I beg leave to state that I likewise observed an astonishing atmospheric luminosity, outside of this town, at 2–3 a.m. in the moonless and foggy night of January 1–2. It is reported that in these days the "Dämerungserscheinungen" have again been very striking at many places in Germany. Here the state of the atmosphere has of late been unfavourable for observing these phenomena; their most brilliant display, a "red glow" of oextraordinary extent and intensity, I witnessed on the morning of December 1, beginning about two hours before sunrise.

The view that these luminosities are caused by volcanic dust acting as nuclei for the condensation of vapour in the higher strata of the atmosphere will have suggested to many of your readers the probability of so-called cosmical dust being often derivable from similar terrestrial sources. To me it has, moreover, recalled an hypothesis on the origin of meteorites, put forth some twenty years ago in an elaborate treatise by Mr. P. A. Kesselmeyer of Frankfort-on-the-Maine ("Abhandlungen der Senckenbergischen Naturforschenden Gesellschaft," vol. iii.). Mr. Kesselmeyer contends for the derivation of meteorites from condensation of metallic and other vapours issued from volcanoes; he distinctly supposes those of Eastern Asia as chief sources, and, among other ingenious reasons for these views, he particularly insists on remarkable statistics of geographical and seasonal distribution of stone-falls (NATURE, vol. xvi. p. 558).

I am well aware of the momentous difficulties of this hypothesis, which fails to explain why such masses of vapour (or dust), after travelling for enormous distances, become condensed into solid bodies. On the other hand, there appears to me not to be such a contradiction to astronomical theories as might seem at first sight; the view in question would merely involve the assumption that there are fireballs and fireballs: those which precede the fall of meteorites being of a distinct nature from those which accompany the periodical swarms of shooting stars, and thereby manifest their cosmical origin. As far as I know there does not exist a connection, which might be expected by the usual theory, between these periodical swarms and increased frequency of stone-falls; on the other hand, it is evident that the late extraordinary manifestations of volcanic activity must furnish a crucial test for the hypothesis in question; if it were right, there must be expected an augmented fall of meteorites to follow this period of dust-spreading. D. WETTERHAN

Freiburg, Badenia, January 5

AMONGST the many interesting points for consideration in connection with the late sunset phenomena is the very general prolongation of twilight produced by them, doubtless from the reflection of the sun's rays from clouds or diffused vapour at a more than ordinary elevation, after the sun had set to all at a lower level. In reference to this subject, Mr. E. Douglas Archibald states that he estimated the height of a *glowing stratum* (*i.e.* diffused clouds) as from ten to thirteen miles; that Miss Ley, from calculation, had given thirteen miles as the height of a similar cloud, and in continuation he says:—"I think this height is far more probable than forty miles, as calculated by Prof. Helmholtz. Besides, can we imagine either vapour, or volcanic dust, or a mixture of both, to be capable of remaining in suspension in the air of such tenuity as must exist at such an altitude?" (NATURE, December 20, 1883, p. 176). To this question I would reply by another, and ask if we can imagine vapour or volcanic dust to be capable of remaining in suspension in air of some 17,000 times less density than water, as, at thirteen miles, high, that is about the calculated comparative density of the two.

Or I will go farther, and ask if any one can imagine that water, which is about 860 times heavier than the air at sea-level, can be suspended in the atmosphere without the aid of some buoyant power.

A theory on the cause of rain, storms, the aurora, &c., which I submitted to the British Association at the Glasgow Meeting, 1840 (see Report), was briefly as follows:—

That, as electricity coats the surface of all bodies, occupies space, and has no weight, in evaporating, the minute particles of water take up electricity in accordance with their surface and temperature, and are buoyed up into the atmosphere by it, where, if condensed (*i.e.* cooled), their capacity for electricity is reduced, and the surcharge is retained or passes away in accordance with the conducting or non-conducting state of the atmosphere. I cannot go further into particulars in this paper, but I may say that I have no knowledge of any phenomenon connected with the cause of rain which is not explicable in accordance with the theory, although forty years' exertion has not enabled me to bring it fairly under consideration.

In my first paper I suggested, as a test for the theory, that conductors should be raised from the earth to the regions of the clouds, under the idea that the withdrawal of electricity by this means would produce rain in temperate, and the aurora in frigid regions. And I hold that I am fully borne out on both these points by Prof. Lemström's grand auroral experiment; as, on the connection being made between the wirework on the top of the mountain and the earth at the foot of it, electric currents were observed, the aurora became visible, and the formation of ice on the wirework was so heavy as to break it down; thus showing that rain would have fallen if the experiment had been tried in a lower latitude. I hold also that the experiment already proves that electricity is the buoyant power of vapour in the atmosphere.

With respect to the undoubted great elevation of vapour and volcanic dust thrown up by the Java eruption, I have long been led to believe that electricity coats the surface of bodies in accordance with their temperatures, and that the non-burning property of superheated metal is from the intense force with which electricity coats the surface, and thus the hand is not actually in contact with the metal when placed upon it; and in the case of effluent high-pressure steam, I believe the particles are so completely wrapped up in their coatings of electricity that they do not touch the object the steam impinges on. Bearing these points in mind, it may easily be imagined that particles of dust or water as vapour, when cast up from a volcano, may be at the highest conceivable temperature, and charged with electricity in a like degree, and that, being driven up by currents of heated air, the particles may rise to an elevation far above that of ordinary vapour, and may remain suspended there, more or less, in accordance with the non-conducting condition of the atmosphere at such elevations. G. A. ROWELL

Oxford, January 2

AMONGST the many interesting questions raised by the discussion on the recent sunsets, not the least interesting is the question of the upper currents of the atmosphere. Mr. Norman Lockyer, in his article in the *Times* of December 8, writes of the presumed translation of volcanic dust round half the equatorial circumference of the earth in six days as being in accordance with our actual knowledge of these currents. There are probably many readers of NATURE besides myself who would be glad to be referred to the observations upon which this statement is founded.

An opinion prevails that, in the rotation of the earth about its axis, the higher parts of the atmosphere must to a certain extent lag behind, thus producing an east wind relatively to the surface of the earth; and if we allow ourselves to adopt this view, we may easily imagine that in the equatorial regions there may exist an upper current from the east having sufficient velocity to meet the case supposed. But can this view be justified? Is it not more reasonable to consider that the whole of the earth's atmosphere rotates with the earth as if it were part and parcel of it? It is difficult to see why it should not do so, unless we suppose a resisting medium occupying the inter-planetary spaces.

It is certainly remarkable how well (on the volcanic hypothesis) the entire observations of the coloured sunsets and associated phenomena agree with the supposition of an east wind sweeping round the earth with hurricane speed in the upper regions of the atmosphere. Not only the observations from the Mauritius, Cape Coast Castle, Brazil, and the West Indies, but even those from the Sandwich Islands and from Australia, may be made to harmonise with this theory, and the dust from Krakatoa may be said to have made "a girdle round the earth" in a fortnight. But in case the theory should prove to be inadmissible, it may be worth while to inquire whether some of these earlier observations may not find their explanation in an earlier eruption of the same volcano. The first eruption of Krakatoa is said to have occurred on May 20, and it is evident that long before the date of the great eruption (August 26) enormous quantities of material had been ejected, vast fields of floating pumice having been met with in the neighbouring seas at various times between July 9 and August 12. GEORGE F. BURDER

Clifton, January 7

ONE feature of the recent sunrises I have not seen described, viz. a large and striking pink semicircle opposite the sun, having a bluish centre. I have only twice seen it well marked, viz. on November 27 and December 15. This seems to be one distinct mark of difference between these sunrises and ordinary ones, inasmuch as I never saw it before, though possibly this may be partly owing to the phenomenon only lasting a few minutes at each time. On November 27 it was at its height at 7.43 a.m. At 7.50 there was only a trace of it left. On December 15 it was at its height at 8.6 a.m. At 8.4 it was very faint, and by 8.16 it had again become so, and was whitish. At 8.6 a.m. the north-western sky was darkish to an altitude of about 5°, and light pinkish purple thence to 10°: so far the appearance was quite ordinary; but on the darkish sky rested the broad half ring, which was pink, but the inner part inclining to salmon-coloured. Being much brighter than the pinkish purple, it obscured it where they crossed. I estimated the radius of its outer edge at about 25°, and therefore its apex was about 30° in altitude. Within the ring was a bluish-white semicircle of about half the radius of the pink semicircle; which was thus 12° or 13° in width. The sky beyond was blue. The phenomenon seemed to be an ordinary cirrus, though this was of an indefinite type; the spaces between its wisps were pretty blue in all parts of the north-western sky, but partook somewhat of its colour. On November 27 there did not appear to be any cirrus, but the semicircle must have been on the film which has been so remarkably coloured during sunrise and sunset. I have noticed traces of this semicircle on one or two other mornings, but so faint that I should not have noticed it if I had not looked for it. I presume that it is of the same character as the pink circle with green or blue centre that has been visible round the sun by day. This also is a phenomenon which I never observed previous to last month; it was most striking about the 26th, but continues to be seen almost daily. This favours the volcanic dust theory; for it is strange that I should never have noticed it before, if it is of common occurrence; still we know that a phenomenon is more easily seen again after it has once been observed, than seen in the first instance. Can these pink rings be accounted for optically? If they could, would it not throw much light upon the cause of the fine sunrises and sunsets?

With regard to the height of the film which has caused these, I should like to ask whether it is considered proved that the sun is actually shining on it so far into the twilight, or whether the glow may not be caused by reflection from bright sky upon which the sun is really shining. The after-glow among the Alps is clearly caused in this latter way, and not by the sun shining upon the mountains themselves. At the same time, the appearance of cirrus clouds dark against the bright sky, as occurred this morning at about 7.40 a.m., seems to point to the film being far above them. THOS. WM. BACKHOUSE

Sunderland, December 19, 1883

P.S.—This morning the pink half-ring was again conspicuous, only the inner half was nearly white; within was the blue, darkish, as before. It was at its best at 8.10 a.m.

December 20, 1883 T. W. B.

I learned from a Dutch paper (but I forget from which) that a *blue sun* was observed at Paramaribo in the beginning of September (I think it was the 2nd or the 6th).

Stuttgart, January E. METZGER

The following letter appears in the *Times* of Tuesday:—

"A shower of matter having 'a white sulphurous appearance' is reported from the vicinity of Queenstown, Cape Colony, towards the close of November. The appended paragraph, giving an account of the phenomenon, is extracted from a Kimberley (Griqualand West) newspaper of December 1. Taken in connection with the description in your correspondence columns of December 25 of a somewhat analogous shower at Scutari, the paragraph is certainly interesting, and, perhaps, of value to physicists investigating the cause of the recent celestial phenomena. "WALTER CLARK

"Edinburgh, January 3

"'We were informed yesterday of the occurrence at Glen Grey, about twelve miles from Queenstown, of a phenomenon which, while it lasted, nearly terrified the white and native population out of their wits. On the afternoon of Wednesday a thick shower of matter, presenting a white sulphurous appearance, fell in the valley in which this village is situate, and, passing right over it from east to west, covered the entire surface of the country with marble-sized balls of an ashy paleness, which crumbled into powder at the slightest touch. The shower was confined to one narrow streak, and while it lasted, we are told, the surrounding atmosphere remained unchanged and clear, as it had been before. Great noises accompanied the shower, and so frightened the people working in the fields, who at first were under the impression that it was a descent of fire—the white substance glistening in the sun—that on perceiving it they fled into their houses for shelter No damage was caused by what fell, and upon examination of the substance afterwards it was found to be perfectly harmless. At first the little balls were soft and pulpy, but they gradually became dry and pulverised, crumbling at the touch. We have before us a piece of earth on which one of them fell, and the mark left behind resembles a splash of limewash or similar matter. It does not smell of sulphur.'"

MR. JOHN TEBBUTT, of Windsor Observatory, N.S.W., writes as follows to the *Sydney Herald*:—The appearance presented by our evening skies for some weeks past has been the subject of general remark. Last evening, the 14th, the sky was almost cloudless after sunset, and the usual brick-red light again made its appearance along the west-south-west horizon. It was reflected apparently from an almost invisible and gauze-like cloud in the higher regions of the atmosphere. About seven o'clock the red glow was at its maximum, when a solitary cloud, whose apparent surface did not exceed ten square degrees, presented itself above it at an altitude of 25°. This cloud, which was at first white, quickly changed to a beautiful green, its borders being of a deeper tint. Of all the cloud phenomena that I have witnessed, it was one of the most remarkable. It retained its green colour for the space of about ten minutes, being all the time subject to much internal commotion. It soon afterwards resolved itself into several cloudlets, and finally disappeared. Two or three other small clouds were visible at the same time, and about the same altitude above the northern horizon, but these were of a gray colour throughout. The eastern sky about the moon was of that deep blue which is frequently observed to surround her when rising during the winter oppositions. Shortly after the dispersion of the green cloud, the ruddy glow gave place to the ordinary pale gray of the twilight, but by half-past seven o'clock the western sky became suffused with red, but this time of a clearer and more aurora-like tint. It did not appear, as in the former case, to be reflected from hazy cloud, and it extended much higher in the sky. This repetition of the ruddy glow on the same evening is a phenomenon which I had witnessed on several occasions during the present month. I remember that many years ago (probably twenty-five) a somewhat similar patch of red light used to make its appearance regularly after sunset in the west-north-west. This phenomenon occurred previously to the commencement of my regular meteorological observations in 1863, and was, I think, contemporaneous with a very dry winter. That the present ruddy skies are not merely a local phenomenon is obvious from the fact that they have been regularly observed during the past three months over a considerable portion of the Indian Ocean.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The following appointments have been made in accordance with Grace No. 19, confirmed on December 6 last:—J. H. Randell, B.A., Pembroke College, Assistant Demonstrator in Physics; J. C. McConnell, B.A., Clare College, Assistant Demonstrator in Physics; R. H. Solly, Demonstrator in Mineralogy, and Assistant Curator of the Museum; Walter Gardiner, B.A., Clare College, Demonstrator in Botany; A. Sheridan Lea, M.A., Trinity College, Senior Demonstrator in Physiology; W. D'Arcy Thompson, B.A., Trinity College, Junior Demonstrator in Physiology; A. Harker, B.A., St. John's College, Demonstrator in Geology. Baron Anatole von Hügel has been appointed Curator of the Museum of General and Local Archæology.

SCIENTIFIC SERIALS

THE *American Journal of Science*, December, 1883.—Some points in botanical nomenclature, a review of "Nouvelles Remarques sur la Nomenclature Botanique," par M. Alph. de Candolle, Geneva, 1883, by Asa Gray. The main object of this very valuable contribution to the vexed subject of botanic nomenclature is to enforce the principles and supplement the data supplied by M. de Candolle in his epoch-making work. His doctrines are on the whole cordially accepted, and often very ably illustrated, while here and there some useful suggestive remarks and criticisms are offered on matters of detail upon which diversity of opinion and practice still prevails.—Precarboniferous strata in the Grand Cañon of the Colorado, Arizona, by Charles D. Walcott. The results are here embodied of over two months' careful examination especially of the Kaibah Division of the Grand Cañon and lateral gorges undertaken during the winter of 1882-3. The author, an active member of the United States Geological Survey, concludes that the Grand Cañon and Chuar groups correspond to that of the Keweenawan of Wisconsin, both being referable to the Lower Cambrian. Jointly with the Paradoxides horizon of Braintree, Massachusetts, and St. John's, New Brunswick, the olenellus of Nevada, Vermont, New York, and Newfoundland, and the Potsdam series of Wisconsin, New York, Canada, &c.; they constitute the Cambrian age as so far determined in North America.—Contributions to meteorology, nineteenth paper, with three plates, by Prof. Elias Loomis. This paper deals at some length with the barometric gradient in great storms. The results confirm in a general way the accuracy of Ferrel's formula:—

$$G = \frac{1076{\cdot}4\,(2n \cos \psi + \nu)\,sP}{\cos i\,(1 + {\cdot}004t)\,P'},$$

where G denotes the barometric gradient in millimetres per degree of a great circle, or sixty geographical miles. But it is shown that the effect of friction is considerably greater than was supposed by Ferrel.—A brief study of Vesta, by M. W. Harrington. The author considers it probable that this asteroid has a iameter of over 500 miles, that she resembles the moon in her bedo, hence lacks an appreciable atmosphere and water, that e irregularities of her light indicate a very rough surface and tation on her axis; lastly, that what is true of Vesta is likely be true, *mutatis mutandis*, of the other asteroids.—On a new rm of selenium cell and some electrical discoveries made by s use, by Charles E. Fritts. This new form of selenium cell as the following properties:—(1) its resistance can be made as w as desired, down to nine ohms; (2) the light is made to rike the cell in the same plane as the current; (3) it is far ore sensitive to light than any before known, one cell having ad fifteen times as high resistance in dark as ordinary diffused aylight in a room. Since the paper was written, the author nnounces the discovery of a new form of selenium, quite lourless and transparent, obtained under conditions excluding verything but selenium.—The Ischian earthquake of July 28, 883, by C. G. Rockwood, jun. The author concludes that this isturbance had its orgin in a rupture taking place along an old olcanic fissure running roughly north and south, and extending dially under the northern slope of Mount Epomeo; and that e cause of the increased tension resulting in this rupture must e referred to the residual volcanic activity which Ischia shares ith the adjacent mainland, rather than to any merely local ubsidence, as suggested by Prof. Palmieri.

Annalen der Physik und Chemie, Bd. xx. No. 11, 1883.—R. Clausius, on the theory of dynamo-electric machines. This is a remarkably clear and able paper, dealing with the fundamental points in the theory of dynamo-electric machines in a masterly way, and introduces several new notions requiring the determination of the arbitrary constants in different machines. The questions of self-induction and mutual induction between different segments of the armature receive special attention. The author promises a further paper with applications of the equations.—L. Sohncke and A. Wangerin, on interference-phenomena in thin and particularly in wedge-shaped films. This paper is a continuation of one in last month's issue, giving new fundamental formulæ for Newton's rings and other interference-phenomena of thin films.—B. Hecht, on the determination of the axis-ratios of the elliptic paths in elliptic polarisation in quartz. A discussion of formulæ of Cauchy, Lommel, Voigt, and Jamin, in reference to the author's experiments.—W. Voigt, on the theory of light: a polemic against Herr Lommel respecting the latter's views on the possible intermolecular friction of the luminiferous ether.—H. Wild, on the application of his photometer as a spectrophotometer; this instrument, constructed by Hermann and Pfister, of Bern, contains a slit, a calc-spar rhombohedron, a Foucault prism, a second rhombohedron, a selenite plate, a Nicol prism, a pair of adjustable glass prisms, a 5-prism Amici direct-vision prism, and sundry lenses. The light to be examined has to pass through these successively.—Researches on forced vibrations of plates; part ii., on vibrations of square plates, by A. Elsas. This paper, which is accompanied by a set of forty-nine figures, is in continuation of a previous research on forced vibrations of round plates. The author points out that we already have the well-known researches of Chladni and Wheatstone on the figures due to natural vibrations of such plates. The aim of this research was to ascertain whether Savart's rule, that the forms of the forced vibrations merge into one another by a perfectly continuous series of modifications, is true for square plates; whether the figures corresponding to forced vibrations agree with those of the free vibrations of the same pitch; and whether the legitimacy of Wheatstone's method of superposition is confirmed or disallowed. The most important of all the results is that it is impossible for a square plate to vibrate in response to any time whatever, higher than its own fundamental, that may be forced upon it.—On Boltzmann's theory of elastic reaction, by Prof. E. Riecke; a mathematical discussion of Boltzmann's equations.—On aqueous solutions, by J. A. Groshans. A discussion of the dependence of the density of the solution on the quantity and molecular constitution of the soluble substance.—Measurement of the quantity of electricity produced by a Zamboni's pile, by Prof. E. Riecke. The values were calculated from currents traversing a long-coil galvanometer and a very high resistance.—On the galvanic-temperature coefficients of steel, rod-iron, and cast-iron, by V. Strouhal and C. Barus. For steel this coefficient diminishes as the hardness of tempering increases, while the specific resistance increases with the hardness. Glass-hard steel has about three times the specific resistance of soft steel.—On the relation between viscosity and electric resistance of solutions of salts in various solvent media, by E. Wiedemann. There appears to be no such relation as has been conjectured to exist.—On Arabian measurements of specific gravity, by E. Wiedemann.—Simplifications in experimenting with the air-pump, by K. L. Bauer, suggests the expedient already well known in England, of placing a sheet of soft caoutchouc under the receiver of the pump instead of greasing its rim; also similarly between the edges of the Madgeburg hemispheres. Gutta-percha paper is suggested as a substitute for bladder to be burst by air-pressure.

SOCIETIES AND ACADEMIES

LONDON

Chemical Society, December 20, 1883.—Dr. W. H. Perkin, F.R.S., president, in the chair.—The following gentlemen were elected Fellows of the Society:—W. P. Bloxam, A. Cobb, J. C. Chambers, A. E. Ekins, F. P. Haviland, F. Keeling, W. H. R. Kerry, J. J. Pilley, M. Percy, J. Phillips, A. W. Rogers, W. J. Saint, G. Smith, A. Smithells. The following papers were read:—Researches on the gums of the arabin group, by C. O'Sullivan. Part I. Arabic acid; its composition, and the products of its decomposition. In this most important paper the author has studied the action of dilute sulphuric acid upon arabic acid. The arabic acid was prepared by the method of Neubauer, and the sulphuric acid was allowed to act for various lengths of time from fifteen minutes to several hours. The molecule of arabic acid, $C_{89}H_{142}O_{74}$, is broken down, a series of eleven acids of gradually decreasing molecular weight (differing by $C_6H_{10}O_5$) having been isolated, and the barium salts formed and analysed; the lowest acid is $C_{23}H_{38}O_{22}$, and is comparatively stable; these acids the author calls α, β, &c., arabinosic acids. Simultaneously a series of sugars having the composition $C_6H_{12}O_6$ is formed of gradually decreasing optical activity, which the author names α, β, γ, and δ arabinose. Arabic acid is the chief constituent of all the lævorotatory gums, but other acids are present which bear a simple relation to it. In a future paper the author promises an account of the dextrorotatory and optically inactive gums, the acids of which are built up in the same manner as arabic acid.—On the decomposition of ammonia by heat, by W. Ramsay and S. Young. This decomposition commences about 500°, and is nearly equal in extent with porcelain, glass, iron, and asbestos, but at 780° ammonia is almost completely decomposed by passing through an iron tube. Copper, when heated, is not so active.—On the halogen compounds of selenium, by F. P. Evans and W. Ramsay.—On the preparation of pure chlorophyll, by A. Tschirch. This substance is obtained by the action of zinc dust on chlorophyllan (*Bot. Zeit.*, 1882, 533); its spectrum is identical with that given by living leaves.

Zoological Society, December 18, 1883.—Prof. W. H. Flower, F.R.S., president, in the chair.—Dr. F. Leuthner read an abstract of a memoir which he had prepared on the Odontolabini, a subfamily of the Coleopterous family Lucanidæ, remarkable for the polymorphism of the males, while the females remained very similar. The males were stated to exhibit four very distinct phases of development in their mandibles, which the author proposed to term "priodont," "amphiodont," "mesodont," and "telodont." These forms were strongly marked in some species; but in others were connected by insensible gradations, and had been treated by the earlier authors as distinct species. The second part of the memoir contained a monograph of the three known genera which constitute the group Odontolabini.—Mr. E. B. Poulton, F.Z.S., read a memoir on the structure of the tongue in the Marsupialia. The tongues of species of nearly all the important groups of this subclass were described in detail. It was found possible to classify the tongues in three divisions. Of these, *Halmaturus* was the type of the lowest, *Phalangista* of the intermediate, and *Perameles* of the most advanced, division.—Mr. J. Wood-Mason, F.Z.S., read a paper on the Embiidæ, a little-known family of insects, on the structure and habits of which he had succeded in making some investigations during his recent residence in India. He came to the conclusion that the Embiidæ undoubtedly belong to the true Orthoptera, and are one of the lowest terms of a series formed by the families Acridioideæ, Locustidæ, Gryllidæ, and Phasmatidæ.—Mr. G. A. Boulenger, F.Z.S., read an account of a collection of frogs made at Yurimaguas, Huallaga River, Northern Peru, by Dr. Hahnel. The collection contained examples of eighteen species, eight of which were regarded as new to science.—Mr. W. F. R. Weldon read a paper on some points in the anatomy of *Phœnicopterus* and its allies. An account was given of the air cells of the Flamingo, which were shown to differ from those of Lamellirostres, and to agree with those of Storks (1) in having the præbronchial air-cell much divided, (2) in the feeble development of the posterior intermediate cell, and (3) in the great size of the abdominal cell. The pseudopiploon was also shown to differ from that of Lamellirostres, and to agree with that of Storks, in extending back to the cloaca. A detailed comparison between the muscles, especially those of the hind limb, gave the same results. The larynx, however, being Anserine, and the skull intermediate, the position expressed by Huxley's term "Amphimorphæ" was considered fully justifiable.—Mr. Sclater read a paper, in which he gave the description of six apparently new species of South American Passeres.

Anthropological Institute, December 11, 1883.—Prof. Flower, F.R.S., president, in the chair.—The election of Mr. E. W. Streeter was announced.—Mr. Walton Haydon exhibited some photographs of North American Indians.—A paper by Mr. A. W. Howitt, on some Australian ceremonies of initiation, was read by Dr. E. B. Tylor. The ceremonies described by the author are common to a very large aggregate of tribes in the south-eastern part of Australia, and as himself an initiated person, Mr. Howitt has had unusual opportunities of observation and of obtaining information from the Blacks. When it has been decided that there is a sufficient number of boys ready for initiation, the headman sends out his messenger, who travels round to the headmen of the same totem, who then communicate the message to the principal men of the different totems which form the local groups. The messenger carries with him, as the emblems of his mission, a complete set of male attire, together with the sacred humming instrument, which is wrapped up in a skin and carefully concealed from women and children. The ceremonial meeting having been called together, that moiety of the community which called it prepares the ground and gets all ready for the arrival of the various contingents. Mr. Howitt then described at length the procession from the camp to some retired and secret place where the ceremonies are to be performed, each novice being attended by a guardian, who fully explains to him all that is said or done. A camp is formed when the spot is reached that has been fixed upon for the site of the tooth-knocking-out ceremony, which was fully described by the author in the latter part of the paper.—Dr. R. G. Latham read a paper on the use of the terms "Celt" and "German."

Geological Society, December 19, 1883.—J. W. Hulke, F.R.S., president, in the chair.—Rev. W. R. Andrews, Robert James Frecheville, and Rev. Philip R. Sleeman were elected Fellows of the Society.—The following communications were read:—On some remains of fossil fishes from the Yoredale series at Leyburn in Wensleydale, by James W. Davis, F.G.S. —Petrological notes on some North-of-England dykes, by J. J. H. Teall, M.A., F.G.S. The author described the stratigraphical relations and the structure, macroscopic and microscopic, of a number of dykes which occur in the north-east of England, giving analyses. He pointed out that they fell into four more or less distinct groups: (1) the Cleveland dyke and that of Acklington; (2) the Heth and its related dykes; (3) the dykes of Hebburn, of Tynemouth, of Brunton, of Hartley, and of Morpeth; (4) the High Green dykes. Groups (1) and (3) resembled one another in specific gravity and chemical composition, as did (2) and (4), the percentage of silica in the first two (except in the Morpeth dyke) varying from 57 to 59, and the specific gravity being about 2·7 or 2·8, while the others had a silica percentage of from 51 to 53, and a rather higher specific gravity. The former present some microscopic differences, the latter are very closely related. The Cleveland, Acklington, and Heth dykes have been examined at intervals far apart, and exhibit no variation or relation to the surrounding rocks; so that evidently they have not taken up any appreciable portion of the material through which they have broken. The dykes of Group (3) being probably pre-Tertiary (the author does not himself find it possible to distinguish igneous rocks by their geologic age) would be termed melaphyres on the Continent; but those of (2) and (4) are nearer to the group of diabases. The Cleveland dyke (Group 1) is almost certainly of Tertiary age, and its structure and composition entitle it to the name of an augite-andesite.—The Droitwich brine springs and saliferous marls, by C. Parkinson, F.G.S.

EDINBURGH

Royal Society, December 17, 1883.—Robert Grey, vice-president, in the chair.—Prof. Tait communicated a paper by Mr. A. Campbell, containing the results of additional experiments on the Peltier effect. The results agreed closely with their values as calculated from the thermoelectric diagram.—Dr. Sang read a paper on the problem of the lathe band, and on problems therewith connected.—Prof. Tait read a note by the Astronomer-Royal for Scotland, on Brewster's line Y in the infra-red. The object of the note was to point out that this line, which had been ascribed by some recent observers to air, and therefore omitted from the spectrum, is a true solar line, which has been found to be due to sodium.—Mr. John Murray read a communication by Mr. P. H. Carpenter, on the Crinoidea of the North Atlantic between Gibraltar and the Faröe Islands; with notes on the Myzostomidæ, by Prof. T. von Graff, Ph.D. —Mr. R. W. Felkin, F.R.G.S., gave a very interesting account of the Madi or Moru tribe, from which the flower of the Egyptian army has been drawn.—A paper was also read, on the structure of the pitcher in the seedling of Nepenthes, as compared with that in the adult plant, by Prof. Alexander Dickson, M.D. Prof. Dickson gave the results of his examination of Nepenthes seedlings lately raised in the Edinburgh Royal Botanic Garden. One of the most important points to which he drew attention was in connection with the annulus or rim of the pitcher orifice. In the seedlings this structure is seen even in the pitcher leaf immediately succeeding the cotyledons, and a row of cushion- or button-like glands is to be found just within its inflexed edge. From observing these glands, Prof. Dickson was led carefully to examine the annulus in the adult plant, with the result of his discovering their representatives in a remarkable series of gigantic glands. If the inflexed rim be examined, there is to be found, just above its free edge, a single line of small orifices, alternating with the ridges of the corrugated annulus and with their tooth-like prolongations, when these are present. On dissection, each of these orifices is seen to be the outlet of a canal-like fossa, from the bottom of which a cellular, nipple-shaped body or mammilla projects. This mammilla is the free apex of a gland, the great bulk of which is immersed in the parenchymatous substance of the annulus. These glands vary in length, according to the species, from 1/37 (*N. ampullaria*) to the enormous measure of 1/12 of an inch (*N. destillatoria*, *N. phyllamphora*, &c.). Prof. Dickson could not speak definitely as to the function of these glands, but thought that they probably secrete honey, affording to the insect the last drops just as it is on the brink of destruction! Sir J. D. Hooker, in his address on insectivorous plants delivered at the Belfast meeting of the British Association, had spoken of the pitcher rim as secreting honey, but without making any reference to these remarkable marginal glands.

BIRMINGHAM

Philosophical Society, December 13, 1883.—Peculiar absorption of a compound of iodine by aluminium, by Dr. G. Gore, F.R.S. This paper contains a statement of the discovery of a peculiar fact by the author, viz. that when a sheet of aluminium was simply immersed in a solution composed of 17½ grains of pure iodic acid dissolved in 3¼ ounces of distilled water, it absorbed as much as 16 per cent. of its weight of a foreign substance, and emitted a strong odour of iodine. It retained its metallic appearance, although it had become peculiarly rough by corrosion. When struck by a hard substance it emitted a less metallic sound. In several similar experiments the plates gained much more in weight by absorption than they lost by corrosion. By examining the edges of the sheets under a microscope, the sheets were found to be partly disintegrated into thin layers. A variety of other methods were tried, including electrolytic ones, to produce the same effect, but in no instance did the metal emit much odour of iodine, or appear to have absorbed freely a foreign substance. With aluminium immersed in dilute hydriodic acid containing dissolved iodine, similar though much less conspicuous effects of disintegration and emission of odour of iodine were, however, observed. By immersing a sheet of the metal in a solution of bromic acid, the metal did not appear to absorb much bromine. A partial investigation was made of the phenomena. By washing the sheets with water, the water became strongly coloured by iodine, and continued to do so after many washings. Although, after having been washed and dried, they continued to emit a strong odour of iodine, they did not by immersion in carbonic bisulphide at 60° F., during thirty-six hours, yield any iodine, or impart any colour to that liquid; the absorbed substance was not, therefore, simple iodine. A flat sheet of aluminium varnished on one side, and then immersed in aqueous iodic acid, did not assume a curved shape. A chemical analysis of the absorbed substance has not yet been made.—Reduction of metallic solutions by means of gases, &c., by Dr. G. Gore, F.R.S. This paper is a record of a number of instances in which various solutions of metals were reduced to the metallic state by contact with gases, and different organic compounds. The solutions chiefly employed were those of palladium, iridium, platinum, gold, silver, and mercury, and less frequently those of copper, lead, iron, manganese, chromium, vanadium, and tellurium. The gases used were hydrogen, carbonic oxide, coal gas, and crude acetylene. The organic compounds included both liquid and solid substances; the liquids were amylene, petroleum, benzene, Persian naptha, xylol, toluol, carbolic acid, "petroleum ether," mesitylene, and liquid chloride of carbon, and the solids were paraffin, ozokerite, naphthalene, anthracene, chrysene, elaterite, solid chloride of carbon, &c. By contact with gases the metals were generally reduced in the form of films upon the surface of the liquids, as well as in that of precipitated powder; some of the films produced, both by the contact of gases and by that of non-miscible liquids, were remarkably beautiful, and of a surprising degree of thinness. Amongst the most conspicuous instances of reduction were the following:—a solution of palladic chloride was rapidly reduced by carbonic oxide, hydrogen, coal gas, and amylene. One of terchloride of gold was quickly decomposed and reduced by coal gas, carbolic acid, and amylene. The most beautiful films were those produced by a solution of terchloride of gold, with coal gas or with amylene. Solutions of chloride of palladium were usually more rapidly decomposed than those of chloride of gold. The films of metal thus produced might prove of service in some optical and other physical investigations. It is worthy of consideration also by geologists, whether the reduction of metals to the native state in the interior of the earth may not in some cases have been effected by contact of their solutions with liquid or gaseous hydrocarbons derived from coal and other mineral substances of organic origin.

PARIS

Academy of Sciences, December 31, 1883.—M. Blanchard, president, in the chair.—Action of heat on aldol and paraldol, by M. Ad. Wurtz.—On a white rainbow (Ulloa Circle) observed at Courtenay (Loiret) on the morning of November 28, by M. A. Cornu. This extremely rare phenomenon occurred under atmospheric conditions closely analogous to those described by Bravais in the *Journ. de l'École Polytech.*, xxx. p. 97. The radius appears to have been much shorter than that of the ordinary rainbow.—Mission to Cape Horn: Summary report on the researches made in natural history and anthropology by the *Romanche*, by Dr. Hahn. In the north-eastern islands of Tierra del Fuego acquaintance was made with the Ua people, who present several remarkable peculiarities. Although living on friendly terms and even intermarrying with the more southern Yahgans, they seem to be related in stock and speech rather to the continental Patagonians. They appear even to exceed them in stature, and thus to rank as the very tallest race on the globe.—Note on the tidal curves registered between November, 1882, and September, 1883, by the maregraph at Orange Bay, Cape Horn.—Observations of the Pons-Brooks comet at the Observatory of Nice (Gautier-Eichens equatorial), by M. Perrotin.—Spectroscopic study of the Pons-Brooks comet made with the reflector of 0·50 m. at the Observatory of Algiers, by M. Ch. Trépied. The following results were obtained:—

	Comet		Flame of alcohol
Reading for line D	13°·18	...	—
First green line (less refrangible) ...	13·92	...	14·09
Second green line	15·12	...	15·20
Blue line	16·76	...	17·04

showing that in its visible parts the spectrum of the comet is identical with that of a flame of alcohol.—On the multipliers of the linear differential equations, by M. Halphen.—On a means of determining the factor of integrability, by M. W. Maximovitch.—On the generation of surfaces, by MM. J. S. and M. N. Vanecek.—Reply to M. Larroque's observations on the experiments recently made in connection with the study of earth currents, by M. E. E. Blavier.—On the temperature obtainable by means of boiling oxygen, and on the solidification of nitrogen, by M. S. Wroblewski. Reserving a description of his process, the author announces as a first result an approximate temperature of − 186° C. When subjected to this intense degree of cold, nitrogen became solidified, falling like snow in crystals of a remarkable size.—On the maximum of solubility of soda, by M. E. Pauchon.—On an incomplete oxygenised monamine (oxallyldiethylmine, by M. E. Roboul.—On the fluorides of sodium, by M. Guntz.—Researches on ptomaïnes and analogous compounds, by M. A. Gabriel Pouchet.—Action of copper on the health of persons engaged in the copper industries; history of a workshop and of a village, by MM. A. Houlès and de Pietra-Santa. The history of this village (Tarn, Durfort) extends over a period of a hundred years, and tends to show that coppersmiths (forgers, braziers, &c.) are on the whole as long-lived if not more so than the agricultural population of the same district.—On the anatomy of a human embryo in the fourth week, by M. H. Fol.—On a new species of the genus Megaptera (*Megaptera indica*) from the Bay of Bassora, Persian Gulf, by M. P. Gervais.—On a rare species of Dolphin (*Orca gladiator*, Gray = *Delphinus orca*, Fab.) recently captured off Tréport, Seine-Inférieure, by M. H. Gadeau de Nerville.—On the vitelline nucleus of the Araneidæ, by M. A. Sabatier.—New ophidological discoveries, by M. Lichtenstein.—On a phenomenon accompanying the red afterglow of the sunsets of December 26 and 27, 1883, at Tortosa (Spain), by M. José J. Landerer.—Terrestrial physics: the Krakatoa catastrophe; velocity of the earthquake waves, by M. Erington de la Croix. From observations made in Ceylon, Mauritius, and other places, the earthquake wave of August 27, 1883, seems to have been propagated across the Indian Ocean at the prodigious velocity of about 550 m. per second, or 2000 km. per hour.

BERLIN

Physiological Society, December 7, 1883.—Prof. Waldeyer brought before the Society the results of investigations pursued by Herr Koganei in his Institute into the histogeny of the retina. It was known that the retina was a development of a vesicular projecting flap of the brain (*Hervorstülpung des Gehirns*), and that this membrane of the eye consisted in its early stages of fusiform cells. Whether there were other cells besides contained in it, how they were developed, and how the different constituents of the developed retina were differentiated, were, on the other hand, all matters of debate. Herr Koganei had now found that in the earliest stages this membrane of the eye was composed of two series of cells, one of fusiform cells on the distal side of the membrane, the other of round cells supplied with caryokinetic nuclei on the proximal side. The fusiform cells were called "fundamental," the round cells "prolific," these latter alone multiplying, as they did, by scission, and furnishing the whole material for building up the retina. The increase in retina elements proceeded therefore altogether from the proximal side, whence the newly-produced cells intercalated themselves into the layer of fusiform cells, all which phenomena entirely corresponded with those of the brain, it likewise growing only by multiplication of cells on the ventricular side. The differentiation of the fusiform cells into separate retina layers began after the ocular chamber was formed by the invagination of its most anterior part which becomes transformed into a double saucer shaped form, or rather it was only the innermost saucer which became the retina, while the outer saucer was converted into the pigment layer, the cells of which were filled with pigment. The differentiation followed a law of quite universal application. In every case it began on the distal side, which, on the invagination of the ocular chamber, became the inner side, and advanced gradually to the outer side of the retina. It began consequently with the oldest fusiform cells, and passed gradually over to the later-formed fundamental cells. As analogous to this was next recognised the membrana limitans interna, with the supporting fibres of Müller. These formed themselves out of the innermost layer of the oldest fusiform cells, which ranged themselves strongly out in a longitudinal direction, and became flattened on their inner end. The basal laminæ (*Fussplatten*) of these cells impinging on each other formed the membrana limitans. Then the layer of ganglion cells appeared, and, almost simultaneously, the layer of optic fibres intervening between the layer of ganglion cells and the membrana limitans. The mode by which the ganglion cells were developed was through the rounding of the fusiform cells and their emission of offshoots. With regard to the layer of nerve-fibres it was ascertained that they developed themselves out of continuations of the ganglion cells. Whether and in what manner they came later into confluence with the optic fibres proceeding from the brain was a point which must be reserved for further investigation. Prof. Waldeyer deemed it not impossible that the optic fibres growing out of the ganglion cells penetrated into the brain, and there merged into the central ganglion. Thereafter was developed the so-called molecular layer. This name had been given to it in consequence of its finely granular appearance under slight enlargement. With the powerful amplification which was now customary it was, however, at the present day, universally recognised as consisting of an extremely fine network of the most delicate filaments. In the middle of this layer Herr Koganei had found a series of round cells which, having issued from fundamental cells, formed the mother-cells of this layer. Since it was now known that cellular protoplasm consisted of a reticular coating and fluid contents, it became intelligible how, from the protoplasm of the series of mother-cells occupying the middle zone, the fine fibrous net of the molecular layer was formed by more vigorous development of the protoplasmic coating and the proportionate reduction of the liquid contents. In the further development of the embryonal retina there now appeared the internal granular layer with the median granular layer, followed, shortly after, by the external granular layer. Both granular layers developed themselves from the fusiform fundamental cells through the latter becoming round and partially emitting continuations. In this manner they formed themselves into ganglion cells, as the granules of the granular layer must be considered. The median granular layer was in the highest probability a layer of fibre-nets intercalating itself, like those of the molecular layer. In the granular layers, besides round and ganglion cells, fusiform cells were also met with. These fusiform cells, by vigorous longitudinal growth, developed themselves into supporting fibres (*Stützfasern*), flattened themselves at their extreme ends, and by superimposition of their terminal laminæ formed the membrana limitans externa. On the development of this last membrane the ganglia or granules of the granular layer began to send continuations outwards striking through the membrana limitans, which, therefore, very soon appeared occupied with the little blunt endings (*Stümpfchen*). These again grew to be granular interior members of the rods and pins that, finally, developed the hyaline external members which were powerfully refractive and cylindrical, or cone-shaped, the last members in the series of the development of retina elements. At this point the fact, of supreme importance to the physiologist, was established, that new-born animals only began to see when the exterior members of the rods and cones were developed. From the foregoing observations, Prof. Waldeyer deduced an important general conclusion, which had equal applicability to the brain as to the retina. The development of the retina demonstrated that all its morphological constituents, the ganglion cells, the nerve fibres, and the supporting fibres were developed from the same fundamental cells. The supporting fibres of the retina, and in like manner the neuroganglia of the brain, must consequently be classed as belonging to the nervous system, and having nothing in common with the ligamental tissue. They were nervous apparatus, which only did not perform nervous functions. In the case of regenerative processes, however, they played an important part. It was known that highly differentiated tissues were not capable of regeneration, which was therefore impossible in the case of ganglion cells and nerve fibres. Supporting fibres and neuroganglia, on the other hand, were capable of regeneration, and, being developed from neurously constituted cells, were also capable of undertaking nervous functions or of further differentiating themselves for those higher functions. This highly important question deserved a very thorough investigation.

FAMILY RECORDS

Record of Family Faculties. By Francis Galton, F.R.S. (London: Macmillan and Co., 1884.)

Life-History Album. By Francis Galton, F.R.S. (London: Macmillan and Co., 1884.)

MR. GALTON is indefatigable in his zeal to promote the cause of eugenics. His most recent efforts in this direction have resulted in the publication of two quarto books, which respectively bear the titles above given, and which betoken no small amount of labour on the part of their author. Feeling the importance of casting a wide net for the capture of facts bearing on the science of eugenics which he hopes to inaugurate, Mr. Galton has here presented to the public a formidable array of blank forms or tables, to be filled up by any one who may have caught a spark of his own enthusiasm in the new cause. And not only so, but, to stimulate the energies of a blind and foolish generation, he has offered rewards or prizes to the extent of 500*l.* for the best writing up of the Records of Family Faculties. Lest any of our readers, however, should be induced from sordid motives alone to invest a few shillings in the purchase of this curious book, we think it is desirable to warn them at the outset that if they intend to write for one of the prizes they must know a good deal more about their family history than was known even by the writer of the book, which begins—" This is the book of the generations of Adam." For, as far as it appears from his preface, Mr. Galton would not award even the least of all his prizes to any one who could prove direct descent from Adam; nay, it would be useless to prove such descent even from any particular gorilla. For, we are expressly told, "no countenance is given to the vanity that prompts most family historians to trace their pedigree to some notable ancestor. . . . We should remember the insignificance of any single ancestor in a remote degree. . . . One ancestor who lived at the time of the Norman Conquest, twenty-four generations back, contributes (on the supposition of no intermarriage of kinsfolk) less than one part in 16,000,000 to the constitution of a man of the present day."

What Mr. Galton wants, therefore, is not the record of a long pedigree, but an accurate and detailed account of a short one. And this is just what makes his tables so difficult to fill up. We must not only know all about our father and mother and grandfathers and grandmothers, but also about our father's father's father, father's father's mother, father's mother's father, father's mother's mother, mother's father's father, mother's father's mother, mother's mother's father, and mother's mother's mother. Even this, indeed, is not enough to satisfy Mr. Galton; for, " besides the direct ancestors, the brothers and sisters of each of them have also to be taken into account," and are accordingly all provided for in the blank tables. Obviously not many of us could answer any of the following questions touching, say, a mother's father's mother's brother:—Date and place of birth, occupation, residences, age at marriage, ditto of spouse, number and ages of sons and daughters, mode of life, height, colour of hair and eyes, general appearance, degree of strength, perfection or imperfection of special senses, mental powers, personal character, favourite pursuits, artistic aptitudes, minor ailments, graver illnesses, cause and date of death, and age at death.

The impossibility, however, of any one competitor filling up all the tables is of course no argument against setting the questions. The same questions are submitted to all the competitors, and those who can answer most or best will receive the 500*l.* Perhaps a few years hence, when Mr. Henry George shall have effected his social revolution in this country, our aristocratic families (who are favourably handicapped in their knowledge of ancestry) will be thankful to assist the science of eugenics upon the terms now offered by Mr. Galton.

The " Life-History Album " is, in size, date, and general appearance, a companion to the " Record of Family Faculties." It runs to 72 pages, which are arranged for entries in five-yearly periods from birth to 75 years of age. We can imagine the melancholy aspect of a man who in the year 1959 sits down to fill up the last page of a copy of this album, the first page of which is now being begun by his parents. What a retrospect will lie before his dim and saddened gaze! Every tooth that he gained in childhood, and every tooth that he lost in age has been duly chronicled; all the fluctuations in his weight, health, and strength are recorded; he can trace the dawn and rise of all his bodily and mental powers from infancy to manhood, and can measure with the most painful nicety their continuous decline from manhood to old age. He has before him a little picture gallery of fifteen photographs taken at five-yearly periods, to impress upon him with yet more cruel vividness what a wreck he has become; and now there is no further page whereon to continue the record so long and so faithfully kept. Even the interest of Mr. Galton in all that he was to be and all that he was to do has come to an end; he has literally turned over the last page of his life, and if his poor old eyes do not drop a tear upon the closing tragedy, it can only be because his zeal for science has devoured every other emotion.

But although this aspect of the matter is irresistibly suggested by the close of the album at 75 years of age, without even the provision of a blank page for any further possibilities (with trembling fingers these might, indeed, be pasted in), we must remember that the evil here lies in the fact of mortality. So long as a man is alive, it may be useful to him in many ways—apart from eugenics —to have such a physical record of his life thus kept from his earliest days. No doubt the sooner it is begun the more value it will subsequently have; but Mr. Galton virtually tells us that, as in the Pilgrim's Progress, so in the pilgrimage of life, " better late than never " in making a beginning.

In order to show some of the personal, as distinguished from any scientific, advantages which may reasonably be expected to arise from keeping such a biological history of one's self, we shall conclude by quoting an extract from Mr. Galton's own exhortation.

" *To the Owner of this Book*

" 1. It will show whether, and in what way, your health is affected by the changes that take place in your residence, occupation, diet, or habits.

“2. It will afford early indication of any departure from health, and will thus draw attention to conditions which, if neglected, may lead to permanent disorder. Without such a record, the early signs of disease, which are commonly slight and gradual, are very likely to pass unrecognised, and thus the opportunity will be lost of seeking advice at the time when preventive or curative measures can be most successfully taken.

“3. A trustworthy record of past illnesses will enable your medical attendants to treat you more intelligently and successfully than they otherwise could, for it will give them a more complete knowledge of your ‘constitution’ than could be obtained in any other way. This knowledge is so important that life itself may in many illnesses depend upon it.

“4. The record will further be of great value to your family and descendants; for mental and physical characteristics, as well as liabilities to disease, are all transmitted more or less by parents to their children, and are shared by members of the same family. ‘The world is beginning to perceive that the life of each individual is in some real sense a prolongation of those of his ancestry. His character, his vigour, and his disease, are principally theirs. . . . The life-histories of our relatives are, therefore, more instructive to us than those of strangers; they are especially able to forewarn and to encourage us, for they are prophetic of our own futures.’—(*Fortnightly Review*, January, 1882, p. 31).”

We have now said enough to show the general character of these original publications. We ought to add, however, that they may be purchased separately, and therefore, notwithstanding the prizes offered for the best Records of Family Faculties, we think it probable that the “Life-History Albums” will have the better sale. They are inexpensive to buy, and, apart from the trouble of writing them up at intervals, require for their keeping no other kind of expenditure.

GEORGE J. ROMANES

SIAM

Temples and Elephants: The Narrative of a Journey through Upper Siam and Lao. By Carl Bock. (London: Sampson Low, Marston, and Co., 1884.)

THE expedition undertaken by Mr. Bock in 1881–82 to the Indo-Chinese mainland was practically a continuation of his previous ramblings in the Eastern Archipelago, a graphic account of which he has given us in his “Head-Hunters of Borneo.” Of both the main object appears to have been rather archæological and ethnographical than strictly scientific, and of both the incidents and results have also been somewhat analogous. In each case some hitherto unvisited tracts were explored, or at least traversed, each was marked by a striking absence of any stirring adventures “by flood or field,” both yielded, besides some additions to our geographical and ethnological knowledge of the regions in question, a considerable amount of “curios and treasure-trove”; but the quest of the “tailed people” proved as bootless in Further India as it had in Borneo.

In other respects “Temples and Elephants,” although far less profusely illustrated, compares not unfavourably with “The Head-Hunters.” It is uniformly written in surprisingly good English, and it gives us for the first time a tolerably clear account of the region of the water-parting between the head waters of the Menam and the Middle Mekong basins, and indeed of the whole course of the Menam almost from its source to the Gulf of Siam. The source itself was not actually reached, but it was ascertained with some certainty to lie altogether within Lao territory, or about 20° N., 99° E., and not further north in the Shan States, as shown on all recent maps, even that accompanying vol. viii. of Reclus’ “Géographie Universelle.” By taking boat at the now ruined city of Fang, and sailing down the Me-Fang and Me-Kok, the Mekong was reached just below Kiang-sen, where, a thousand miles from its mouth, it was found to be still a magnificent stream “twice as wide as the Menam at Bangkok.” This was the furthest point reached, and on the return route the narrow but rugged water-parting was crossed by a pass 2000 feet high leading down to the Meping, as the Upper Menam is here called. Henceforth the rest of the journey was made entirely by water, proving that for small craft the Menam is navigable almost from its source to its mouth. Even the dangerous rapids near Mutka, above the Lao and Siamese frontier, were successfully run by the ingeniously constructed boats specially adapted for navigating this section of the great Siamese artery.

All the chief towns in this basin were visited, and a very full account is given of such important but almost unknown places, as Raheng (Rahein), Lakhon, Lampoon (Labong), Cheng-mai (Kiang-mai), Muang-Pau (Prau), and Kiang-hai), all except Raheng lying within the western Lao domain. Raheng, the northernmost town in Siam proper, appears to be the centre of a very considerable trade with the surrounding lands, and some strong arguments are urged in favour of the projected railway between that place and the capital. Such a line would present no engineering difficulties, running as it would through an almost perfectly level country; it might be cheaply constructed by Chinese coolie labour, available on the spot; it would run through the most densely peopled districts in Siam, and would at once open up a vastly productive region, whose almost boundless resources are now lying waste.

“The agricultural resources of the district of which it [Raheng] is the centre and natural outlet are extremely rich. Its timber alone is sufficient to insure prosperity; but it has further sources of wealth in the varied indigenous products of the country, and still more in the entirely undeveloped resources of its fertile soil. All that it wants is a railway to carry the products of the country at all seasons and without delay to the markets of the world, and to enable it to receive the large imports which an increasing population would at once necessitate” (p. 137).

But most readers will probably turn most eagerly to the chapters devoted to the habits and customs of the Karians (Karens), Mussus (Mossos), Ngiou (Shans), and especially of the Laosians (Laotians, Laos), whose political and social institutions, domestic life, religion, arts, and daily pursuits are here very fully described. The remarks on all these subjects will be found both interesting and valuable to the ethnologist, because mainly the result of personal studies made on the spot by a shrewd and experienced observer. Mr. Bock speaks of the Laos as of a finer type, fairer, and better-looking not only than the Malays but even than the kindred and more civilised Siamese. They are described as of superior physique, lighter complexion, with good, high foreheads, more regular features, and nostrils not so dilated as those of their neighbours. A curious peculiarity is the power of bending the elbow the wrong way, and similarly distorting the wrist joint, so that the hand can be bent over till the back of it touches the arm. This, however, does not appear to be the result of any special conformation of the joints, but rather of a long and severe course of training, in which "force is often resorted to in order to distort nature's handiwork" (p. 321). It will be remembered that one of the distinctive features of Krao, the little specimen brought from Bangkok by Mr. Bock, was a remarkable pliancy of the joints, extending even to the toes, which were almost as prehensile as those of the higher apes.

Amongst the illustrations is a curious design by a native artist (unfortunately "invested with artistic merit" by the English engraver) representing a scheme of the universe, with Mount Zinnalo, the Meru of the Hindus, as the centre. Above all is the outer darkness, or Buddhist *Nirvana*, usually supposed to involve extinction, or at least absorption in the divine essence, but which our author agrees with Mr. Alabaster in identifying rather with the highest heaven, a place of perfect happiness or repose. But however this be it is obvious that the Laotian Buddhism has been otherwise profoundly modified by the older cult, on which it has been engrafted, and from which it still takes its colouring. This older cult was little more than a universal spirit-worship, probably the first distinct stage in the evolution of all religious systems. Hence "the desire to propitiate the good spirits and to exorcise the bad ones is the prevailing influence on the life of a Laosian. With 'phees' to right of him, to left of him, in front of him, behind him, all round him, his mind is haunted with a perpetual desire to make terms with them, and to insure the assistance of the great Buddha, so that he may preserve both body and soul from the hands of the spirits, and, by making merit either in almsgiving, in feeding the priests, in building temples or prachedees, he may ultimately attain supreme happiness" (p. 198). At Muang-Fang the people are shown a telescope, whereupon they immediately ask, "Can you see the spirits through it?" And when it is reversed so that everything seems to fade away in the distance, they are hugely delighted at such a wonderful instrument, which has the power of making all things—spirits of course included—near or far off at the will of the owner!

Then these spirits, some of which, such as the phee-ka, are very baneful, require to be thwarted by all sorts of counter-charms, conjurings, exorcisms, spirit-dancings, and other devices of the professional medicine-men, and even of "paid mediums." For this institution—somewhat of an anachronism in the West—still flourishes in the Far East, where almost every family has its private mediums, who are consulted on all urgent affairs, and who, when required to question the spirits, work themselves into a state of ecstasy, and utter short, incoherent sentences, regarded as the oracles of the spirit world.

Amongst the illustrations are a coloured engraving by the author, giving a good idea of the "white elephant" visited by him at Bangkok, and a life-size portrait of the enlightened young King of Siam, to whom the work is dedicated. There are also an index and a small sketch-map of the route followed, in which the geographical nomenclature is, as usual, at variance with that of the text. Thus we have Kiang-mai, Toune, Me-ouang, Chandaw, for Cheng-mai, Tunn, Me-wang, and Shandau respectively.

A. H. KEANE

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

The Remarkable Sunsets

ALTHOUGH the prevailing mist and fog do not make the summit of Ben Nevis as a rule a favourable situation for viewing sunsets, yet, when clear and fine, the colours of the sky shine out with far greater clearness and purity than at lower levels. For about a week at the end of last month we had fine weather, and the colours of the sky before sunrise, after sunset, and even during the day, were of the most extraordinary character.

On December 30 before sunrise the lower sky to eastward, between a cloud-bank and a thin dark band of stratus, was pale green, above the stratus it was yellow, passing into red higher up. This arrangement of colour was not observed again; on other days the sky was red or yellow at the horizon, passing into green and blue higher up. At sunset on the 30th the colours were of the most gorgeous description—dark smoky red below, passing into blue and violet without any intermediate shade of green.

Similar colours have no doubt been seen as well at lower levels at sunrise and sunset, but here we see the sky round the horizon coloured in the most wonderful manner all day long—usually a copper red under the sun, and a peculiar dirty green at the opposite azimuth. But it is impossible to give any idea of the exceeding beauty and weirdness of the tints at sunrise and sunset—the whole sky near the sun gleaming with constantly changing masses of colour, indescribable tints of red and green mingled in wild confusion.

On December 31 the thin edge of the crescent moon (three days old) was bright green, but I have not observed any unusual colour in the sun itself.

R. T. OMOND

Ben Nevis Observatory, January 9

I BEG your acceptance of the two inclosed clippings from the *Saturday Press* of this city, together with an advance sheet from Thrum's *Hawaiian Annual* for 1884, which contain nearly all that has been put into print here about the wonderful "afterglow" which has excited such attention in so many parts of the globe. In the first communication of September 19, I recorded the important date of September 5, when the first and most brilliant display was observed, being moved thereto by the arrival of the news of the Java eruption, whose proximity in time seemed to lend especial importance to the phenomenon. In the second notice is recorded an observation of like phenomena in lat. 24° 06′ N., long. 140° 29′ W., 1100 miles east-north-east of us, from the log of the bark *Hope*, Penhallow, master, on September 18.

In my article in the *Hawaiian Annual*, the record is brought down to November 25, during which month the glow continued, somewhat diminished. Since then it has again increased in a marked degree. I have also been enabled to definitely connect ourselves with Melanesia and Micronesia. Brig *Hazard*, Tierney, master, arrived from those parts on December 5. Capt. Tierney is reliable and intelligent. He reports to me that on September 1, when off the south-west coast of New Ireland, about lat. 5° S., long. 152° E., he first observed the "glare," as he termed it; and again on September 3 off New Hanover, two degrees further west. It was identical in character with what he has seen since arriving in Honolulu. It would seem to have been rather less brilliant than was first observed here September 5, as described in the inclosed clipping. During his voyage from New Hanover, sighting Ascension, calling at the Marshall Islands, and thence to Honolulu, over ninety days in all, the "glare" was of *constant occurrence.* By the arrival of O.S.S. *Mariposa* from San Francisco, December 1 to 8, I am happily able also to trace a continuous line of these phenomena hence to that point. They were not observed there until about November 23. Two of our leading citizens who came down by the *Mariposa* assure me that the appearances there were identical with ours, and further that they were of frequent recurrence during the whole passage. We thus prove a continuous chain of these phenomena from New Zealand to California.

Permit me to call special attention to the very peculiar corona or halo extending from 20° to 30° from the sun, which has been visible every day with us, and all day, of whitish haze, with *pinkish* tint, shading off into *lilac* or purple against the blue. I have seen no notice of this corona observed elsewhere. It is hardly a conspicuous object.

The long continuance and extending diffusion of this haze or dry fog seems to justify expectation that it may become visible around the globe, and give ample opportunity for investigation.

Although not seen in San Francisco until November 23, it was brilliant in Santa Barbara on October 14. A rapid upper current seems to have borne it in a belt within the tropics in a very few days, leaving a slow diffusion to extend it to the temperate zone. Australia is perhaps an example of this.

I trust this letter may be a useful contribution towards a complete history of the diffusion of this very peculiar element around the globe. A good record of dates of earliest appearances might contribute something to our limited knowledge of currents in upper strata of the atmosphere.

Honolulu, December 14, 1883 SERENO E. BISHOP

[We have already referred to Mr. Bishop's letters in the Honolulu journal, but give here the following extract from his article in the *Hawaiian Annual*:—

"It now seems probable that the enormous projections of gaseous and other matter from Krakatoa have been borne by the upper currents and diffused throughout a belt of half the earth's circumference, and not improbably, as careful observation may yet establish, even entirely around the globe. This implies an amount of matter discharged that seems incredible. We learn, however, that the ocean was thickly and closely covered with floating pumice for hundreds of miles from the crater. A steamer 150 miles distant reports her barometer falling and rising half an inch every two or three minutes! This almost incredible statement implies a terrific undulation of the atmosphere, such as could only be produced by a vast and continuous jet of gas projected upwards beyond the limits of the atmosphere, and driving the air in vast waves in every direction. So abnormal and gigantic a force may well have propagated not only its tidal waves as it did across the Pacific, but it may also have transmitted its portentous and lurid vapours to belt the globe with flaming skies."]

FOR the last two months these appearances have in this province excited no small wonder and admiration, not unaccompanied in some cases with awe and dismal forebodings of impending calamity. As an example of what has been witnessed in greater or less intensity almost every morning and evening, about an hour before sunrise and after sunset, I may instance what was observed on the evening of the 29th and morning of the 30th ult. The ground from my residence rises towards the south and west, and the city of Fredericton lies towards the north-east, on a flat 100 feet lower, and at a distance of half a mile or more. On the evening in question, at an hour after sunset, the red glow in the sky was very conspicuous, and seemed to light up the whole heavens, so that the houses in the city were distinctly seen by the reflection from their sides, and the intervening snow appeared of an orange colour. It was bright enough to suggest the impression of a second sunset. Next morning at an hour before sunrise the deep red glow was equally decided. W. BRYDONE-JACK

Fredericton, New Brunswick, January 3

IN response to your note in NATURE of December 13, 1883 (p. 157), I beg to inform you that the recent red sunsets have been especially observed by me on the following occasions:—

November 30, 1883, lasting until 5.30 p.m.; barometer at 1 o'clock 30·22 inches, at 9 p.m. 30·10.

January 2, 1884, lasting until 7.30 p.m.; barometer at 1 p.m. 30·48, at 9 p.m. 30·43.

January 3, 1884; Barometer at 1 p.m. 30·30, at 9 p.m. 30·23.

On several other occasions the same phenomenon has been observed in a less degree. AD. WENTZ'L, JUN.

Krasnicza Wola, Grodzisk, near Warsaw, January 11

THE "red glow" has again been very brilliant here on the evenings of January 9 and 10, as well as on the morning of January 10. On the following morning, January 11, the sky being likewise very clear, I confidently expected another display, but to my astonishment no trace of red did appear, the sun rising after an ordinary twilight of pale yellow. During the night a strong south wind had set in, which prevailed through the whole day, with extraordinary transparency of the air. In the evening clouds arose in the west, at first showing the red marginal colouring of ordinary sunsets, but later on there came again, distinctly higher than even the cirri, a very brilliant and lasting red luminosity.

It would be interesting to know whether at other places too the phenomena in question had been, as it were, suspended on the morning of January 11, in spite of a clear sky, or whether such a suspension had occurred on other days under similar meteorological circumstances. D. WETTERHAN

Freiburg, Badenia, January 12

THE last two days and nights here have been very fine with sunrises and sunsets as already described. This evening especially the colours were most brilliant, and did not fade away until at least an hour after sunset. It may interest those who are trying to account for this extraordinary appearance of the sky to know that here it has been followed by excessive rain and very bad weather. During December we had 9·57 against an average for the last twenty-two years of 4·46 inches. The greatest December rainfall registered at our Scutari Cemetery was 10·36 in 1862, the least being one inch in 1868. A printer's error makes me speak, in my letter of December 21, of a crescent moon "eighteen" days instead of 1·8 day old. W. E. J.

Constantinople, January 11

Dust Atmosphere of China

IN the remarkable work on China by V. Richtofen, he gives (vol. i. p. 97) the following description of the *dust atmosphere* of the Loes country, China, which, it seems to me, bears upon the question of the influence of dust on the appearance of the sun and sky, the question now under discussion.

"All these, and other similar operating causes, give rise to that dust atmosphere (*Staubatmosphäre*) so characteristic of Central Asia, and still more particularly of the Loes District. Even during nearly complete calms the air is often for many days yellow and opaque. The view is completely hemmed in, and the sun appears merely as a dull bluish disk. More markedly is this character presented by these peculiar dust-storms so well known to travellers visiting Tien-tsin and Peking, and even more so to those who travel in the interior of the north-western provinces of China. The wind then blows from Central Asia; when it acquires motion, everything becomes coated with a fine, yellowish dust coating.

"In Shensi, where the atmosphere is but rarely clear and transparent, the whole landscape has a yellow tint; streets, houses, trees and crops, even the traveller one meets on the road, and the air itself, one and all are yellow-coloured."

He also cites Johnson's "Journey to Ilchi, the Capital of Kotan" (*R. Geogr. Soc.* xxxvii. 1867, p. 5), as bearing on this same character of those dry, dusty atmospheres.

Dublin, January 7 J. P. O'REILLY

Electric Shadows

ON reading Prof. Thompson's communication to NATURE of the 13th ult. (p. 156), giving the result of Prof. Righi's researches on the production of electric shadows in air at the ordinary pressure, I at once endeavoured to repeat the experiments with such simple means as were at hand. Two sticks of sealing-wax stuck to a small iron stand sufficed to support a long, big-headed pin and the screen or object for casting the shadows. Instead of a plate of ebonite I used a cake of resin of six inches diameter, which serves ordinarily for the production of Lichtenberg's figures; and from subsequent experiments it would seem that the resin serves the purpose *almost* as well as ebonite as far as clearness of definition is concerned. A metal plate, which may or may not be insulated, formed a base for the resin. I mention these details since the ebonite rods and plate are not so well within every one's reach, on the score of greater expense and the necessity of having them specially constructed for the experiments. A plate machine of some size (18-inch plate) seems necessary, as I find that, unless the Leyden jar is charged to rather high potential, no shadow is formed, and, further, that the sharp definition of the shadows increases with the charge of the jar. The screen used was a design, cut out in cardboard and tinfoil pasted over it, very similar in shape to that given in Fig. 2 in Prof. Thompson's paper, and the shadows obtained were substantially similar to that in Fig. 3. But here a small point not before recorded came out:—If the pin, from whose point the discharge is made to take place, be slanted in any direction, which is easily done with the sealing-wax holder by simply heating, the shadow of the object then lengthens out curiously, just as do the shadows formed by an object intercepting light rays as the obliquity of incidence is increased.

The new feature, however, which appeared from my experiments, and which is not recorded by Prof. Thompson, although very likely the experiment may have been done before, is as follows:—Instead of starting with the resin plate in a neutral condition, I gave it a rather strong negative charge by rubbing it vigorously with a fox's brush and discharging the Leyden jar as before on to the pin, using precisely the same object to cast the shadow as before. Its character now, however, was completely altered, appearing as I have endeavoured to represent it in the figure. A simple cross, having little resemblance as to outline with the object, was the result. The red-lead of course was picked out by the negatively-charged resin under the object and piled up to form the cross, which was much more strongly red, as one would expect, than the former shadow. There was also a rather wide neutral region around the cross, considerably more than in the former experiments. It seems to me that this effect is something more than the attenuation of the shadow spoken of by Prof. Thompson, where the screen is electrified independently. Since the subject is one of considerable interest, perhaps it may be useful to show that any one having access to a fairly good electrical machine can repeat and possibly extend Prof. Righi's investigations.

Cosmic Dust

I found in the *Nieuws van den Dag* of December 28, 1883, that a violet sand had been found in the dunes (probably near Scheveningen). The paragraph runs as follows:—When seen under the microscope (feeble magnifying) the ordinary yellow sand seemed to be composed for the greater part of almost white transparent grains, among which were a few light yellow, and pink, and single black grains. The violet sand, however, showed almost all the grains imbibed by a light violet tint, and moreover it contained a very great number of black glittering grains. An idea which occurred to me made me take up a small magnet, and on stirring with it in a glass full of the sand, the ends were covered by feathers formed by the black grains quite the same as the feathers which are formed on putting a magnet into filed dust. Probably I had there grains of a combination of iron; of the latter there was a great deal in it. Now this is the question: Are these grains of the same kind as those which the naturalists have found and gathered on the snow-fields in the Polar regions, thus called cosmic dust?

Diffusion of Scientific Memoirs

I think it would promote scientific information if it were more the custom for those who need copies of papers to make direct application for them. Authors are usually provided with separate impressions for distribution, but are often much in the dark as to how to turn them to the best advantage. The bulk of such copies usually find their way to men of established scientific position who have worked at the subject of the paper in past years, but have perhaps ceased to take interest in it; while those who are actively engaged upon the subject, if they do not happen to have already published matter of importance, are left unprovided for.

I believe that most authors would willingly send copies of their memoirs to younger men, known to be engaged in scientific work, who should make application. But there is one rule which must be observed with the utmost stringency—otherwise I should feel that the evil of the present suggestion outweighs the good—viz. *the applicant must never expect a written answer.*

Weather on Ben Nevis and Snowdon

I was much interested with the account of a visit paid to the Ben Nevis Observatory on December 26, 1883, described in Nature of January 3 (p. 219), more particularly as the weather experienced on the summit was almost identical with that on Snowdon at the same time. I ascended Snowdon on December 23, 25, and 26 from the west, east, and north, and a neighbouring mountain, Glyder Fach, on the 24th. The views from the summit on the 25th and 26th can be best described by the following quotation from Nature (p. 219), referring to Ben Nevis:—"The view from the summit was magnificent. All round there floated a billowy ocean of white mist" (extending from the slopes of the mountain to the horizon north, south, east, and west), "through which rose here and there black mountain peaks." "Overhead the sky was blue," and the sun shone brilliantly. The upper surface of the ocean of clouds was on the 25th about 2000 feet, and on the 26th 1000 feet, above sea-level.

On the 24th I ascended Glyder Fach through about 2500 feet of mist, and, to again quote from Nature (p. 219), on reaching the ridge "suddenly emerged from the gloom of the mist into the brightest of daylight. Overhead the sky was blue, a fresh light breeze was blowing" from the north-west. I here noticed a curious phenomenon. I became suddenly aware, whilst standing in the sunlight on the ridge, that the air was full of an exceedingly minute dust driven by the wind from the north-west and descending at an angle of about 40°. The fall ceased quite suddenly one or two minutes after I noticed it. The impression left on my mind was that anything popularly spoken of as dust would be exceedingly coarse compared with it. There was no snow on the ground.

The phenomenon known under the name of the "Brocken Spectre," mentioned by Mr. Chrystal, may frequently be seen from the summit of Snowdon by any one not afraid of a little mist.

Teaching Animals to Converse

J. S. B. seems to have misunderstood Sir John Lubbock's idea. It would be no great test if drawings were made, as the dog would see so little difference. Thus a dog of mine knows instantly whether he may go out with my housekeeper or not according to whether she wears her hat or her bonnet. In the first instance he knows she is going where he may go, and he is on his feet barking with joy as soon as she appears. If she has the bonnet on, he knows it to be church, or a visit to friends in the country, where he cannot go, and, like the "eldest oyster" (I quote from memory), he "winks his eye, and shakes his hoary head." If drawings of hat and bonnet were made, he would know them at once.

Some years since I had a remarkably clever Skye terrier, whose wisdom was at the time shown in a letter to the *Times*. This dog I taught as follows. When I went out it was quite sufficient to say "Yes" or "No" in an ordinary tone; but wanting to take him beyond that, I taught him very quickly to know the two words when printed on cards, YES or NO, and after a few weeks' teaching he never mistook them. I have no time now for much teaching; if I had, I am sure it could be done with the dog I now have. The intelligence of cats is greatly underrated. My wife's favourite cat follows her everywhere, and comes when called wherever she may be. Cats, too, are very grateful for kindness. When I went into the Malakhoff I found a cat on whose paw a bayonet had fallen and pinned it to the ground. I released it and took it home, and it always followed me all over the camp till the end of the war. And this cat did as follows. I took her to a doctor of the nearest regiment for two mornings to have her foot dressed. The third morning I was away on duty before daylight, and the cat went herself to the doctor's tent, scratched the canvas to be let in, and then held up her paw to be doctored. The intelligence that can be developed in almost any animal depends in most cases on our treatment of it. H. STUART WORTLEY

South Kensington Museum, S.W., January 14

Circling to the Left in a Mist

ONE generally reads that persons walking without landmarks perform a large circle and cut their old tracks again. This circling, as far as my present knowledge goes, is *to the left.*

My present theory is that in most persons the right leg is the stronger and the more forward to step over any obstacles, and hence that it slightly outwalks the left; this theory involving as further consequences that those in whom the left leg is the stronger would circle to the right, while those whose legs are of equal strength would either keep straight on or would wander either way indifferently. I imagine this "outwalking" of one leg by the other to be similar to the manner in which a body of troops wheels to one side or the other.

In the following I use the expression "*right-legged.*" By this I mean that the right leg is that chosen to kick with, jump from, &c.

My negative evidence is as follows:—

1. I myself am right-legged, and in a mist I always circle to the left. I have only come across cases similar to my own in these respects. On the other hand, my left arm has been trained (by always rowing on the bow-side) to be stronger than my right for rowing purposes; and in sculling I always circle to my right side.

2. Those savages of whom I have read that they could keep a straight course without any landmark were also represented as using both arms (and legs?) impartially.

I have given the above evidence chiefly to show how weak it is, in the hope that some of your readers will try to collect data of the following nature from any of their acquaintance who have had experience in the matter:—

(*a*) To which side, if any, do they circle?

(*b*) Are they right- or left-armed, right- or left-legged? or are the two sides equally strong?

It might also be interesting to learn from boating friends if they have observed any connection between the side on which they have been accustomed to row and the side to which they circle in sculling; such connection as that indicated above.

Finally, I may suggest that more might be known on the question of the heredity of right- or left-sidedness; and as to whether persons are often right-armed but left-legged, &c. But it must be remembered that tendencies of this nature are often "educated out" in childhood. W. LARDEN

Cheltenham College

THE PORPITIDÆ AND VELELLIDÆ

PROFESSOR ALEXANDER AGASSIZ has quite recently (July) published an important contribution to our knowledge of the morphology and embryology of these families of marine Hydrozoa. This appears as one of the quarto memoirs of the Museum of Comparative Zoology at Harvard College, and is illustrated with twelve plates. While at the Tortugas, during March and April, 1881, examining the structure of the coral reefs, Prof. A. Agassiz took advantage of every possible opportunity of exploring the surface fauna of the Gulf Stream, and when not otherwise occupied he devoted his time to completing the notes and drawings which he accumulated regarding Porpita and Velella under less favourable circumstances at other points of Florida, at Newport, and on board the *Blake*. These notes are now published as forming the principal points in the natural history of a small and limited group of oceanic hydroids, interesting from their affinities on the one hand to the Tubularians, with which Vogt, Kölliker, and Agassiz were inclined to associate them, and on the other hand with the Siphonophoræ proper, with which they have, however, but little in common. Mr. C. O. Whitman was sent this spring to Key West to complete this memoir, and especially to investigate anew the whole subject of the structure and functions of the so-called yellow cells; but although he spent six weeks at Key West, he was unable to accomplish the object of his trip, as not a single Velella appeared at Key West during the whole of his visit. Under these circumstances Prof. A. Agassiz thought it advisable to at once publish his drawings and notes, completing the descriptive part when the necessary preparations can be finished. The Florida species of Velella (*V. mutica*, Bosc) is much larger than the Mediterranean form (*V. spirans*); specimens measuring nearly four inches in length are not uncommon. On plate 1 is figured in profile and from above and below a huge Velella nearly five inches in length, and in all the glories of its metallic colouring. Thousands of this species are brought by favourable winds and tides into Key West Harbour; they are usually seen in large schools, and although capable of considerable independent movement by means of their tentacles in a smooth sea, yet are they practically at the mercies of the winds and currents. Even moderate waves destroy them in vast numbers. When kept in confinement they soon die, and are rapidly decomposed. The dead floats are thrown ashore in enormous numbers. The large central polypite of the system is the main feeding mouth, but the smaller lateral polypites feed also to a limited extent. All these are connected at their base with the general vascular system, through which as in the polypites the fluids are rapidly propelled by the action of ciliæ lining the inner walls. At the base of the polypite there are, according to its size, from five to eight clusters of Medusæ buds: the small ones already contain the peculiar yellow cells so characteristic of the free Medusæ. The young Medusæ have a very striking resemblance to such Tubularian Medusa as Esuphysa and Ectopleura. It has like them a row of lasso cells extending from the base of the tentacles to the abactinal pole. The yellow cells are arranged in clusters along the sides of the four broad chymiferous tubes, as well as on the surface of the short, rounded, conical, rudimentary proboscis. The young Medusæ move with considerable activity by sudden jerks. The air-tubes branch much less frequently than is the case in the Mediterranean species. All the Velellæ floats examined were left-handed.

The Florida species of Porpita (*P. linneana*, Less.) is nearly related to but is larger than *P. mediterranea.* It is capable of a considerable control over its movements, and is not stranded at all in the same numbers as is Velella. If upset by wind or waves it can, by the great size and power of its numerous long marginal tentacles force itself back again into its normal position. It does this by bringing its tentacles together over the disk and throwing up the free edge of the mantle slowly in a given direction, then expanding the tentacles of one side far over in the opposite direction beyond the central part of the disk, it readily changes the centre of gravity, and so tilts the overturned disk back again. Round the base of a large central polypite are five to six rows of small, stout, flesh-coloured, feeding and reproductive polyps; these have a slightly rectangular head capable of considerable expansion, with four clusters of lasso cells. At their base are to be found Medusæ buds in all stages of development. When the clusters of these are well developed they completely fill the space between the small polypites, giving to the ring which they occupy on the lower surface of the float, a dark yellowish tint from the colour of the yellow cells, found along the rudimentary proboscis of the Medusæ buds, as well as along the chymiferous tubes. The large marginal tentacles are of a bluish tint, their knobs of a darker colour. The smaller polypites occupy on the lower surface that portion of the mantle which covers the ring formed by the so-called white plate of Kölliker round the base of the single central polypite. Sometimes these polypites are seated in cavities of the white plate, and sometimes projections of this latter will be found to extend far up into the lower part of the small polypites. This white or pinkish plate consists of an irregularly anastomosing system of needles and spurs, or of bars of greater or smaller size, leaving a series of narrow openings for the passage of the tubules. Prof. A. Agassiz suggests the alliance of Porpita with the Hydrocorallinæ, basing this suggestion on the presence of the white plate, and of its peculiar structure, which reminds him of the porous structure of the corallum of Sporadopora, Allopora, Millepora, and although, of course, not having the regular horizontal floors of the latter, yet possessing, like these genera, large pits, the whole mass being riddled with passages and openings, forming the spongy mass of the white plate. If this homology be correct, it shows far-reaching affinities in the Porpitidæ. The Plates, twelve in number, give a great number of anatomical details, and there are full-sized and coloured representations of the two species described.

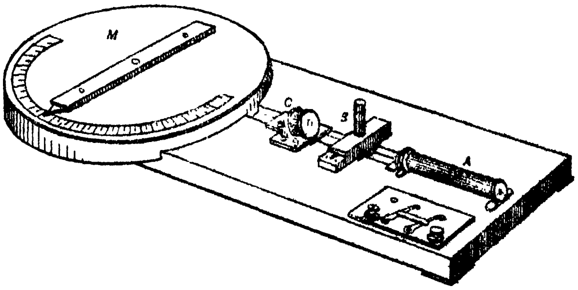
HUGHES' NEW MAGNETIC BALANCE

A NEW magnetic balance has been described before the Royal Society by Prof. D. E. Hughes, F.R.S., which he has devised in the course of carrying out his researches on the differences between different kinds of iron and steel. The instrument is thus described in the *Proceedings of the Royal Society*:—

"It consists of a delicate silk-fibre-suspended magnetic needle, 5 cms. in length, its pointer resting near an index having a single fine black line or mark for its zero, the movement of the needle on the other side of zero being limited to 5 mms. by means of two ivory stops or projections. When the north end of the needle and its index zero are north, the needle rests at its index zero, but the slightest external influence, such as a piece of iron 1 mm. in diameter 10 cms. distant, deflects the needle to the right or left according to the polarity of its magnetism, and with a force proportional to its power. If we place on the opposite side of the needle at the same distance a wire possessing similar polarity and force, the two are equal, and the needle returns to zero; and if we know the magnetic value required to produce a balance we know the value of both. In order to balance any wire or piece of iron placed in a position east and west, a magnetic compensator is used, consisting of a powerful bar magnet free to revolve upon a central pivot placed at a distance of 30 or more cms. so as to be able to obtain delicate observations. This turns upon an index, the degrees of which are marked for equal degrees of magnetic action upon the needle. A coil of insulated wire, through which a feeble electric current is passing, magnetises the piece of iron under observation, but, as the coil itself would act upon the needle, this is balanced by an equal and opposing coil on the opposite side, and we are thus enabled to observe the magnetism due to the iron alone. A reversing key, resistance coils, and a Daniell cell are required."

The general design of the instrument, as shown in a somewhat crude form when first exhibited, is given in the figure, where A is the magnetising coil within which the sample of iron or steel wire to be tested is placed, B the suspended needle, C the compensating coil, and M the magnet used as a compensator, having a scale beneath it divided into quarter degrees.

The idea of employing a magnet as compensator in a magnetic balance is not new, this disposition having been used by Prof. von Feilitzsch in 1856 in his researches on the magnetising influence of the current. In von Feilitzsch's balance, however, the compensating magnet was placed end-on to the needle, and its directive action was diminished at will, not by turning it round on its centre, but by shifting it to a greater distance along a linear scale below it. The form now given by Hughes to the balance is one of so great compactness and convenience that it will probably prove a most acceptable addition to the resources of the physical laboratory.



WINTER LIFE AT SPITZBERGEN

THE following is an extract of a report by one of the *personnel* of the Swedish Meteorological Expedition of the wintering at Spitzbergen:—

One of the deepest fjords of Spitzbergen is the Ice Fjord on the west coast. On a map of the islands it will be seen, some fifteen miles from the mouth, to split into two smaller ones. The promontory which divides the two is Cape Thordsten. It is formed of slate rocks some 2000 feet in height, from which in some places precipices descend perpendicularly into the sea, and in others valleys slope down into the plain. The latter is furrowed by streamlets and deep ravines, while the rocks around are the breeding places of every sea bird of the Arctic fauna, as, for instance, the seagull, the auk, the rodge, and the *Uria grylle*. In the plain reindeers graze, and on the mountains ptarmigans and snow-sparrows breed. The plain is covered with grass, rather strongly interspersed with moss, but here are to be found many plants and flowers, such as *Polymonium pulchellum*, *Dryas ortopetula*, the white and red saxifrage, the Spitzbergen poppy, and the common buttercup.

In the plain close to the mountain the huts are situated which now bear the name of "Smith's Observatory," from the munificent equipper of the expedition. The buildings were erected here some ten years ago by the Ice Fjord Company, which was formed for the utilisation for guano of the coprolite deposits found in the adjacent mountains.

On July 21, 1882, the vessels of the expedition arrived here, but it was at that period doubtful whether we should establish our station here, as the mountains around contain a large quantity of hyperite, a mineral which it was feared would affect the magnetical instruments. We found on landing a line of metals up the hill, with a gradient of 45°, a winch being fixed at the other end for its working. Here was also, still intact, the little dwelling house on four poles, alongside which we found the material required for the building of a new house as stated in works on Spitzbergen. Near to the house is a cross raised with the following inscription: *Her hviler. Stövet af* 15 *Mænd, som döde her i Foraaret* 1873. *Fred med deres Stöv.* This is the epitaph to the Norwegian fishermen who sadly perished here ten years ago.

We found by experiments that the mineral in question did not affect the magnetic instruments, and decided therefore to establish the station here. We had a hard time to get everything in readiness, as, for instance, the building of the magnetic hut and the thermometer cage, by August 15, when the observations were to begin, but on August 22 we had so far advanced that both magnetical and meteorological observations could be prosecuted simultaneously.

The view from the observatory was grand. Heavy clouds generally cover the sky, driven hither and thither by strong gales; below the sea roars, with ice floes floating on its crest, while thousands of sea birds wheel in the air. Suddenly the clouds part, and the sun comes forth, the snow-white peaks flash in the rays, the stony ridges become purple, and down below the dark gloomy sea assumes the colour of the sapphire.

On August 23 the sun set for the first time, and on October 23 it did not appear. Already, on August 31, the ground became covered with snow, but early in September, and towards the middle of October, it again thawed, and it was not until October 21 that the snow remained. The birds now began to leave, and the *Tringa maritima* were last seen on August 20. The brent geese soon departed in flocks, and flew cackling southwards out of the fjord. The last was seen on September 13. On October 14 we saw an eider, and some specimens of *Procellaria glacialis*, and on October 21 a snow-sparrow appeared at the station. From that date none of the migratory fauna was seen until the spring. Quite alone, however, we were not, as the mountain foxes soon appeared, and were not the least shy. Ptarmigans were plentiful, too, in the ravines, where they feasted on *Polygonum* seed. On October 26 we shot the first two reindeer at Sauriehook, but it was not until the spring that they came in any numbers.

Our work progressed too. We had first of all to fix the anemometer and the weathercock on the mountain above the station, or 800 feet above the sea, and to connect it with the observatory by a telegraph wire, as the readings were to be made by electricity. Then there was a workroom to be constructed, and the astronomical observatory for the passage instruments to be erected. On October 3 the wire to the anemometer was ready, and the hut carried up to the top of the mountain, where it was fixed. On October 25 the astronomical observatory was finished. It was now so dark that no work could be done outdoors, and on October 23 it was necessary to light up at 3 p.m., on October 28 at 2 p.m., and on November 2 light was necessary throughout the day. The Polar night had set in.

From October 23 until February 18 the sun remained below the horizon; thus for a period of 118 days and nights. At first it was not quite dark at noon, but from November 11 it was a night throughout. On November 12 a thin layer of ice appeared on the Ice Fjord, which gradually increased in thickness, but it was afterwards broken up and again formed several times during the dark winter. It was only when the light came back that the ice formed in a bridge across the fjord.

Now the island was in darkness and perfectly deserted. The terrible winter storms had commenced, and it was 16° C. below freezing-point. And the snow! Snow on the mountains, snow on the plain, snow on the huts, snow covers the little windows, snow comes in through the chimney, and even the thermometer cage cannot exclude the tiny, pointed crystals which penetrate even a keyhole. In such an hour it was a delightful sensation to seek the hearth in the library!

Again I stand by the shore. The clouds have cleared away; only one enormous mass, which we never saw lifting, lies over the mountains across the fjord. The sky is clear, the ocean roars below, there is no ice; the moon is about to pass her meridian.

Slowly one long tidal wave after another comes rolling towards the shore; they gather into one tremendous wave, which, striking the lofty rocks, sends its spray a couple of hundred feet into the air. Then it recedes with a deep sigh, leaving two or three magnificent ocean algæ, each a yard long, on the shore.

When the moon is absent, it is, however, pitch dark, provided there is no aurora borealis. The aurora borealis was observed throughout the winter, when it was clear, and in every form and position.

Now a faint arc appears far down on the south horizon. Below it is a dark segment. Slowly it travels towards the zenith, increasing in intensity. It is perfectly symmetrical, and both its points almost touch the horizon, and strike east and west as the arc moves upwards. No streamers can be made out in it, and the whole forms one continuous layer of light of a strange transparent yellow colour. The arc is broad; its size is three times that of the rainbow, and its edge, which is far more defined than that of the rainbow, forms a strong contrast to the dark sky of the Arctic heavens. Higher and higher the arc travels; in the whole display there is a solemn rest, and only here and there a wave of light suddenly leaps upwards. Above the snowy fields yonder it begins again to get clearer. Still it is far from the zenith, and already another arc separates itself from the segment in the south, and by degrees others follow. All of them now travel towards the zenith, traverse the point and descend on the northern horizon, while some rapidly recede to where they originated. Seldom, however, does the aurora appear in this regular and defined form.

In the corner of the horizon lies a light cloud-mass. Its upper rim is illuminated, and from this a luminous band is quickly developed, which spreads east and west, increases in intensity, and travels towards the zenith. The colour is the same as that of the arc, but the intensity is greater. In a constantly changing play the band slowly alters, but remains continuous in form and plane. Now it is interlaced into several plaits and folds, but throughout there is an undulatory motion which throws waves of light through the band in its entire stretch from right to left, or *vice versâ*. Again it unfolds itself and forms into draperies and festoons, which are lost in the depths of the horizon.

On another occasion the band assumes quite a different form. It then consists not only of luminous matter, but also of solitary streamers ranged in a parallel plane, all pointing to the magnetic pole. In each of the streamers the intensity is, through the light-waves which follow in rapid succession, greatly increased, which gives the streamers the appearance of being in a constant leaping motion, while the two edges, green and red in colour, move wave-like up and down, according to the play of the coursing waves of light. Often the streamers prolong themselves throughout the entire band; they stretch even as far as the magnetic pole, and then remain at rest. They are sharply defined, but fainter in light than the band itself, and do not lie close together. They are yellow in colour, and appear like millions of fine threads of gold thrown across the firmament. Again a thin veil of light creeps over the starry heavens, and the golden threads of which it is woven stand clearly out from the background, while its lower *garniture* is formed of a broad, intense, yellow-white border with a thousand filaments in a slow but constant motion.

Again it appears in a third form. Throughout the day bands of every form and grade of intensity have been drifting over the sky. It is eight o'clock in the evening, the hour when the aurora borealis reaches its greatest intensity. At the present moment only a few groups of streamers stand in the firmament, while down in the south, just above the horizon, lies a faint band which is hardly noticed. But suddenly it begins to move upwards with great rapidity, spreads its folds out east and west, the light-waves begin to leap in it, and long, solitary pillars shoot towards the zenith. At this moment there comes life into the sky. From every quarter of the firmament streamers come rushing with the speed of lightning towards the zenith. The little, fiery tongues whirl round, or sway to and fro, appearing as though they were Cupids in golden mantles with borders of purple. They dart and leap in vain to reach the zenith; they begin to move wave-like, slower and slower; they seem to get tired, still they whirl on towards the north, when suddenly they lose in intensity, and, in a fraction of a second, vanish!

It is again dark and cold; a thin veil of light again begins to form over the star-covered sky. This is as the aurora appears in its grandest form, and any description of it would fail to give even an idea approaching its real majesty and even grandeur.

In addition to the meteorological and magnetic observations, those of the aurora borealis were also made during the Polar night by means of the well known theodolite, and from October the electricity of the air was also examined. On the two agreed dates, the 1st and 15th of every month, the magnets and the aurora were examined and registered every fifth minute, and during one hour, every twentieth second. Besides these observations, meteors and shooting stars were watched and carefully noted, attempts made to measure the quantity of the snow, measurements of the aurora borealis effected, along with astronomical determinations of hour and place, absolute magnetic measurements, simultaneous observations every twentieth second of the magnets, the aurora, and the electrometer, and researches on the moisture of the air, and the nightly radiation, while the temperature of the snow was examined at various depths.

Already in October the remarkable depressing influence which darkness exercises on the human mind, with which every one who has wintered in the Arctic regions is familiar, began to be manifest. In that month it was, however, felt only slightly, but with November it rapidly increased, and at the end of December it had reached "the first stage of insanity." This influence caused a remarkable dislike to conversation, accompanied by great lassitude. When lying down, phantoms of the scurvy crept over one's mind, and the thought uppermost was that here, next to us, the bodies of fifteen brave men were found in a horrible condition ten years ago. The best cure for this was, we found, an exhausting walk, a good dinner, and a few glasses of lime-juice accompanied with the cheering thought that our expedition formed one of the moments in the great work of the human race.

The moonlight during midwinter was very remarkable, and imparted in the day a transparency to the air which we had never seen before. The greatest mountains did not oppress the eye, but seemed to assume a lightness which made them appear as if they were floating on the dark background.

On February 19 the sun was to reappear, but already on January 23 it was so light that we could read fine print out of doors, and on February 8 we could, at 11 a.m., read the thermometers in the cage without a lantern. On February 19 the sun came at last. During these days the scenery was magnificent. On the light sky clouds of every shape floated, coloured in the loveliest tints by the sun's rays, while over the whole was cast a hue of purple and gold.

In the beginning after the sun's return, auroræ were still seen in the night, but on March 25 we saw the last of this phenomenon. Eventually on April 19 the sun became circumpolar, and from that date we had perfect daylight.

We often noticed during the spring a thick, cold haze lying over the landscape, in which mock suns and some other optical phenomena were frequently seen, caused by the reflection of the sun's rays in the ice-crystals.

The fjord was in the light period entirely covered with ice, and, as the sun reappeared, even the open leads which could be seen between the ice-floes became covered with thin ice. Only far out on the horizon above the fjord a "water cloud," bespeaking open water, could be seen, and the increase or decrease of this we watched with great interest.

The migratory birds now began to arrive, and the *Procellaria glacialis* was already seen on February 7. On April 13 the first snow-sparrow came, soon after followed by the auks, the rodges, and the seagulls. The ptarmigans, which had lived in flocks during the winter, now began to separate, and preferred the mountains to the plains.

The observations were steadily continued, and the particular object of the researches of the meteorologist at this period was the radiation from the snow's surface. We thus believe we have discovered that the thermometers in the cage did not give the true temperature of the air, which was to be tested by means of a "swing" thermometer, *i.e.* a thermometer fastened to a cord, and then swung rapidly round, as such a thermometer will give the air's exact temperature as near as possible. Under these observations, which were made every hour, it, however, often happened that the cord broke, and the instrument suffered injury. In order to avoid this a mechanism was constructed, driven by hand, which kept the thermometer in a constant rotary motion, and from May 4 until the end of the month, when the thaw set in, this thermometer was read every hour. Another subject also investigated, from February 15, was the temperature of the snow on the surface and at three different depths.

During the light period three hydrographic-magnetic excursions of research were made on the ice in the Ice Fjord, viz. on April 19, April 24, and May 24. The longest of these, the one on May 24, extended six miles from the shore, and it was very difficult work to drag the sleigh over the rough ice. The results of the same were several absolute magnetic measurements, observations of the temperature of the sea at various depths, and testings of the saltness of the water. The greatest depth found was 250 metres.

At the same time, while the snow still remained on the ground, several topographical works were effected. A base some 600 metres long was measured between the universal instrument and a pole south of the same, while two signal posts were erected on two crests south-west and north-east of the station, and three miles apart. Afterwards the greater base was determined by means of triangular measurements from the smaller, in order to serve as a basis for further work. In addition to this there was built, on the sun's return, an astronomical observatory for the universal instrument, which was finished on February 14, and finally a magnetic hut was built for the Wrede's variation instrument, finished on May 19.

There was, during the dark period, one question which was much discussed, and which we were anxious to test, viz. whether the Polar night has the effect of turning the complexion white. On January 23, therefore, when it was light enough to see out of doors, we assembled in the open to examine our faces, and the concensus of opinion was that the darkness had not affected the skin in the least.

In the end of May the thaw set in in earnest, and soon mosses and shrubs came forth. In the beginning of June the fjord was still covered with ice, but by the 11th it commenced to open towards the sea, and by the 21st it began to break up and drift. On July 4 the fjord was free from ice.

The fauna now began to appear: thus already on June 2 the red blossoms of *Saxifraga oppositifolia* came out from the snow; on June 11 *Salix polaris* was in bloom, as well as *Draba wahlenbergii*, and soon the plains were covered with flowers.

At that time some exceedingly interesting experiments in horticulture were commenced. A small garden was first formed by breaking up the layer of turf on the surface, to enable the sun to thaw the frozen earth underneath, and in this manner sufficient mould was obtained to lay out proper beds. In these were then planted seeds, among others radishes brought from Sweden, while several species of the Spitzbergen fauna were planted here. Both flourished remarkably, as did also the rye and oats which we planted here. The latter grew well, although slowly, and were, at the end of July, six to eight centimetres long. Their growth was measured every fifth day, while studies of the sun's chemical influence on the same were simultaneously prosecuted.

The migratory birds continued to arrive: thus on June 2 the brent geese put in their appearance, and in great flocks took possession of the innumerable lagoons. They were, however, very shy, and comparatively few were shot. Of wild reindeer several were shot, and one Polar bear was seen, but escaped.

At last on June 26, at 4 p.m., the first reminder of the outside world appeared in the shape of a fishing smack, but, although every effort was made to attract attention, she passed northwards. On July 8 an expedition was despatched to Cape Staratschin, the "general post-office" of Spitzbergen, which brought back news, letters, and the literature of the civilised world for a whole twelvemonth, the period of our isolation.

Shortly afterwards we had several calls of Norwegian hunters, among whom may be mentioned the well known Capt. Kjeldsen, of the *Isbjörnen*, who participated in the Payer-Weyprecht expedition of 1872, and in the Austrian to Jan-Mayen, 1882-83. He made the remarkable report that he had found the sea at the Norse Islands early in July this summer entirely free from ice, not even seeing the "ice-blink," *i.e.* the light reflected from new ice formed out of sight. This was in the exact spot where the Swedish expedition was compelled to return on account of enormous pack-ice, at the same period in 1882. He was of the opinion that a steamer would have been able to penetrate very far north of the Seven Islands this summer.

In the middle of August the relief boat *Urd* arrived, and, after having cleared the houses, and nailed up the windows and doors, we went on board, and steamed out of the Ice Fjord on August 25, having for a period of exactly 400 days, contributed our quota to International Polar research.

THE WEIGHTS OF BRITISH NOBLEMEN DURING THE LAST THREE GENERATIONS

IT is of considerable interest to know in an exact way the amount of change that may have occurred in our race during recent generations. I therefore send the following results concerning the changes in weight, which I have calculated from data obligingly furnished to me by Messrs. Berry, of 3, St. James's Street, London. Messrs. Berry are the heads of an old-established firm of wine and coffee merchants, who keep two huge beam scales in their shop, one for their goods, and the other for the use and amusement of their customers. Upwards of 20,000 persons have been weighed in them since the middle of last century down to the present day, and the results are recorded in well-indexed ledgers. Some of those who had town houses have been weighed year after year during the Parliamentary season for the whole period of their adult lives. I examined two of the ledgers at my own house, and was satisfied of their genuineness and accuracy; also that they could be accepted as weighings in "ordinary indoor clothing" unless otherwise stated. Much personal interest attaches itself to these unique registers, for they contain a large proportion of the historical names in our upper classes.

I have ventured to discuss only a small and definite part of this mass of material, and I selected the nobility for the purpose, because the dates of their births could be easily learnt, which had to be done in order to connect the years in which they were weighed with their ages at the time. They formed a more homogeneous group than one that included younger brothers and men about town, who marry late and lead less regular lives. I therefore begged Messrs. Berry to find a clerk for me who should make the required extracts under their direction in an anonymous form for statistical purposes. I also asked to be furnished with an alphabetical list of the persons weighed, that I might know generally with whom I was dealing, and that each schedule should bear a reference to the folio whence it was extracted, so that, whenever verification was needed, the original might be referred to. All this was done, and I am in possession of 139 schedules referring to as many different persons, namely, 109 peers, 29 baronets (who were added as makeweights), and 1 eldest son of a peer. They were born at various times between 1740 and 1830, or thereabouts. Each schedule gives the age and year of the several weighings, the highest and lowest weights recorded in that year, and a copy of such remarks as were entered at the time about the dress. An age-weight trace similar to those in Figs. 1 and 2 was plotted on a large scale on each schedule. My best thanks are due to Messrs. Berry for their careful oversight of the tedious clerical work and for the intelligent assistance they gave in having it satisfactorily accomplished.

Specimens of the Age-Weight Curves of Individuals

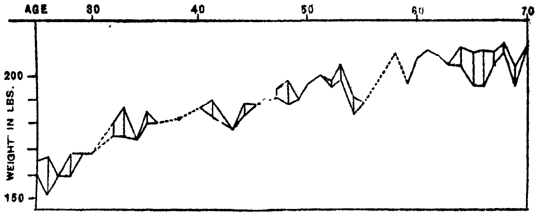


FIG. 1.—One-fourth of the Series are more irregular than this Specimen. (The Upper Quartile.)

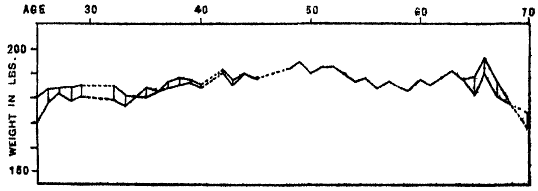

FIG. 2.—One-fourth of the Series are less irregular than this Specimen. (The Lower Quartile.)

The age-weight traces differ widely and in many ways: (1) in the annual range of weight, (2) in its fluctuations from year to year, (3) in the age at which the weight reaches its maximum, (4) in the bluntness of the culminating point.

The annual range is shown in Figs. 1 and 2 by the short, vertical lines that connect the upper and lower contours. The top of each line corresponds to the highest weight recorded in the year to which it refers, and the bottom of the line to the lowest. I find the average annual range in my whole series of cases to be 6 lbs., and that, in the successive decades extending over ninety years, it has decreased prettily steadily from 7 lbs. to 5 lbs. This points to an irregularity in the mode of life that was greater two or three generations back than now, and we shall shortly see that it is by no means a solitary indication of this well known fact. It would be interesting to learn how much annual irregularity in the weight of an adult is consistent with perfect health.

The only evidence I know that could throw much light upon it is summarised in a Parliamentary paper on prison discipline,[1] whence it appears (p. 54) that a certain amount of irregularity is normal among prisoners, that they are heavier in summer than in winter, and that the changes are abrupt; also, that fluctuations in weight, bearing no sort of proportion to previous changes of diet, are of constant occurrence.

I calculated a rough numerical measure of the irregularity of each trace for the purpose of classifying them. I did so on the same principle that one might adopt to measure the discursiveness of a rambling path, in comparison with that of a straight turnpike road between the same points, namely, by finding the proportion that the length of the one bore to the other. I measured the trace and also the general sweep of the trace with a map-maker's "perambulator," divided one by the other, and corrected each result on the principle that a fluctuation of 12 lbs. in a man of 16 stone should not count more than one of 9 lbs. in a man of 12 stone. I also exercised some judgment in my measurements, to avoid the error of dealing with ups and downs in the trace that were apparently due to the fragmentary character of the observations (sometimes only one record in a year, and sometimes two), as if they were real fluctuations. Each available trace was marked on this principle, and the traces were classified according to their marks. Figs. 1 and 2 are the "quartiles" of this class.

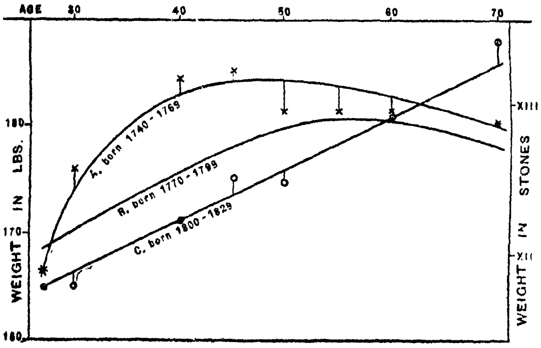

FIG. 3.—Mean Age-Weight of British Noblemen in three successive generations

One quarter of all the traces are more irregular than Fig. 1, one quarter are less irregular than Fig. 2, and the remaining two quarters lie between them. The "median" trace occupies the half-way position; it is unnecessary to reproduce it here, as an imaginary interpolation between Figs. 1 and 2 will suffice.

I next divided the traces into three divisions, A, B, and C, according to the dates of birth of the persons they referred to. It happened that each division covered a period of thirty years, so A, B, and C may be taken to represent three successive generations, born respectively between 1740 and 1769, 1770 and 1799, 1800 and 1829. The numbers of traces available for the present purpose were 21, 22, and 26 respectively. It appeared that the most irregular trace in Group C would rank only as the seventh in Group B, and as the fifth in Group A, and yet C contains the greatest number of cases.

There can be no doubt that the dissolute life led by the upper classes about the beginning of this century, which is so graphically described by Mr. Trevelyan in his "Life of Fox," has left its mark on their age-weight traces. It would be most interesting to collate these violent fluctuations with events in their medical life-histories; but, failing such information, we can only speculate on them, much as Elaine did on the dints in the shield of Launcelot, and on looking at some huge notch in the trace, may hazard the guess, "Ah, what a stroke of gout was there!"

The age at which the weight reaches its maximum is earlier in the earlier generations. I attempted eye estimates, and found it comparatively easy to form them in respect to the traces of the earlier period, where the culmination was usually distinct, and found that it frequently occurred at an early age; the number of times in which it took place in the successive decades of life in those days being as follows: under the age of 29, 2 cases; 30-9, 5 cases; 40-9, 6; 50-9, 7; 60-9, 12; 70 and upwards, 2. In the latter generations the culminating point was frequently too indistinct to be localised, so that I am unable to offer a corresponding statement for comparison that would be trustworthy. In short, the development of the latter generations was more regular.

The clearest evidence of the different age-weights in the three generations, A, B, and C, is obtained by comparing their Means. The following is a brief numerical abstract of them to which the number of cases upon which each mean is based is added in a different type below it. The figures in parentheses are doubly meaned results, those to the left being derived from observations made at the ages of 26 and 28, and those to the right from observations at 68 and 72. For purposes of comparison I subjoin the weights of the professional classes, extracted by interpolation from the table, published by the Anthropometric Committee of the British Association in their Report, 1883, p. 40. The number of observations on which these are based, are given in a form that does not admit of strict comparison with those of my series. They are 24, for observations at the ages 30-35; 24, for 35-40; 44, for 40-50; 13, for 50-60; 5, for 60-70.

Mean Weights at Various Ages

CLASS	YEARS OF AGE					
	27	30	40	50	60	70
A	(166) (13)	176 18	184 24	181 21	181 18	(180) (12)
B	(168) (24)	171 23	172 24	184 26	178 26	178) (15)
C	(165) 35	165 44	171 43	175 37	181 22	(188) (7)
Professional	151	167	173	174	174	—

These figures are rendered much more expressive by translating them into smoothed curves; those from which A was drawn are shown by crosses; those from which C was drawn are shown by small circles; but those from which B was drawn are omitted for clearness' sake.

Whatever may be the exact significance of these mean values, which is by no means so clear as may at first sight be imagined, and whatever may be their absolute worth, which I do not rate very highly, there can be no doubt as to their differential importance. They show with great distinctness that the noblemen of the generation which flourished about the beginning of this century attained their meridian and declined much earlier than those of the generation 60 years their juniors. They were nearly a stone heavier at the age of 40.

The weights of these two generations were identical at the age of 62 or 63, but at that period of life the earlier generation was declining in weight with almost the exact speed at which the latter was continually rising. The steadiness of the rise of the latter from early manhood to late years is very striking; it is almost in a straight line. I have not sufficient data to justify me to say when its curve culminates; I have closed it at 70 with a dotted line.

---

[1] Copies of correspondence between the Secretary of State for the Home Department and the Inspector of Prisons, &c., and the Report of a Committee, &c. Ordered to be printed May 20, 1864.

It is only necessary to add that the ledgers of Messrs. Berry are a quarry from which, with some labour, much further information of the kind just given might be drawn. Perhaps the publication of this paper will suggest methods of treating them that have not occurred to myself.

FRANCIS GALTON

THE ERUPTION OF KRAKATOA[1]

"SIXTEEN volcanoes now working between the spot where Krakatoa was before and Sebesie." Such was one of the first reports which was sent by cable to Singapore, and which we heard at Pontianak. Never before had we been so longing for news from Java, for when H.M. ship *Hydrograaf* steamed into the Padang-Tikar River, we heard heavy detonations and explosions like far-off shots, so that we were alarmed about Java. As we expected, our ship was soon ordered to survey the Sunda Straits. This survey was finished at the end of October, and the reader will probably feel interested to know what really has happened there.

Krakatoa has not entirely disappeared, while, till now, no new volcanoes are visible in the neighbourhood. But the report that new islands were said to have arisen between Sebesie and Krakatoa is easily to be explained, for the new islands are like a mass of smoking and steaming rocks, and if seen from afar they may easily suggest the idea of a great number of working volcanoes. But, when looked at closely, it appeared that the masses of rock were composed of hot pumice-stone, mixed with eruptive masses. In them there were a great many cracks and splits, in which, by the heavy breakers, steam of water was continually generated.

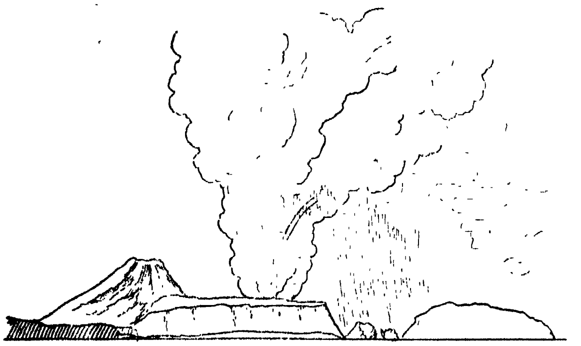

FIG. 1.—Krakatoa during the eruption of May, after a drawing of the Military Survey Bureau, Batavia.

The northern part of the island has entirely disappeared. At what is now the northern edge the peak rises nearly perpendicularly from the sea, and forms a crumbled and rugged wall, and shows a vertical cutting (which is more than 800 metres high) of Krakatoa.

Where was land before, there is now no bottom to be found; at least we could not fathom it with lines of 200 fathoms (360 metres) long. When we had quite calm weather, and steamed slowly and cautiously to and fro along the base of the peak, or had turned off steam and let the ship drift, and were busy in measuring the depth, we could distinctly see the different strata and rocks of the bare, opened mountain. Only here and there a slight trace of melted volcanic matter was to be seen, which, after half of the mountain had crumbled away, had flowed over the wall, which is still there. What remains of the slopes is covered with a grayish-yellow stuff (which, as plainly appears, had been in a melted or fluid state), full of cracks or splits from which steam is continually coming out.

In the same way steam is also coming forth from the deeper cracks of the steep wall, which is still remaining. Sometimes this is accompanied by slight explosions; at that time clouds of brown dust fly up from the cracks, and stones roll down which are often so big as to disturb the sea around the entire base of the mountain. Our entire survey of the north of Krakatoa suggested the idea that we were above a crater which had been filled with water and quenched by it, and this idea was still strengthened on observing that the decrease of depth, south of Sebesie, had principally been caused by matters which were cast out and flung away.

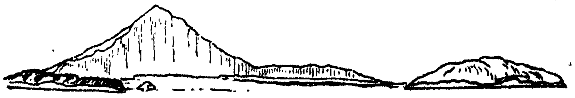

FIG. 2.—Krakatoa after the eruption in May, after a drawing of the Military Survey Bureau, Batavia.

Almost in every place here the lead came up from the bottom, filled with black sand or carbonised dust, sometimes mixed with pulverised pumice-stone and little black stones, which apparently had been in a red-hot or melted state. Moreover, the soundings were very different, and the new rocks resemble clods of substances which, when in a melted or very hot state, had contact with water. Probably such a whimsical shape of the rocks above the sea-level suggests the state of the bottom of the sea in the neighbourhood. The stones were still too hot to allow us to discover whether massive stones are under the pumice-stone also. It was not difficult, it is true, to knock off large pieces of these rocks by a hatchet or a chopper, but when a big block fell unexpectedly down, the sailors had often to flee on account of the gases which suddenly arose. The knocked off pieces which were brought on board were still warm after they had been in the boat for an hour.

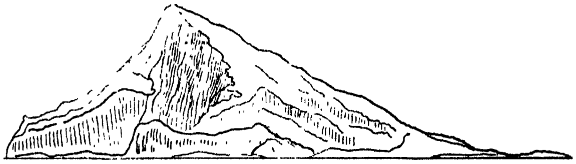

FIG. 3.—Peak of Krakatoa after the eruption in August, by M. C. van Doorn.

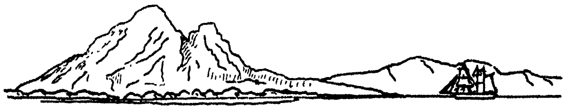

FIG. 4.—Peak of Sebesie and the volcanic rocks before it, by M. C. van Doorn.

As is to be seen from the map, a great part of the lost ground of Krakatoa is found again at the bottom of the sea, a few miles to the north at least, if we suppose that no undulations of the ground took place. After having passed the limits to which the matters were thrown out, one finds the same soundings as were found before, and the decrease of depth is so local that the idea of an upraised bottom is dissipated at once. If such an elevation had taken place, it certainly would be remarked over a far greater extent and be more regularly ascending and descending. The firmer and stronger part of the crater wall, the peak of Krakatoa, which is still there, remained standing when the lower and feebler part dropped down, and the water found its way into the fearful boiling pool. We cannot wonder therefore that then a quantity of steam came forth (of which we are not able to form an idea), which caused a strong explosion. The movements of the sea which followed it caused tidal waves, the destroying force of which was experienced in such a fearful manner at the coast of Bantam and the Lampongs.

---

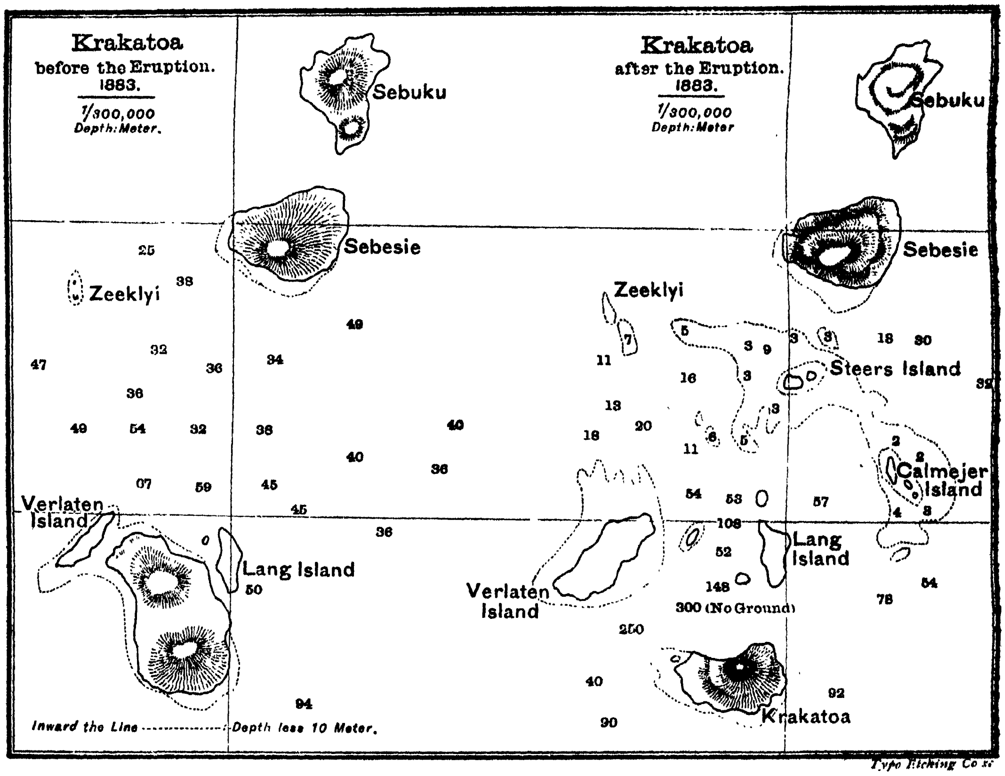
[1] By M. C. van Doorn, officer in command of H.M ship *Hydrograaf*. Translated (and partially abridged) by E. Metzger from *Eigen Haard*, 1883, No. 51.

It is also worth mentioning that a change took place in the figure of Verlaten Island; the area is now triple what it was before, though it is plainly visible that large pieces of the beach were there knocked off a short time ago.

Lang Island, in size and formation, has remained almost unaltered. The sight of these islands, which were formerly covered by a luxurious vegetation, is now very melancholy. They are now buried under a mass of pumice-stone, and appear like shapeless clods of burst clay (*i.e.* covered with cracks). After a torrent of rain, the coming forth of steam is sometimes so dense that these islands, when seen from afar, appear like hilly ground covered here and there with snow. If looking at these spots with the telescopes, one can plainly see that these white specks are formed by a great number of clouds, which issued like steam from the fissures.

Sebesie is also covered with ashes up to the top—859 metres—which appear like a grayish-yellow cloth. But it seems that the cover is already less thick here, for here and there one sees the stumps of dead trees peeping out from the crust.

Sebuku shows a dreadful scene of devastation. Perhaps all that lived here is not so completely destroyed as was the case on the southern islands, but the sight of the bare fields of ashes, alternating with destroyed woods, the trees of which are all either dead or uprooted, gives one a still better idea of the destructive powers which were here at work. It is not until we come to the small islands northward of Sebuku that our eyes are gladdened by little specks of green.



Typo Etching Co sc

Krakatoa and neighbouring islands before and after the eruption, from official surveys.

I do not try to describe the scene of destruction and misery which we saw at Anjer and the villages along the coast. The papers have already reported the full particulars, and therefore I do not care to repeat melancholy facts which are already known.

It was a dreadful narrative which was related to us by a native, a lighthouse-keeper of Fourth Point, one of the few men at the lighthouse, who by a wonder was saved.

When the wave approached, all fled to the tower (the light was 46 metres above the sea), which, though shaking, resisted the violent waves for a long time. It was a terrible moment, when at last an enormous rock, which was swept away by the stream, crushed the base of the tower, which then fell down. The man who was saved saw his wife and his children drowned before his eyes. He related this fact in the very resigned way of a Javanese, and considered it the most natural thing in the world that he was now obliged to light the interim light, which was erected as soon as possible.

It has been almost a month that we have been in the Sunda Straits, and even in this short period we could observe that the coasts of Bantam commence to revive. From many places from the heavy rain the ashes are washed down, and a fresh green appears again. Even on the beach young cocoanut trees and banana trees are shooting out between the chaos of dead trees, blocks of rocks, &c.

Off Batavia, October 23, 1883

CHARLES WATKINS MERRIFIELD, F.R.S.

MR. CHARLES WATKINS MERRIFIELD, F.R.S., who died at Hove on the 1st inst., at the comparatively early age of fifty-six, was a native of Brighton. Having entered for the Bar, he in 1847 received from the then Marquis of Lansdowne an appointment in the Education Department of the Privy Council Office. Though called to the Bar in due course, he never practised, but was speedily promoted to the office of an Examiner, the duties of which he discharged with marked attention and success, while finding time for other work which made for him a name among men of science. Though well versed in Greek and Latin, as well as in the classic authors in French and Italian, both of which languages he wrote well and spoke fluently, the bent of his mind was decidedly towards the more exact sciences. He was an early member of the Royal Institute of Naval Architects, of which he was for many years Honorary Secretary, receiving a handsome testimonial on his retirement in 1875. Some mathematical papers he had contributed to the *Transactions* of some of the learned societies, and especially some memoirs on the calculation of elliptic integrals in the *Philosophical Transactions*, led to his election as a Fellow of the Royal Society in 1863. In 1867 the Government established the Royal School of Naval Architecture and Marine Engineering at South Kensington, and Mr. C. W. Merrifield, at the request of the authorities, accepted the office of Vice-Principal. He only intended to take this as a temporary measure, but as the result of the lamented death of Mr. Purkiss, who was to have been Principal, Mr. Merrifield was appointed to that office. On the transfer of the Institution to Greenwich in 1873, he resumed his office of Examiner in the Education Department. Mr. Merrifield was a frequent attendant at the annual meetings of the British Association, and filled the office of Vice-President of its Section of Mechanical Science at the Brighton meeting in 1875, and was President of the same Section at the Glasgow meeting in the following year. He served on many important committees .of that Association; one of these was the committee whose report on the stability, propulsion, and seagoing qualities of ships in 1869 was drawn up by him, and another was the committee for reporting on Babbage's celebrated analytical machine. Mr. Merrifield was a member, and in due course became President, of the London Mathematical Society, and he held the office of Treasurer until he was compelled by his health to resign it in 1882. To some of the leading scientific journals and periodical publications his contributions, extending from 1853, have been very numerous; they may be found in the publications of the Royal Society, the *Philosophical Magazine*, the *Assurance Magazine*, the *Messenger of Mathematics*, &c. His acquaintance with mathematical arithmetic, methods of interpolation, and tabular work in general, was very wide and complete. Mr. Merrifield edited many of the works in the Textbooks of Science published by Messrs. Longman, and himself wrote a successful treatise on arithmetic and mensuration as one of that series. Some of his papers on the difficult and scientifically interesting subject of sea waves were translated into Italian for the *Rivista Marittima*, in which they appear, and a footnote to one of them, after bearing testimony to the author's extensive knowledge and excellence of style, expresses the satisfaction of the editor at his adding to these qualifications that of "writing correctly our language." He was closely connected with the Association for the Improvement of Geometrical Teaching from its foundation, and took an active and leading part in the work of the Association. Mr. Merrifield served on several important Royal Commissions, including one on the seaworthiness of ships, of which the Duke of Edinburgh was President. During the last few years he frequently sat as scientific assessor to Mr. Rothery in the Wreck Court. A part of his unofficial work consisted of the conduct for many years of the mathematical part of the May examinations of the Science and Art Department. All his arrangements for this purpose were completed in 1882, when, in April of that year, he was prostrated by an attack of apoplexy. He had so far recovered as to give hopes that his life might be spared for some years, but on October 18 last he was seized with a third attack, from which he never rallied.

GEOLOGICAL SURVEY OF PRUSSIA

THE Report of this important Survey for 1882 has just been issued as a well-printed octavo volume with maps, sections, and plates of fossils. The first division is devoted to an account of the operations of the Survey in the field. These were conducted in the Harz, where the keen-eyed Lossen still wields his powerful hammer among the eruptive rocks of that classic region; where, also, Dr. von Groddeck and Herren Halfar, Dames, Branco, and von Koenen bore a share; in northern and eastern Thuringia and the Thuringerwald, where ten geologists were engaged; in Hesse-Nassau, with a force of five surveyors; in the southern part of the Rhine province, where Herr Grebe was at work; in Silesia, where the Survey was commenced by Dr. Dathe; in the Berlin district, where the superficial deposits and agricultural features were mapped, and the special geological and agricultural map of that district, consisting of thirty-six sheets, was completely surveyed; in the low grounds about Stendal and Gardelegen, in the plain of the Lower Elbe, and further east in West and East Prussia; and lastly among the diluvial and alluvial formations to the north-west of Halle.

In the course of the year eighteen sheets of maps and sections were published, including fourteen of the geological-agricultural survey of the Berlin district and four sheets of the map of older formations. The total number of sheets now published amounts to 109. There were likewise issued in 1882, besides the Annual Report, three parts of the Transactions of the Survey: viz. an account of the Coal-basin of Lower Silesia and Bohemia, by A. Schütze; descriptions of the Regular Echinids of the North German Chalk, by C. Schlüter; and a monograph of the species of Homalonotus in the Lower Devonian rocks of the Rhine, by C. Koch.

The plan of operations for 1883 included further surveys in the Harz, Thuringia, and the Thuringerwald, Hesse-Nassau, Rhine province, Silesia, and the great lowlands of Prussia.

The most important feature of the Annual Reports of the Prussian Geological Survey is the series of papers by members of the staff and others, with illustrative coloured maps and sections. Of these papers no fewer than twenty-two are published in the Report for 1882, including four by geologists not attached to the staff, and amounting in all to nearly 700 pages, with 23 plates of maps, sections, and fossils. Among these the following important communications may be cited:—"The Kulm of the Upper Harz," and "The Kersantite Dyke of the Upper Harz," by A. von Groddeck; "The Fauna of the Taunus Quartzite of the Rhine," by E. Kayser; "Preglacial Freshwater Formations in the Diluvium of North Germany," by K. Keilhack; "The Variolite-bearing Kulm Conglomerate of Hausdorf in Silesia," by E. Dathe; "New Borings in East and West Prussia," by G. Berendt and A. Jentzsch; "The Lower Devonian Rocks of the Siegerland and their Associated Veins," by H. Schmeisser; "The Trough of Eifel Limestone of Hillesheim," by E. Schulz.

NOTES

PROFESSOR SYLVESTER has been elected a Foreign Member of the Royal Academy of Sciences of Göttingen, of which he was previously a Corresponding Member. *Science*, in speaking of Prof. Sylvester's departure from America, says:—"Prof. Sylvester's departure removes from the University not only the most distinguished scientist but the most interesting personality connected with it; and his absence will make a gap in the general life of the University no less than in his own department. It is somewhat noticeable that no American college has conferred an honorary degree upon him during his residence in this country."

AT a meeting on Tuesday, in connection with the memorial to the late Mr. Spottiswoode, Mr. De La Rue stated that he believed a portrait would be painted by Mr. John Collier, and that it would be placed along with those of other presidents of the Royal Society, in the Society's rooms.

THE death is announced, in his fifty-third year, of Mr. John Henry Dallmeyer, the well-known optician.

DR. JOHNSTON-LAVIS writes to us from Naples, Jan. 10:—"For some six days the seismographs at the Vesuvian Observatory have been in a disturbed state, and on Monday, January 7, at 1.48 p.m., a distinct shock was registered. As the sirocco was blowing, the mountain was enveloped in fog and cloud, so that on Wednesday morning when the news arrived at Naples of an eruption during the night it was received with half incredulity. The volcano appears to have commenced its violent throes about 1 a.m. on the 9th, when there issued a stream of lava which has flowed down the north-north-west side of the cone and crossed the Atrio del Cavallo. Those who were fortunate enough to look towards the mountain at about 2.30 a.m. on Wednesday morning describe the sight as splendid. The maximum explosive violence was at about 10 a.m. We passed the afternoon and evening on the mountain between the observatory and the lava stream, but were paralysed by the quantity of cloud, which prevented a near approach. To-day the view of the mountain has cleared up, but the activity seems to have much diminished. I hope to visit and photograph the crater to-morrow, when I will send more details." The *Standard's* Naples correspondent, writing on the 11th inst., says:—"The violent eruption of Vesuvius has come to a sudden close. The new mouth, which had opened just below the old crater, and from which a large stream of lava issued, flowing down the north-eastern side of the mountain, has to-day ceased to be active. On examination of the old crater, a fissure can be seen directed in a straight line to the new mouth. No signs of similar activity have been experienced since 1875, and a much stronger eruption is now looked for by Prof. Palmieri."

WE understand that Prof. McIntosh, who has undertaken some investigations for the Trawling Commission, is about to institute inquiries at St. Andrew's in connection with the Fishery Board for Scotland, in order to throw some light on the habits and time of spawning of the sole, turbot, and other flat fish. These investigations are intended to enable the Fishery Board, by artificial cultivation or otherwise, to increase the supply of these important and much-esteemed fishes, and bring them within the reach of the general community more than is at present possible, owing to their being in great part imported from Grimsby and other fishing stations, and where, the supply being often very limited, the prices are extremely high. In this and other work we believe the Fishery Board is making arrangements to provide Prof. McIntosh with tanks and other appliances, so that, in addition to assisting the Board in its scientific investigations, he will be better able to prosecute his inquiries for the Trawling Commission. It is anticipated that, while the sole and other flat fish are being studied at St. Andrew's, the herring and its allies will be investigated in a laboratory to be formed by the [illegible] at North Berwick. Besides Prof. McIntosh, it is expected that Prof. McKendrick of Glasgow, Prof. Stirling of Aberdeen, and Prof. Schäfer of University College, London, will assist in these investigations. It is also interesting to note that, in addition to this work which it is intended to undertake, the fishery officers of the Board, at its twenty-six stations on the coasts of Scotland, and the Board's cruiser *Vigilant*, are engaged with great success in collecting materials for the Board, which, when examined, will go far to clear up many of the mysteries as to the food of fishes. The materials collected are being sent from time to time to the University of Edinburgh, where they are examined by Prof. Cossar Ewart, the convener of the Scientific Investigation Committee of the Fishery Board, and by Mr. J. Duncan Matthews, one of the laboratory assistants.

THE thirty-seventh annual general meeting of the Institution of Mechanical Engineers will be held on Thursday, January 24, and Friday, January 25, at 25, Great George Street, Westminster. The chair will be taken by the President at half-past seven p.m. on each evening. The following papers will be read and discussed as far as time will admit:—On Thursday, 24th, Experiments on Friction: Report of the Research Committee (adjourned discussion); On the Consumption of Fuel in Locomotives, by M. Georges Marié, of Paris; on Friday, 25th, On the Physical Conditions of Iron and Steel, by Prof. D. E. Hughes, F.R.S.; On Portable Railways, by M. Decauville, of Petit-Bourg, Paris; On the Moscrop Engine Recorder, and the Knowles Supplementary Governor, by Mr. Michael Longridge, of Manchester.

WE are glad to see that Dr. Doberck's enterprise is meeting with the approval it deserves in Hong Kong and China. "Dr. Doberck, the Government Astronomer, who arrived at Hong Kong a few months ago," the *Hong Kong Free Press* of Nov. 6 says, "has since been most usefully employing his time in visiting the different coast ports and Formosa, and returned from the latter yesterday. He has, we understand, verified a number of instruments belonging to the Imperial Maritime Customs of China, and has studied the geographical conditions of the coast as bearing on meteorology, a very necessary matter in order to arrive at accuracy in discussing observations. We are glad to learn that the Chinese Imperial Maritime Customs Authorities evince a strong disposition to cooperate with the Hong Kong Observatory in the matter. It is of the first importance, in order to be able to arrive at any definite results so as to be able to forecast the weather, and compile a reliable weather table, that the meteorological observations conducted at different ports on the China coast should be made at the same hour, in the same manner, and by instruments corrected to the same standard. It is to be hoped therefore that Sir Robert Hart will allow his able staff to take part in this work, and that monthly registers will be kept at all the treaty ports from Newchwang to Pakhoi and transmitted to the Hong Kong Observatory, which, by situation, is best fitted to become the centre of such a system. The Observatory in this colony is on a very modest scale, and the vote for its maintenance is a mere trifle when the good that is to be gained from it is considered, and we trust that the efforts of the astronomer will not be paralysed by too great attention to economical considerations on the part of the local government. The Inspector-General of Customs has always displayed a most laudable desire to promote improvements in lighting the coast and facilitating navigation; and he will, we hope, see his way to promote the success of Dr. Doberck's work by cooperating with the Hong Kong Observatory. The Sicawei Observatory has done some good work, but its operations have necessarily been limited owing to the absence of reliable observations at the ports. What is expected from the Government Astronomer is that ultimately he may be able not only to give forecasts of the weather but to furnish such a guide to mariners as would render it possible to make voyages and to avoid typhoons or bad weather. The value of such a service is not measurable by mere money; it means greater security to life and property, fewer risks to shipowners, and a diminution of loss to underwriters. It would, in short, have an appreciable effect on commerce generally, and the business of this great shipping port in particular." We trust that this just and accurate view will prevail among those in a position substantially to help Dr. Doberck in his valuable work.

PROFESSOR FOREL (Morges) writes in the *Gazette de Lausanne:* —We are again passing through an earthquake period. On December 18, 1883, at 6.25 a.m., a shock was observed at Neufchâtel; on December 22, at 3 a.m., another one at Cortaillod, and at 4 a.m. at Neufchâtel and Cortaillod. On December 17 and 18 earthquakes were noticed in various parts of Italy, and on December 22, at 3.39 a.m., one at Lisbon.—A rather violent shock, followed by another an hour afterwards, was noticed at Laibach on December 31 at 3.30 a.m.—At Sadikli, near Brussa, an earthquake caused some destruction on January 3, fortunately unattended by loss of life.—The Siberian newspaper *Ssibir* reports that at Korssa Kowskoje Sjelo on Lake Baikal no less than nine earthquakes occurred during the month of September last, *i.e.* on the 3rd, 7th, 12th, 14th, 17th, 20th, 24th, 27th, and 30th of that month (old style).—A sharp shock, causing some alarm, was also felt at Messina at 11.30 on the night of the 13th inst., but no damage was done.

AT 5.25 p.m. on January 11, at Fort William, a ball of light, shaped like a pear, with the broad end downwards, was seen as if suspended midway between Ben Nevis and the Caledonian Valley. It descended till near the surface of the earth, and then it burst, lighting the whole valley. In colour it resembled the electric light. Mr. W. Gunn writes from Berwick-on-Tweed:—"On January 11, at 5.33-34 p.m., I saw a remarkably brilliant white meteor—certainly as bright as Venus—rather low down in the sky to north-north-west. Apparent motion about in a line from Vega towards a point in the horizon nearly vertically below the end of the tail in Ursa Major; seen for two or three seconds moving slowly; seemed to largely and suddenly increase in size and brightness just as it was lost to view behind some trees. Perhaps this was the bursting seen at Fort William."

THE list of lectures to be delivered before the Association Scientifique de France has been published. They will be delivered as usual at the Sorbonne, under the control of M. Milne Edwards, president of this association. Some of them will be delivered by members of the council of the Association Française, a rival institution, and it is pretty certain that the two societies will be incorporated into one single body. The Association Scientifique is the older of the two, and was created by Leverrier about twenty years ago.

WE learn from *Science* that Mr. H. M. Wilson, in charge of one of the topographical parties in Prof. A. H. Thompson's Wingate division of the U.S. Geological Survey, surveyed, during the season of 1883, about ten thousand square miles in North-Western New Mexico and North-Eastern Arizona. The area covered by his work lies between parallels of latitude 36° and 37°, and extends from meridian 109° to 111°. He also worked some smaller detached areas outside of the limits thus indicated. This region has hitherto remained a *terra incognita*, partly on account of its aridity and barren condition, and partly on account of the difficulty of traversing it. So little has been known of it that within the area surveyed by Mr. Wilson a small mountain range has been indicated as occupying two places on the same map. On the engineer's map of 1879 it is called Calabesa Mountains in the northern place, and Squash Mountains in the southern; and on the Land-Office Map for 1882 both are indicated without names. Mr. Wilson's work proves that they are one and the same, occupying a position very close to that assigned to the Squash Mountains.

NEWS has been received in Berlin from the African traveller, Dr. Richard Böhm, dated July, 1883, from Qua Mpara, on the western shore of Lake Tanganyika, near the estuary of the Lufuku River. Dr. Böhm and his companion, Paul Reichardt, seem to have settled there for some time. Before reaching Qua Mpara they met with considerable difficulties, having to combat the natives, by whom Dr. Böhm was seriously wounded. He left the Belgian station Karema at the end of June, and reached Qua Mpara on July 8. There he was seized by a fever, yet he retained sufficient energy to complete his zoological investigations (principally ornithological) and to forward the results to Europe. All his collections and his scientific instruments were unfortunately destroyed by fire on the Mto ja Ugalla. Dr. Böhm, however, set to work again and commenced making new collections, which he left at Karema in safe keeping. Amongst other things he is reported to have discovered a beautiful freshwater Medusa, with a broad, umbrella-shaped body and numerous long and short prehensile filaments; he found it in Lake Tanganyika. At the same time a report from Herr Paul Reichardt was received describing in detail the Soko so well known to readers of Livingstone. The animals live together in herds of from six to twenty individuals, and build nests on trees at an elevation of 8–19 m., the nests measuring from 1–1·2 m. in diameter. Reichardt found groups of nests in which he counted over fifty separate nests. Up to the time of sending the report Reichardt had not succeeded in securing a specimen.

IN the *Bolletino of the Italian Geographical Society* for December, 1883, Sig. Colini continues his valuable notes on the information supplied by Cavaliere Luciòli on the topography and ethnography of the Upper Amazons regions. The paper is accompanied by a large map of the Huallaga and Ucayali river basins, based on Petermann's South America, but corrected and supplemented by fresh data furnished by Luciòli. The position of a large number of tribes, many hitherto unknown, is determined along the banks of the head waters of the Amazons, and to these is added a list of about sixty others, supplied by Dr. Colini from the old records and the writings of recent explorers. But it is obvious that many of these are mere duplicates or even triplicates of the same tribes due to careless transcription, ignorance, change of tribal designations, and other sources of confusion. Thus Carapacho and Picambio are only older names of the present Caribes and Remos of the Middle Ucayali. So with the Amalmacas, Chuntagurus, and Tambas of the older writers, who may be safely identified with the modern Amahuacs, Chontaguiros, and Campas respectively. Nor, as Colini rightly remarks, are these names always distinctly tribal, but the designations of mere clans, or small family groups, or members of larger divisions. These are continually shifting their locality, disappearing, or becoming absorbed in more powerful groups, another fruitful source of perplexity in the ethnical terminology of the Amazons regions. But, after making all due allowance for this uncertain nomenclature, there still remains a surprising number of really distinct tribal groups scattered along the banks of the Huallaga, Napo, Ucayali, and other Amazonian streams, groups differing from each other always in speech and frequently in habits, usages, and physical type.

ON January 26 the Berlin Wissenschaftliche Central Verein and Humboldt Academy will celebrate the fiftieth anniversary of its foundation.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♂) from India, presented by Mr. C. S. Norman; two Great Kangaroos (*Macropus giganteus* ♂ ♀) from New South Wales, presented by the Zoological and Acclimatisation Society of Melbourne; a Dorsal Squirrel (*Sciurus hypopyrrhus*) from Central America, a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, twenty-five Indian Crocodiles (*Crocodilus palustris*) from India, deposited.

OUR ASTRONOMICAL COLUMN

PARALLAXES OF SOUTHERN STARS.—We learn from Mr. Gill, H.M. Astronomer at the Cape, that he has completed a memoir on the parallax of some of the principal southern stars, founded upon observations by himself and Dr. Elkin; the memoir contains investigations on parallax of

By Gill { α Centauri (two series with different comparison-stars); Sirius; ε Indi; Lacaille 9352 (Gould's star with proper motion of 7″); o^2 Eridani, and β Centauri.

By Elkin { α Centauri (two series with different comparison-stars from Gill's); Sirius; ε Indi (also with different stars); ζ Tucani; *e* Eridani and Canopus.

Mr. Gill's important memoir has been communicated to the Royal Astronomical Society, and its publication will doubtless be awaited with much interest by astronomers.

The large proper motion of Lacaille 9352 was detected by Dr. Gould, and announced in No. 2377 of the *Astronomische Nachrichten*. The annual P.M. in arc of great circle is 6″·96 in the direction 79°·2. It is a star of 7·5 m. in Piscis Austrinus: Mr. Stone's place for 1880·0 is in

R.A. 22h. 58m. 5·43s., N.P.D. 126° 32′ 40″·0.

In only one instance has the existence of a larger proper motion been discovered, viz. in that of the well known 6·7 m. Groombridge 1830 in Ursa Major, where the amount is 7″·05. *e* Eridani, 4·4 m., is in R.A. 3h. 15m. 8·16s., N.P.D. 133° 31′ 46″·8 for 1880, according to Stone, who attributes to it an annual proper motion of 3″·0 in the direction 75°·5. ζ Tucani, a fourth magnitude, is in R.A. 0h. 13m. 48·60s., N.P.D. 155° 34′ 49″·0 for 1880, with an annual proper motion of 4″·35 on an angle of 74°·8, by Stone's values.

Mr. Gill expects to be in England early in February, to superintend a large amount of official printing, for which he brings copy with him.

PONS' COMET.—For a few evenings this comet will form a pretty conspicuous object as it descends in the south-western sky; after it ceases to be visible in Europe observations may be continued at the observatories of the other hemisphere for several months. On March 26 the theoretical intensity of light will be ten times, and a month later, five times, greater than at the beginning of September, when the comet was discovered through the diligent scrutiny of the heavens, followed up by Mr. Brooks, who found it considerably beyond the limits of the sweeping ephemerides then in the possession of observers. Mr. S. C. Chandler has conjectured that a meteor-stream may be connected with this comet. MM. Schulhof and Bossert's orbit for 1884 gives the radiant in R.A. 197°·8, Decl. + 67°·3.

THE MINOR PLANETS.—The *Berliner Astronomisches Jahrbuch* for 1886 contains elements and approximate ephemerides for the present year of 231 of the known members of this extensive group, only four therefore being omitted in the absence of the necessary data. In addition there are twenty-six accurate opposition-ephemerides. Four of these small planets approach the earth, within her mean distance from the sun, in 1884. At the end of December No. 132 *Æthra*, situate in the vicinity of α Orionis, will approach the earth within 0·85, and shining as a star of the ninth magnitude, will afford another favourable opportunity for the investigation of solar parallax, on the method advocated by Mr. Gill.

SCIENCE IN RUSSIA[1]

THE *Memoirs* (*Zapiski*) *of the Novorossian Society of Naturalists*, at the University of Odessa, founded only in 1873, have already reached their eighth volume, and contain a good deal of valuable work. Confining our analysis to the last three volumes, we notice in them the following papers:—In the domain of geology Prof. Sintsoff contributes several papers. One of them is an elaborate monograph on the sponges from the chalk of Saratoff. Revising his former work on the same subject, and taking advantage of the well-known work of Prof. Zittel, as well as of new extensive collections, M. Sintsoff creates a number of new species and four new genera: *Mæandroptychium*, which he proposes to substitute for those of *Cæloptychium*, *Etheridgia*, and *Tremabolites*; *Labyrintholites*, closely allied to *Plocoscyphia*; *Polyscyphia*, akin to the preceding; and *Zittelispongia*. The author describes (with figures) seven species of the first, four species of the second and the third, and one species of the fourth, as well as the following species:—*Cuculispongia triloba*, Trautschold, *Craticularia cylindrica*, Mischl.; two species of *Ventriculites*, two species of *Coscinopora*, *Leptophragma simplex*, T. Smith, *Actinosiphonia radiata*, Fisch, and the new species *Hallirhoa peskowi* and *Isoraphinia cavata*.—The same author contributes a second paper on Mesozoic fossils from Simbirsk and Saratoff (the first paper having appeared in vol. iv.), and describes the following species:—*Ammonites longispinus* and *caletanus*, *Scalaria dupiniana*, var. *rhodani*, *Astarte beaumontii*, *Panopæa neocomiensis*, and as new species *Aporrhais striata-carinata*, *Nucula subarduennensis*, and *Lucina neutralis*.—A third paper by the same author contains a description of the following Tertiary fossils of Novorossia:—*Dreissena rostriformis*, Desh., *Hydrobia mathildæformis*, Fuchs, *H. dimidiata*, Eichw., *Valvata variabilis*, Fuchs, *Neritina danubialis*, Pfeif., var. *liturata*, Eichw., *N. prevostriana*, Partsch., and *N. capillacea*, Brusina, from the Pliocene; *Trochus rollandianus*, d'Orb., *Phasianella kischinerviæ*, d'Orb., and as new species *Trochus minutus*, *semistriatus*, and *elegantulus*, *Hydrobia substriatula*, *Amnicola cyclostomoides*, and *Valvata pseudo-adeorbis*, from the Miocene. All these fossils are represented in the plates.—M. Prendel contributes a paper on the geological structure of the districts of Elizabethgrad and Alexandria, in the government of Kherson. The rocks are granites, mostly as schists, and considered by the late Barbot-de-Marny as a product of metamorphism of sedimentary rocks, and very small patches of Huronian schists, covered with numerous isolated islands of Eocene. The whole is covered with the "White Sands," where M. Prendel has found a stem of *Cupressonoxylum severzovi*, Merklin (Miocene?), and with loess, which contains, besides the usual fossils, remains of *Arctomys bobac*, which does not now extend in Russia south of 52°–54° N. lat.—The same author contributes (vol. viii.) another paper on the crystalline rocks on the Bazavlouk and Saksagan Rivers, right tributaries of the Lower Dnieper. The paper is accompanied by a map of coloured sections of microscopic specimens of crystalline rocks.

The chief papers in these *Memoirs* are however devoted to comparative anatomy and zoology. Without attempting to summarise their varied contents, we can merely enumerate most of them. All are profusely illustrated with plates. In the sixth volume we notice a preliminary communication by Madame Olga Mechnikoff, on the anatomy of cartilaginous fishes; and a note, by Prof. H. Mechnikoff, on the larva of the *Anisoplia*.—M. Repyakoff contributes an elaborate paper on the morphology of the *Bryozoa*. Without attempting to determine the place that the Bryozoæ ought to occupy in systematic classification, the author devotes his special attention to the relations between the two great subdivisions of the Endoproct and Ectoproct Bryozoæ, and his paper is a valuable contribution to the work undertaken by Nitsche, Hatschek, Joliet, and Barrois.—M. Zabarinsky contributes a paper on the morphology of the Hydra.—In vol. vii. M. Buchinsky publishes a paper on the development of the earthworm, devoting his special attention to the development of its mesoderm and of its nervous system.—In vol. viii. M. Krasilschik contributes an elaborate paper on the development of the *Polytrema*, and the place it occupies with regard to other Flagellatæ; M. Repyakoff publishes a note on the larvæ of the *Polygordius flavocapitatus*; M. Depp, on the life of the Macropodes; and M. A. Kovalevsky, on the development of the Chiton.—In physiology we notice the researches, by M. Spiro, into the development of bile, being the result of various experiments, and accompanied with tables showing the dependence of its amount upon the food.

In botany we find the researches by M. Rishavi on the development of the organs of reproduction in *Dasya elegans* (vol. vi.); a list of lichens collected on Mount Castel in the Crimea, and determined by Dr. Brutann in Dorpat (vol. vii.); and a work, by M. Kojernikoff, on the anatomical structure of the corolla in flowers. The author has extended his researches to a great number of flowers, and has come to the conclusion that, however great the analogy between the petals and the leaves, still the former have a series of well-established anatomical features which enable us to characterise them as well as any other part of the plant. Some of their anatomical features can be explained by the physiological function of the organ, whilst the others have no connection with them, and the explanation of these peculiarities must be sought for elsewhere—says the author—in the yet unknown internal structural form of the plant as also, perhaps, in the position occupied by the flower in the whole of its organic life.

---

[1] *Memoirs of the Novorossian Society of Naturalists* (*Zapiski Novorossiyskago Obschestra Estestvoispytateley*) vols. vi.. vii., and viii. Odessa.

In chemistry and physics we notice two papers, by M. Tanatar, on the fumaric and maleinic acids (vol. vi.), and on their compounds with chlorite (vol. viii.); by M. Klimenko, on the lactic and propionic acids (vol. vi.); by M. Melikov, on the compounds of acrilic acid; and by M. Geritch, on electrical phenomena observed during the diffusion of several liquids.

A paper of general interest, intended to show some relations between animals and plants at their lowest degrees of development, is contributed by M. Shmankevitch (vol. vii.). When the Flagellate, *Anisonema acinus*, Blütochli—having a relatively high organisation—is cultivated for many generations in a medium which is slowly modified, for instance, in sweet water to which a certain amount of lake salt is added, its structure is modified, in proportion as the concentration of the solution of salt is increased. The individuals become less developed, their size diminishes, and the feeding-canal loses its former development. Numberless intermediate forms between the *Anisonema acinus* and its new, less developed representatives, make their appearance, as well as between these and the still lower *Anisonema sulcatum*, which would be thus but a lower organised variety of the former. When the concentration of the medium in which the *Anisonema* lives is carried on side by side with a change of temperature of the medium, the transformation goes further on, and the lowest *Anisonemæ* are transformed on the one side into algæ-like organisms, and in another direction into organisms which seem to belong to the category of fungi. The individuals not only become smaller, but they give rise also to a progeny long before reaching their full size. Under the influence of the sun's rays the uncoloured Flagellatæ acquire a new physiological function, and develop chlorophyll. "We see thus," the author says, "the beginnings of two kingdoms, animal and vegetable, radiating from one common stem. We see the transformation of one of them into the other, not only in its morphological features, but also in its physiological functions, under the direct influence of physical and chemical agencies. The saline solutions, as compared with sweet water, diminish the size of the lower organisms, and at the same time they contribute towards the development of chlorophyll in the sweet-water algæ, thus giving them, so to say, a more vegetable character, together with an increased productivenes." And further: "While descending from the *Anisonema sulcatum* to a unicellular alga, we see the regressive development, a simplification of organisation; we descend towards the plants containing chlorophyll. . . . While descending from the same *Anisonema* on another branch, we enter into the region of such lower organisms which, under the influence of another medium, do not develop chlorophyll, and having no nutrition from the air, find their food from the substratum; they could be described as parasitic Rhizopodæ, and this the more as from the fungoid form we can ascend, under some circumstances, not only towards the Amœba-like uncoloured Flagellata, but also towards the moving Monad. On the contrary, by reversing the physical agencies, we can arrive, from the unicellular alga, as well as from the fungoid form, to an uncoloured form having the structure of the *Anisonema*." The researches of A. Giard, Cienkowsky, and Famintzyn, and some observations by Ray Lankester, seem to be, in the author's opinion, in accordance with the above.

PROFESSOR HAECKEL ON THE ORDERS OF THE RADIOLARIA[1]

[THE following translation of a recent paper of mine, by Miss Nellie Maclagan, has been revised by myself.—ERNST HAECKEL.]

THE "Outline of a Radiolarian System founded on Studies of the *Challenger* Radiolaria," published by me in the *Jenaische Zeitschrift für Naturwissenschaft* (Bd. xv. pp. 418-472), shortly before starting for Ceylon in October, 1881, gave a very short survey of the systematic results of the researches which I had been carrying on since 1876 among the inconceivably rich Radiolarian material of the *Challenger* collection. At that time I distinguished in this Rhizopod class seven different orders (p. 421) and 24 families, containing in all 630 genera ("Prodromus Systematis Radiolarium," *l.c.*, pp. 423-472). I was able even then to distinguish no less than 2000 new species, and this goodly number has since been considerably increased. Further investigations corroborated all the principal essential points of the views then briefly given as to the morphologico-phylogenetic conditions of relation among this Protista class, but I gradually came to simplify my views as to the relation of the principal groups, and have now reduced the seven orders to four, which makes the complicated system much more comprehensible.

The systematic arrangement of the 15 families, given in my "Monographie der Radiolarien," 1862 (following Johann Müller, who first broke ground in his treatise, 1858) was essentially improved by Richard Hertwig, whose admirable work on the "Organismus der Radiolarien," 1879, thoroughly explained for the first time the difficult histology of these Protista, and definitely determined their unicellular nature, despite all peculiar modifications of the cell structure. On the ground of important differences discovered by him in the structure of the membrane of the central capsule, and the consequent varying comportment of the passage of pseudopodia, Hertwig distinguished the following six orders (*l.c.* p. 133):—1. *Thalassicolleæ*, monozoic uninuclear Radiolarians, having the capsule membrane pierced on all sides: skeleton siliceous, irregular, or wanting. 2 *Sphærozoea*, polyzoic multinuclear Radiolarians, having the capsule membrane pierced on all sides: skeleton siliceous, irregular, or wanting. 3. *Peripylea*, monozoic uninuclear Radiolarians, having the capsule membrane pierced on all sides: skeleton siliceous, consisting of fenestrated spheres or modified fenestrated spheres or disks. 4. *Acanthometrea*, monozoic uninuclear Radiolarians, having the capsule membrane pierced on all sides: skeleton non-siliceous, consisting of twenty spicules arranged according to J. Müller's law. 5. *Monopylea*, monozoic uninuclear Radiolarians, the capsule open on one side, and with a peculiar porous area: skeleton siliceous. 6. *Tripylea*, monozoic uninuclear Radiolarians; capsule membrane double, with one principal and two accessory openings; skeleton siliceous, formed of tubes.

As I found that the important differences in the structure of the membrane of the central capsule and the consequent passage of the pseudopodia, discovered by Hertwig in the comparatively limited material at his disposal, were corroborated in their most essential points by my researches among the wider world of the *Challenger* Radiolaria, I adopted his scheme in my "Conspectus Ordinum Radiolarium Classis," 1881 (*l.c.* p. 421), but with this difference, that I divided Hertwig's *Sphærozoea* into two orders—*Symbelaria* and *Syncollaria*. The latter, *Syncollaria*, includes the families of the *Sphæroizoida* in the wider sense, and, from the absence or incompleteness of the skeleton, corresponds as a polyzoic group to the monozoic *Thalassicollea*, whilst the former, *Symbelaria*, includes the family of the *Collosphærida* in the wider sense, and by its spherical, reticulate, siliceous skeleton corresponds as a polyzoic group to the monozoic *Peripylea*.

Recent researches, which have brought to light an immense number of new, hitherto unknown Radiolarians belonging to the last-mentioned groups, have, however, convinced me that the distinction between the monozoic (solitary) and the polyzoic (social) Radiolarians is of much less importance than was formerly supposed. They are as insignificant and of as little value in forming a system as the differences between monozoic Hydropolyps (*e.g. Hydra*, *Myriothela*) and polyzoic Hydropolyps (*Tubularia*, *Coryne*), or as the differences between solitary Infusoria (*Vorticella*, *Trichodina*) and social Infusoria (*Carchesium*, *Epistylis*). According to Hertwig, the essential difference between the two groups is that the solitary *Thalassicollea* are uninuclear, the social *Sphærozoea* (= *Symbelaria*) multinuclear. Nevertheless, the central capsule in all Radiolaria (without exception) is uninuclear at an early stage and multinuclear later on. We would require to be more exact about this distinction, inasmuch as in the *Sphærozoea* (= as in the *Acanthometrea*) the division of the simple nucleus into a number of nuclei (spore nuclei) takes place at a very early period, whilst in the *Thalassicollea* (as in the other Radiolaria) it only takes place later on. This relative modification is, however, of no standard value for the systematic distinction of the orders, and is, moreover, subject to various exceptions.

---

[1] "Separat-Abdrück aus den Sitzungsberichten der Jenaischen Gesellschaft für Medicin. und Wissenschaft." Jahrg. 1883. Sitzung. von 16 Februar.

Among the new Radiolaria of the groups above mentioned discovered in the *Challenger* collection, there were, moreover, monozoic and polyzoic species which correspond completely, even in the specific characteristics of the skeletal form. For example, a monozoic *Thalassoxanthium* has precisely the same characteristic spicules as the common cosmopolitan *Sphærozoum punctatum*, but whilst in the latter the small polyzoic central capsule incloses a large central oil globule and numerous small peripheric nuclei, in the former the central capsule, which is three times as large, incloses a single, large central nucleus and numerous small peripheric oil globules. The complete identity of the characteristic skeletal form might even lead us to suppose that a kind of alternation of generation may take place between the two forms. In the same way, a social *Collosphæra* corresponds completely to a solitary *Cenosphæra*, the polyzoic *Acrosphæra* to the monozoic *Conosphæra*, and so forth.

On the ground of these observations—the importance of which I shall explain in detail in my work on the *Challenger* Radiolaria—I consider the distinction between monozoic and polyzoic Radiolarians (which I contrasted in 1862, according to Müller, as *Monocyttaria* and *Polycyttaria*) as practically unimportant, and for the present connect the polyzoic families in the system immediately with the monozoic. In this way the number of the six or seven groups is reduced to four, as I refer all the groups thus formed to Hertwig's Peripylea. As I have already shown (1881, *l.c.* p. 421), these may be again divided in pairs into two principal groups or sub-classes—into *Holotrypasta* and *Merotrypasta*. The *Holotrypasta* (*Acantharia* and *Peripylea*, the latter including the *Collodaria*, *Symbelaria*, and *Syncollaria*) includes all Radiolaria in which the capsule membrane is pierced on all sides by fine pores, and the pseudopodia consequently radiate equally on all sides. The *Merotrypasta* (*Monopylaria* and *Phæodaria*) include all those Radiolaria in which the membrane is pierced at one side either by a single area of pores or by openings confined to a few spots, so that the pseudopodia project from the central capsule as a single bunch or as slightly separated bunches.

The high standard importance of the central capsule for the proper conception of the Radiolaria to which I first drew attention in my monograph, 1862, has since been recognised by Hertwig and most other investigators of these Protista, but recently disputed by Carl Brandt (*Monatsb. Berlin. Akad.* 1881, p. 391). As I reserve the detailed reasons for my opinion for my work on the *Challenger* Radiolaria, I shall now merely remark that my more recent researches have fully corroborated my former views, and that in all true Radiolaria the central capsule is separated by a distinct membrane from the extracapsularium (or external gelatinous soft part). The so-called "freshwater" Radiolaria (which, from absence of the membrane, are not Radiolaria but Helizoa) do not of course furnish any counter-proof. Brandt's erroneous assertion rests upon the extremely limited amount of material investigated by him. Careful investigation enabled me to discover the capsule, even in all species which he regards as "without capsule." In isolated species, however, the capsule membrane is somewhat late in forming a definite boundary between the capsule and the gelatinous sheath (sometimes just before the formation of spores), whilst in other cases it usually takes places at a very early stage. I therefore maintain now, as formerly, that the chief character of the class is the differentiation of the unicellular body into two essential, principal component parts, viz. the inner central capsule with nucleus and membrane, and the outer gelatinous sheath with matrix and forest of pseudopodia. On the other hand, it is immaterial whether "yellow cells" (or "zooxanthella") are present or not. I found them wanting in many cases, though they are usually present. I therefore agree with Cienkorosky, and regard the symbiosis of these unicellular Algæ as an accidental and not an essential phenomenon. They are in no way necessary for the nourishment of the Radiolaria, though they may be important agents in the matter.

Meantime I am convinced that the four orders of the class Radiolaria, *Acantharia*, *Spumellaria*, *Nassellaria*, and *Phæodaria* represent four distinct, perfectly natural, principal divisions. In each of these four orders the numerous forms belonging to it, despite their astonishing variety, may be referred by morphological comparison to a common primitive form, which may therefore be regarded as their ancestral form in a phylogenetic sense. This phylogenetic view of the four orders as distinct monophyletic groups is justified by the fact that the remarkable and extremely complicated relations of all the forms of each common ancestral group have the same natural, strong phylogenetic signification as they have in the comparative anatomy of the Vertebrata or of the Articulata. Bütschli was therefore in the right at the close of his admirable dissertation on the skeletons of the Cyrtida (1881, *l.c.* p. 538), where he lays stress on the fact that the complicated phylogenesis of this section, so rich in specific forms, may be regarded as an excellent argument in favour of the doctrine of descent, and that in this way those painstaking investigations of the microscopic world (which many "exact physiologists" consider mere morphological trifling) come to be of real importance.

I. The Acantharia, which are distinguished from the three other orders by their organic acanthine skeleton—they never have a true siliceous skeleton—correspond on the whole to the *Acanthometræ* of J. Müller (including, however, part of the *Haliomma*), and to the *Acanthometreæ* of Hertwig, which he divides into *Acanthometrida* and *Acanthophractida*. I hold the remarkable *Actinelius* to be the ancestral form of this order. It was first described by me in 1865, but I have lately found several forms closely allied to it, partly Astrolophida, partly Litholophida, in the *Challenger* collection. In *Actinelius* the spherical central capsule is pierced by numerous simple, radial spicules (without definite number and arrangement) meeting in the centre of the capsule. *Actinelius* may be held to have arisen immediately from *Actinosphærium* by the hardening of the firmer axial fibres in the radial pseudopodia of the latter into radial spicules. *Actinelius* is the common ancestral form, on the one hand, of the whole *Actinelidæ* (Astrolophida and Litholophida), all with indefinite number and arrangement of the spicules, and, on the other hand, of the remaining *Acantharia*, in which twenty radial spicules are invariably arranged according to J. Müller's law in five four-rayed zones. The oldest of these are the Acanthonida (or Acanthometra in the more limited sense) from which the Dorataspida and Diploconida having shells are derived later on.

II. The Spumellaria, by which I understand Hertwig's *Peripylea*, *Thalassicollea*, and *Sphærozoea*, had been previously united with tolerable accuracy by Ehrenberg, on the ground of observations made by him on the skeletons of the fossil Radiolaria of the Barbadoes, and opposed to the Nassellaria as *Polydictya* or *Polycystina composita*. His *Spyridina* (our *Spyroida*) belongs, however, to the latter, not to the former. All Spumellaria (which may also ultimately be termed Peripylaria or *Peripylea*) have—in contradistinction to the Nassellaria and Phæodaria—a central capsule pierced on all sides by fine pores, and agree in this respect with the Acantharia, from which, however, they are distinguished by the absence of the acanthine skeleton. All Spumellaria may be easily referred to a common ancestral form—to *Actissa*, the simplest form of the Thalassicollida. An interesting species belonging to *Actissa* was accurately described by Hertwig in 1870, under the name *Thalassolampe primordialis* ("Organismus," p. 32, taf. iii. fig. 5). It has neither the extracapsular alveola of *Thalassolampe* nor the intracapsular alveola of *Thalassicolla*. I observed another species of the genus, which I shall describe later in detail, as *Actissa princeps* in Ceylon, 1881. *Actissa* certainly represents the simplest possible Radiolarian form, in a measure the actual embodiment of the simplest ideal type of this whole Rhizopod class. In a phylogenetic sense it may therefore claim to be regarded as the ancestral form not only of all Spumellaria, but perhaps also of all Radiolaria. All *Collodaria* (the solitary Thalassicollida and Thalassosphærida, the social Collozoida and Sphærozoida) are derived immediately from it, then all *Sphærellaria*. The ancestral group of the latter section, which is richest of all in specific forms, is the *Sphæroida* (or *Sphærida*), and, first among them, the Monosphærida, furnished with a simple, fenestrated spherical shell. From the latter all the others, viz. Pylonida, Zygastida, Discoida, and Lithelida, can be derived without difficulty.

III. The Nassellaria, which correspond on the whole to Hertwig's Monopylea, had already been defined by Ehrenberg as *Monodycta* or *Polycystina solitaria*, in contrast to his Spumellaria. His definition was correct on the whole, though the *Spyridina* (our *Spyroida*), which he places among the latter, belong rather to the former. Hertwig was the first to determine correctly the essential characters of this large order, so wonderfully rich in forms, viz. the simple area of pores at one pole of the capsule axis, 1879 (*l.c.*), and I would therefore have retained his name, *Monopylea* or *Monopylaria*, for the entire order, had it not been equally suitable to part of the Phæodaria. I therefore prefer

Ehrenberg's older nomenclature. Like Hertwig, I regard the skeletonless *Cystidium inerme*, discovered by him (*l.c.* pp. 87, 136, taf. vii. fig. 1) as the ancestral form of the order. *Cystidium inerme* is distinguished essentially from *Actissa* by the restriction of the capsule pores to a single area, and the consequent monaxonous fundamental form of the central capsule. All other Nassellaria are derived from *Cystidium* by the development of a characteristic siliceous skeleton. Hertwig assumes that there are at least two or three entirely different original forms for the Nassellaria skeleton, viz. a simple siliceous ring (*Lithocircus*) for the Cricoid skeleton of the Acanthodesmida and Zygocystida, and a triradial siliceous framework consisting of three spicules united at one point (*Plagiacantha*) for the Plagiacanthida and Cystida (*l.c.* p. 126, &c.). I then endeavoured to refer these two fundamental forms to a single form, as I made out the combination of the simple siliceous ring and the triradial framework in many Cystida and Spyroida (or Zygocystida). In my "Prodromus" (October, 1881, *l.c.* pp. 423-444) I divided the Nassellaria order into five families, and placed the *Plectida* (with triradial siliceous framework) as the common ancestral group. From it I derived first all the *Cystida*, from these again the *Botryoida* and *Spyrida* (= Zygocystida), and from the latter the *Stephida* (= Cricoidea). At the same time, and quite independently of my researches, Bütschli was busy with the same morphological problem, and arrived at essentially the same conclusion, except that he reversed the phylogenetic series of the forms. In his admirable treatise on the skeletons of the Cystida (also dated October, 1881, published in the *Zeit. f. wissen. Zoologie*, 1882, bd. 36, p. 485) he tries to prove the morphological connection of all Nassellaria (his *Cricoidea*), but regards the *Stephida* (= *Acanthodesmida*) as the primitive ancestral form, not as the last degenerated scion, an opinion which I myself formerly shared (compare Hertwig, 1879, p. 126). Which of these two opinions is correct cannot be determined at present. Important facts favour my present view, that the triradial siliceous framework may be the common ancestral form of all Nassellaria (*Triplagia*, *Plagiacantha*). Again, other important facts favour Bütschli's view that this ancestral form may be the simple siliceous ring (*Lithocircus*, *Monostephus*). Finally, there are good grounds for supporting Hertwig's opinion, that both these ancestral forms (the triradial and the annular) may have arisen independently from the skeletonless Cystidium. I shall discuss this difficult and interesting question at length in my work on the *Challenger* Radiolaria.

IV. The Phæodaria were only known up to 1876 by three types described by me in 1862 (*Aulocantha*, *Aulosphæra*, *Cœlodendrum*). By the discovery of numerous forms in the *Challenger* collection this has since acquired an importance of which we had no previous idea, as those Radiolarians far surpass all others both in size and singularity of form, as well as in peculiar combinations of structure. In my preliminary paper on the Phæodaria, 1879 (*Jena. Naturwissen. Sitzungsb.*, December 12) I distinguished 10 families with 38 genera, a number which has since been increased considerably by the continuous and astonishing discovery of new forms. As in the majority of these the skeleton is composed of hollow, siliceous tubes (differing therefore from that of all other Radiolarians), I termed the whole order *Pansolenia*, 1878 ("Protistenreich," p. 102). This name, however, suits all members of the family as little as the name *Tripylea*, proposed by Hertwig, 1879. On the other hand, the present name *Phæodaria* indicates the common characteristic of the whole order, the peculiar *phæodium*, a voluminous, dark body of pigment, lying excentrically outside the central capsule. The latter is, moreover, universally distinguished by its double membrane and by the peculiar opening furnished with a radiated operculum, which lies at the pole of the axis, and may therefore be termed the principal opening. In addition to it there are usually (though by no means invariably) two small accessory openings, lying one beside the other at the opposite (aboral) pole. Sometimes there are more than two, whilst at other times they are entirely wanting. Despite the extraordinary diversity of the peculiar, and often very complicated siliceous skeleton, all Phæodaria may likewise be derived from a common ancestral form—the skeletonless *Phæodina*.

The further phylogenetic question, whether all the hypothetic primitive forms already mentioned of the four Radiolarian orders can be referred to a single common primitive form, may now in all probability be decided in the affirmative. From *Actissa* the parent form of the Spumellaria, the ancestral form of the three other orders may be derived without difficulty. *Actinilius*, the ancestral form of the Acantharia, may have arisen from *Actissa* by the thickening of part of the radial pseudopodia into acanthine spicules. *Cystidium*, the probable ancestral form of the Nassellaria, may be derived from *Actissa* by the pores of the capsule membrane, originally developed equally and on all sides, becoming restricted to a single distinct porous area. *Phæodina*, the ancestral form of the Phæodaria may have arisen in a similar way from *Actissa* by the porous area becoming replaced by a single, simple opening, or small, additional, accessory openings, still being left, whilst at the same time the capsule membrane became double, and the pigment mass of the phæodium deposited excentrically round it. Whilst, on the one hand, the simplest Spumellaria form, *Actissa*, may be easily accepted as the ancestral form of all Radiolaria, *Actinosphærium* and *Actinophrys* show, on the other hand, how it may be derived from the simplest Rhizopoda.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

The Technical Schools in connection with the University College, Nottingham, will be formally opened by Sir Frederick Bramwell on the 24th inst.

Mr. J. T. Dunn, M.Sc., Demonstrator in Chemistry at the College of Science, Newcastle, and formerly Demonstrator in Physics, has been appointed Science Master and Director of the Chemical Laboratory in the High School for Boys, Gateshead. In the Gateshead High School, which opened in May 1883, there are already about 175 boys, and it is intended that all the boys shall learn Physics and Chemistry at some period of their school course.

SCIENTIFIC SERIALS

Journal of Franklin Institute, vol. cxvi. No. 696, December, 1883.—The cheapest point of cut off, by W. D. Marks. Partially based on, and in criticism of, a previous paper by Mr. Hill.—Experiments upon non-conducting coverings for steam pipes, by Prof. J. M. Ordway. In this research calorimeters are used, consisting of sheet-brass vessels so shaped that they can be clamped together outside the steam pipe, inclosing a known length of it and of its covering. Of more than fifty substances tried, simple hair-felt with a cheap cover of burlap proved best; seventeen other compositions owed their efficiency to hair. Asbestos hard pressed was a very bad material; it was non-conductive only in the downy state when full of air.—Pressure attainable by the use of the "Drop Press," by Prof. R. H. Thurston. These presses appear to be very efficient for forging hot iron.—The theory of turbines, by Prof. R. H. Thurston. This is the first part of an abstract of a most valuable mathematical discussion of the subject.—A new valve-motion, by Carl Angstrom. This is a so-called "radial" valve-motion, resembling those of Brown, Marshall, and Joy.—A simple and sensitive thermostat, by Dr. N. A. Randolph, designed for incubation and other experiments in the physiological laboratory. The adjustment is obtained by the more or less closing of the orifice for the gas by the expansion of alcohol causing mercury to rise toward the orifice.

Annalen der Physik und Chemie, xx. No. 12 (*a*), December, 1883.—On the condensation of carbonic acid on smooth surfaces of glass, by Prof. R. Bunsen. The condensation of the gas goes on for years, in spite of continual changes of density and pressure. In three years each square centimetre absorbs, at standard pressure and temperature, 5·135 cubic centimetres of the gas, about two-thirds of this amount being absorbed during the first year.—Density proportions of normal salt solutions, by C. Bender.—The law of rotational dispersion, by E. Lommel.—A simple method of investigating the thermo-, actino-, and piezo-electricity of crystals, by Prof. A. Kundt: consists in applying Lichtenberg's powder.—On the measurement of electric forces by means of the electric mill, by D. Kaempfer.—On the question whether the condensation of steam produces electrification, by S. Kalischer.—On the influence of the hardness of steel on its magnetisability, by V. Strouhal and C. Barus; also, on the influence of annealing on the retentivity of the magnet, by the same authors. These are two very elaborate and important papers, covering the ground of many previous scattered researches. The first gives the curious result that, to obtain the highest possible degree of magnetisation, short magnets should be tempered glass hard, but long magnets should be at the other extreme of softness. The second research gives the result that the most constant magnets are those which, after fairly hard tempering, are annealed for twenty to thirty hours by heating in a steam bath, then magnetised, finally heated in steam for five hours more.—Correction, by A. Guébhard, relative to his electrochemical figures.—Use of the method of "Schlieren" for investigating intrusions in quartz, by A. Kundt.—On absolute measure, by Prof. C. Bohn.

Journal de Physique, t. ii. No. 23, November, 1883.—A. Potier, on the experiments of Wroblewski and Oltzewski on the liquefaction of oxygen, nitrogen, and carbonic oxide.—B. Elie, electrodynamic and magnetic potentials in elasticity.—A. Terquem, description of a new cathetometer of M. Dumoulin Froment. This cathetometer is divided into two parts—a vertical standard scale mounted on three levelling feet, to be set up near the apparatus, and a levelled observing telescope sliding upon another vertical stem to be set up at a distance, this second part of the apparatus being just an ordinary cathetometer without a scale.—Bichat and Blondlot, influence of pressure on the electric difference between a liquid and a metal in contact.—Krouchkoll, on immersion currents and on those due to the movement of a metal in a liquid, and on currents of emersion.—E. H. Hall, abstracts (by M. Leduc) of papers on so-called rotational coefficient.—Aug. Righi, on Hall's phenomenon. Righi finds this phenomenon to be 5000 times as strong in bismuth as in gold. The process by which his film of bismuth, only 0·079 mm. in thickness, was procured is not stated.—H. Roiti, on Hall's phenomenon in liquids.—H. Koch, on magneto-electric rotations.

Bulletins de la Société d'Anthropologie de Paris, tome vi. fasc. 3, Paris, 1883, contain :—A paper by M. Hamy, on the interpretation of an inscription on the Mexican stone tablet in the Museum of the Trocadéro, supposed by him to refer to the foundation, in 1483, of the temple of the great Aztec divinity, Hiutzilopochtli.—On the special frequency in criminals and in the insane of an anomalous medial occipital fossa, by Prof. Lombroso.—On the significance of the interlaced hearts common in the ornamentation of rings, crosses, &c., in use in La Bretagne and La Vendée, by M. Bonnemère, who regards them as of mediæval origin, and connected with marriage, while Madame Clémence Royer showed that they were of modern design, and religious in character, representing the hearts of Jesus and the Virgin, as symbolised in the convents of the Sacré Cœur.—A communication from Madame Clémence Royer, setting forth her claim to be regarded as the first person who pointed out that Lamarck was the true father of the theory of evolution, she having expounded his doctrines in a course of lectures on philosophy given by her in 1859-60.—On the explorations of the Grotto des Cottés in Poitou, by M. de Rochebrune. The finds exhibit fossil bones in great abundance, well-cut flints, and a human skeleton, which has been submitted to M. de Mortillet.—On the Chelléan deposits of Ternifine, in Algiers, by M. le Dr. Tommasini. These contain remains of so-called *Elephas atlanticus*.—On Prof. Putnam's recent explorations of Kjökkenmöddings, mounds, ash-pits, and stone-graves in Maine, Ohio, and Tennessee, by M. de Nadaillac.—On a more correct mode of classifying the colour of the eyes and hair in reference to the determination of ethnic characteristics, by M. Ikow.—On the "Er Fousen," or pit-graves in St. Pierre-Quiberon, in La Bretagne, by M. Gaillard.—On the anthropomrtric determination of the principel races of France, by M. le Dr. Collignon. A detailed and exhaustive treatise, in which the author, after setting apart a distinct group of Frenchmen, considers the rest of the French nation, somewhat arbitrarily, under four heads—Celts, Cimri, "Lorrainians," and so-called "Mediterranéens." Under the latter term he treats of those south-western races of France, whose chief source of origin is the Eastern Pyrenees, and who designate themselves as Catalans.—On the craniometric study of plagiocephalics, by M. le Dr. Manouvrier, bearing on the question af cerebral asymetry as a characteristic of superior brain-capacity.—On anomalous muscles in man, by M. le Dr. Testut.—Note on the various objects of fetish from Upper Ogooe, by M. Delisle. In the discussion to which the communication gave rise, M. de Mortillet maintained the view, to which he has frequently given expression, that in Africa originated the use of iron for industrial purposes, while the African was the only savage who knew how to extract and work the metal. In the iron projectile arms from the Congo M. de Mortillet believes we have analogous weapons to those seen in the hands of the Assyrian kings when represented as engaged in lion-hunting.—On the decrease of the population in France, by M. Lagneau. This decrease was known to amount to seven for every hundred inhabitants in twenty-six Departments, although there were only eight of these in which the deaths exceeded the births.—On the "Questionnaire de Sociologie et d'Ethnographie" of the Society, drawn up by MM. Hay, Hovelacque, and Vinson, and submitted by them to their *confrères*.—On two crania found in the Department de la Drôme, by M. le Dr. Delisle. One of these is dolichocephalic, and similar to the Cro-Magnon type; the other is brachiocephalic.—On the dangers of premature exercise of the higher intellectual faculties and of the physical powers in relation to the present excessive academic requirements and early term of military service in France, by M. Dally.—On M. Testut's elaborate prehistoric chart of La Dordogne, by M. Hamy.—On the practices and superstitions which prevail in Artois and Picardy in connection with bees, by M. E. T. Hamy. Such practices in no way differ from those described in the "Georgics," excepting in as far as concerns the aspersion of the hive with holy water by the modern peasant bee-cultivator. In Artois, as in Berry, when the master of the house dies his hives must be covered with black, and the fact of his decease whispered to the bees to avert their otherwise inevitable death.—On some cephalometric determinations on the living subject in Greece, by M. Apostolides. He consiners that the people of the Peloponnesus have best preserved the dolichocephalic type of the ancient Greeks, as shown in the crania of tombs belonging to the fourth century B.C.—The first part of a paper by M. de Ujfalvy on the "Kafirs-Siapochs," or "Black-robed" tribe of the Hindoo-Koosh.

Archives of the Physical and Natural Sciences, Geneva, Nov. 15, 1883.—Researches on the absorption of the ultra-violet rays by aqueous and vitreous humours, albuminoids, and other substances, by M. J. L. Soret.—On electrolytic condensers, by Dr. C. E. Guillaume.—Sixty-sixth session of the Helvetic Society of Natural Sciences held at Zurich in August, 1883: Report on the Geological Session, president, Prof. Suess of Vienna. Papers were read on the structure of the Alps, by the President, who rejected the theory of upheaval, denying the existence of any natural motive power capable of raising lofty mountain ranges; on the old glaciers of the northern slopes of the Alps, by M. Alph. Favre; on the climateric zones during the Jurassic and Chalk epochs, by Prof. Neumayr of Vienna; on the Kimmeridge formations of the Vaude Alps, by M. Schardt of Montreux; on the fossils of the same geological area, by M. de Loriol; on the physical and chemical changes undergone by rocks subject to glacial pressure, by Prof. Mühlberg of Aarau; on some specimens of spath fluor recently found in the dolomitic limestones of Trolerengraben, Valais, by M. Ed. de Fellenberg; on the hydrographic system of the Jura range in the canton of Neuchâtel, by M. Jaccard; on the mollasse and glacial formations of Upper Suabia, by M. Probst of Essendorff; on the gypsum formations of Vorarlberg, by M. Chavannes; on a sectional profile of the Schlossberg in the Titlis range, showing the geological dispositions of the limestone rocks of the twelfth sheet in Dufour's map, by Dr. C. Moesch of Zurich; on the fauna of the coal and limestone formations in the Permian system of Bohemia, by Dr. A. Fritsch; on an ancient post-Glacial lacustrine basin in the Soleure district, formed by three concentric frontal moraines, slight traces of which still survive in the Aar valley, by M. Alph. Favre; on the earthquake at Ischia, by Prof. Suess.

Nachrichten of the Royal Society of Sciences and of the University of Göttingen, July 30, 1883.—On some historical documents connected with the history of Bavaria during the fourteenth century, by Ludwig Weiland.—Remarks on Jacobi's theory of elliptical functions, with special reference to his logarithm of theta functions (continued), by A. Enneper.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 20, 1883.—"Note on the Constitution of Chlorophyll." By Edward Schunck, F.R.S.

The author having for some time been engaged in examining the derivatives of chlorophyll, the question of the constitution of that body presented itself. Whatever chlorophyll may be from a physiological point of view, for the chemist it is simply an organic colouring matter. The colouring matters occurring naturally in the organs of plants and animals are of several kinds. The greater number belong to the class of so-called glucosides, *i.e.* bodies which by decomposition with acids or ferments yield some kind of glucose or sugar as one of the products. The author was led to suspect that chlorophyll might turn out to be a glucoside, its general properties being such as characterise that class of compounds. To prove this by direct experiment was almost impossible, on account of the difficulty in preparing chlorophyll in a state of purity; but the author describes some experiments made with solutions of chlorophyll, which tend to show that when decomposed with acids it does behave as a glucoside, splitting up into glucose and other bodies, the phyllocyanin and phylloxanthin of Fremy being products that are formed at the same time.

Mathematical Society, January 10.—S. Roberts, F.R.S., vice-president, in the chair.—Messrs. D. Brockelbank and Asutosh Mukhopadhyay were elected members, and Messrs. Fortey and Heppel admitted into the Society.—The Chairman spoke upon the late Mr. C. W. Merrifield's mathematical work and upon his services to the Society, and concluded his remarks by reading the words of a vote of condolence with the family of the deceased which the Council had requested the President to communicate to them.—Mr. A. Buchheim stated an extension of Pascal's theorem to space of three dimensions, and communicated a paper on the theory of screws in elliptic space. His special object was to show that Grassmann's "Ausdehnungslehre" supplies all the necessary materials for a calculus of screws in elliptic space, and that Clifford was apparently led to construct his theory of biquaternions by the want of such a calculus.—Mr. H. Fortey read a paper on contacts and isolations, a problem in permutations.—Mr. Tucker presented a paper by Prof. H. Lamb on the induction of electric currents in cylindrical and spherical conductors, and spoke on a group of circles which are connected with the "triplicate-ratio" circle.

Edinburgh

Royal Physical Society, December 19, 1883.—Dr. R. H. Traquair, F.R.S., president, in the chair.—The following office-bearers were elected for the year 1883-84, viz. Presidents, Dr. R. H. Traquair, F.R.S., B. N. Peach, F.R.S.E., F.G.S., J. A. Harvie-Brown, F.R.S.E., F.Z.S.; Secretary, Robert Gray, V.P.R.S.E.; Assistant Secretary, John Gibson; Treasurer, Charles Prentice, C.A., F.R.S.E.; Librarian, J. T. Gray, M.A.—The following papers were read, viz.:—Notes on the genus Gyracanthus, by Dr. H. Traquair, F.R.S.—On a specimen of Pecopteris in circinate vernation with remarks on the genera Spiropteris and Rhizomopteris of Schimper, by Robert Kidston, F.G.S.—On a new species of Schutzia from the calciferous sandstones of Scotland, by R. Kidston, F.G.S.—On the structure of Sarcodictyon, by Prof. W. A. Herdman, F.R.S.E.—Notes on the islands of Sula Sgeir or North Barra and North Rona, with a list of the birds inhabiting them, by Mr. John Swinburne. Specimens of eggs from the islands were also exhibited.—Mr. J. A. Harvie Brown, F.Z.S., exhibited, with remarks, a specimen of the Little Gull (*Larus minutus*), shot in the island of North Uist.—Mr. Hoyle exhibited, with remarks, a skeleton of the extinct Moa (*Dinornis didiformis*).—Dr. Traquair exhibited a specimen of the Osprey (*Pandion haliæetus*), shot in Midlothian—Prof. Arch. Geikie, F.R.S., was elected an honorary Fellow of the Society.

Mathematical Society, January 11.—Mr. Thomas Muir, F.R.S.E., president, in the chair.—Prof. Chrystal delivered an address on surfaces of the second order, in which he advocated strongly the study of the properties of these surfaces from the surfaces themselves. The address was illustrated by a large number of beautiful models in wood, plaster, cardboard, and thread.—Prof. Tait communicated an analytical note, and one or two geometrical problems were discussed.

Dublin

Royal Society, December 17, 1883.—Rev Dr. S. Haughton, F.R.S., in the chair.—On the Ringhals or Cape Cobra, by M. G. R. O'Reilly. The author briefly describes some of the habits of this snake (*Sæpedon hæmachates*), called "ipimpi" by the Kafirs. He is peculiarly subject to fear, but, when compelled, fights savagely. Raising one-third of his length perpendicularly, and with expanded hood, he advances, dashing his head repeatedly to the ground and hissing furiously. Should he come close enough, he strikes repeatedly, not open-mouthed, but only with the point of the fangs that protrude slightly downwards over the lower lip. But little poison is introduced into the superficial wound produced in this way, and such wounds are not nearly so often fatal as those produced by the puff-adder. There is, however, a time when the Ringhals is much more to be dreaded. When driven to an extremity, he sometimes subsides into a kind of swoon, and lies as if dead with his mouth somewhat gaping, but woe to the man who should curiously venture his finger therein; it would be instantly locked as in a vice, the fangs would be buried in the flesh, and the poison would flow unceasingly. He will not let go, but, like a bulldog, will allow himself to be beaten to death rather than relinquish his hold. When he finds fatigue coming on, he exerts himself to hold the faster, and each new exertion causes the deadly venom to flow more and more. By degrees fatigue overcomes him, and inch by inch, from the tail upwards, his muscles lose their rigidity, till at last after perhaps a quarter of an hour, finding himself unable to hold on any longer, he lets go. Then if again attacked he fights anew, apparently as fresh as ever; but if allowed a little peace he will lie still a few moments, and then calmly glide away to feast again on the frogs in the sedges, or sun himself once more by the heated rocks on the hillside.—On more convenient equivalents for converting British into metrical measures than those hitherto in use, by G. Johnstone Stoney, D.Sc., F.R.S. Capt. Clarke's determination of the length of the British yard in metrical measure, made at Southampton in 1866 for the Ordnance Survey (see *Philosophical Transactions* for 1867), differs by a small amount from that which had previously been made by Capt. Kater, and it is noteworthy that the small difference between these excessively careful determinations is greater than the difference between Capt. Clarke's determination and the very simple equivalent,

The yard = 914·4 millimetres;

so that the outstanding error which will be incurred if this very convenient number is adopted is of an amount which is inappreciable in ordinary good scientific work. It is less than the expansion produced in iron standards of length by one degree of temperature. Again, the pound avoirdupois differs, according to Prof. Miller's determination (which is the most elaborate we possess), from the simple equivalent,

The pound = 453·6 grammes,

by only one-quarter of a grain avoirdupois in a kilogramme. This is about 1/70 of the correction which would have to be made in weighing water in order to reduce its apparent weight to its weight in vacuo, and is of small account even in carefully conducted scientific work. The value of the gallon, which follows from Capt. Clarke's determination of the metre, is 1·000027 times that adopted in Dowling's Metrical Tables, and differs from the simple equivalent,

The gallon = 4544 cubic centimetres,

by an amount which is less than a cubic centimetre in ten litres, an error which is inappreciable; measures of capacity not admitting of being compared so closely as weights and measures of length. Hence we may take as our fundamental units—

The yard = 914·4 millimetres,

with an error of less than a fifth-metret[1] in the metre, on the authority of Capt. Clarke;

The pound = 453·6 grammes,

with an error of one-quarter of a grain avoirdupois in a kilogramme, on the authority of Prof. Miller;

The gallon = 4544 cubic centimetres,

with an error of less than one cubic centimetre in ten litres, on the authority of the best previous determinations corrected by Capt. Clarke's. It is a truly remarkable circumstance that the first of these numbers happens to be divisible by 3^2 and 2^3, the second by 2^2 and 7, and the third by 2^6. Divisors more convenient could hardly have been chosen for dealing with the disorderly way in which British measures are subdivided. They furnish the following tables, which may be safely recommended:—

---

[1] By metrets are to be understood decimal subdivisions of the metre. The fifth-metret is the fifth of these, or the hundred-thousandth of a metre. It is about the diameter of one of the red disks in human blood.

TABLE I.—*Measures of Length.*

The yard = 914·4 millimetres.
The foot = 304·8 ,,
The inch = 25·4 ,,

TABLE II.—*Weights.*

The pound = 453·6 grammes.
The half-pound = 226·8 ,,
The quarter pound = 113·4 ,,
The ounce = 28·35 ,,
The grain = ·0648 ,,

[This last gives the gramme = 15·43210 grains, a number which it is singularly easy to recollect.]

TABLE III.—*Measures of Capacity*

The gallon = 4544 cubic centimetres.
The quart = 1136 ,,
The pint = 568 ,,
The half pint = 284 ,,
The noggin = 142 ,,
The fluid ounce = 28·4 ,,

If any person using these tables wishes to carry refinement farther, he may do so by subtracting one in every hundred thousand after using Table I., by subtracting one in sixty thousand after using Table II., and by subtracting one in ten thousand after using Table III. These corrections will carry accuracy to the limit of Prof. Miller's and Capt. Clarke's determinations.—R. J. Moss, F.C.S., showed an experiment illustrating the use of Rohrbach's heavy liquid—a solution of baric and mercuric iodides. Minute garnets occurring in Dublin granite were separated from the roughly pulverised rock in a state of purity, and in quantity quite sufficient for an exhaustive analysis.

SYDNEY

Linnean Society of New South Wales, October 31, 1883.—The President, C. S. Wilkinson, F.G.S., in the chair.—The following papers were read:—Occasional notes on plants indigenous in the immediate neighbourhood of Sydney, No. 5, by Edward Haviland.—Notes on the temperature of the body of the *Echidna hystrix*, by N. de Miklouho Maclay. This is a detailed account of some experiments made by the writer at Brisbane in July, 1879. He found, after observations carefully made on two occasions, that the average temperature of the body of the Echidna is 25° C., equal to 78° F., or very little more than that of fish, and about 25° under that of mammals generally.—On the Plagiostomata of the Pacific, part ii., by N. de Miklouho Maclay and William Macleay, F.L.S. The continuation of a paper by the same authors, written some years back, on the genus Heterodontus. The present paper gives descriptions and illustrations of a new species from Japan, named *Heterodontus japonicus*.—Notes on some reptiles from the Herbert River, Queensland, by William Macleay, F.L.S. In this paper, after enumerating all the Reptilia contained in the collection sent to him by Mr. Boyd from the Herbert River, Mr. Macleay describes as new a lizard, *Tiaris boydii*, and three snakes, *Tropidonotus angusticeps*, *Dendrophis bilorealis*, and *Herbertophis plumbeus*, the latter a new genus allied to Coronella.—Notes on some customs of the aboriginal tribes of the Albert District, New South Wales, by C. S. Wilkinson, F.G.S., president. The President read some notes furnished him by Mr. W. H. J. Slee, the Government Inspector of Mines, regarding a singular ceremony which the aboriginal tribes of the Mount Poole district perform, when, as is often the case in that arid region, they need rain. Occasionally pieces of the fibrous variety of gypsum, Satin-spar, are found by the natives, who highly value them and call them "rain-stones," for they believe that the Great Spirit uses them in producing rain. The President exhibited one of the "rain-stones" which had been secured by Mr. Slee, who witnessed the ceremony when performed two years ago by the Mount Poole and Mokley tribes.—On the brain of Grey's whale (*Kogia greyi*), by William A. Haswell, M.A.—On a new genus of fishes from Port Jackson, by Wm. Macleay, F.L.S. This paper consists of the description of a large fish taken a few days ago in a seine net at Watson's Bay. It is of the family *Cirrhitidæ*, and somewhat allied to the genus *Chilodactylus*. The generic name given to it is *Psilocranium*, from its naked head, and the specific name *Coxii*, in honour of the President of the Commissioners for Fisheries of New South Wales. This fish was exhibited by Mr. Morton, Assistant Curator, Australian Museum.

Royal Society of New South Wales, October 3, 1883.—Hon. Prof. Smith, C.M.G., president, in the chair.—Two new members were elected and thirty-five donations received.—A paper by H. Ling Roth, F.M.S., on the roots of the sugar-cane, was read.—Mr. H. C. Russell exhibited a modification of Faure's bichromate battery.—Mr. Russell exhibited several new photographs of the sun taken by him at the Sydney Observatory.

November 7, 1883.—H. C. Russell, F.R.A.S., in the chair.—One new member was elected and eighty-eight donations received.—A paper, on irrigation in Upper India, was read by H. G. McKinney, M.E.—Prof. Liversidge exhibited portions of a fossil crocodile from the Flinders River in Queensland, and other fossils.

November 14, 1883.—Hon. Prof. Smith, C.M.G., president, in the chair.—An adjourned meeting was held, and a paper, by Mr. A. Pepys Wood, on tanks and wells of New South Wales water supply and irrigation, was communicated by Mr. Warren, C.E.

PARIS

Academy of Sciences, January 7.—M. Rolland, president, in the chair.—M. Bouley was elected vice-president, and MM. H. Milne Edwards and Becquerel added to the Central Committee of Management for the year 1884.—The President reported on the papers, memoirs, and documents of all kinds issued by the Academy and received from various sources during the year 1883. The changes that took place amongst the members and correspondents during the same year were announced.—Report on the hydrographic explorations of the *Romanche* in Tierra del Fuego, by M. F. Martial. The work accomplished comprised three distinct parts—(1) the regular triangulation of a portion of Beagle Passage and of several islands, besides twenty plans of various roadsteads; (2) the survey of the north-western branch and about half of the south-western branch of Beagle Passage and the Ildefonsus Islands; (3) exploration of the north-west extremity of Talbot Passage, of the west side of the archipelago from Cook Bay to Black Head Cape, and of the various channels connecting Brecknock Passage with Whaleboat and Darwin Sounds.—Report on the climate of Cape Horn, by M. J. Lephay. Appended to the report are various meteorological tables showing the temperature, barometric pressure, atmospheric currents, direction and velocity of the winds observed at the station of Orange Bay from September 26, 1882, to August 31, 1883.—On the spectrum of the Pons-Brooks comet, by M. Ch. Trépied.—Spectroscopic observations made at Nice on the Pons-Brooks comet, by M. Thollon.—Observations at Marseilles on the same comet (one illustration), by M. E. L. Trouvelot.—On certain doubly periodical functions of the second species, by M. E. Goursat.—On the application of Vandermonde's notation to the representation of hypergeometrical polynomes in a condensed form, by M. Radau.—Calculus of the contact arc of a flexible, spiral, metallic rod, according to any given conditions, on a circular cylinder, by M. H. Léauté.—Note on the action exercised on polarised light by the cellulose solutions in the Schweizer reagent, by M. A. Levallois.—On the compound heat of the soluble fluorides and the law of substituted thermic constants, by M. D. Tommasi.—Some new sulphuretted salts derived from the trisulphuret of phoshorus, by M. G. Lemoine.—On the law of free surfaces in vegetable anatomy, by M. C. Eg. Bertrand.—On the modifications presented by the muscles after severance of the nerves communicating with them, by M. J. Babinski.—On progressive atrophic myopathy (hereditary myopathy beginning in infancy with the muscles of the face, without change in the nervous system), by MM. L. Landouzy and J. Dejerine.—Researches on some recent pretended infallible specifics against hydrophobia (second note), by M. P. Gibier. Garlic and pilocarpine (active principles of jaborandi), tested on rats and cats, were found to be powerless to prevent the development of rabies.—Note accompanying the photographs of natural size of two children delivered by the operation of paratomy in cases of extra-uterine pregnancy by M. Championnière, of the Tenon Hospital, by M. Just Lucas Championnière.—Observations on the remarkable sunsets and dawns observed at Campan during the month of December, 1883, by M. Soucaze. No solution of the phenomenon is offered; but to the volcanic theory it is objected that the effects should be permanent if due to the permanent presence of minute igneous particles in the atmosphere.

BERLIN

Physical Society, December 14, 1883.—Prof. Börnstein described an apparatus for measuring the momentum of the wind, constructed and set up by him in the High School of Agriculture. Hitherto, as is well known, in order to compute the momentum of the wind, people had either registered its velocity by means of the Robinson anemometrical scale, or its pressure by means of the so-called pressure table. The cross-cup instrument laboured, however, under this disadvantage, that it was incapable of following a rapid change of the wind's velocity, being neither able, under an increase of velocity, to pass at once to the duly accelerated pace, nor in the case of an abrupt abatement of the wind's speed, to fall back, till after a considerable time, to the commensurately slower rate. The pressure-table, again, was attended with this disadvantage, that on each occasion it had to be placed in the direction of the wind, and in the case of a relief of pressure, performed oscillations of its own, which registered themselves on the writing apparatus. Prof. Börnstein's instrument consisted essentially of a ball, 126 mm. diameter, affixed to a vertical descending rod, which by an axle-system, at four-fifths of its length, was rendered freely movable on all sides. To the lower end of the rod was fastened a long wire, likewise movable on all sides, and suspended inside a tube 4 metres long. At a still greater distance was placed a quadrilateral vertical prism, movable between rollers, so that each lateral movement of the ball became converted into an up and down movement of the prism. To the prism there hung a frame with a pencil, which marked in curves on a passing strip of paper the movements produced by the pressure of the wind on the ball. At the lower end, again, there was fixed a horizontal plate, by way of a damper. Several of the curves described by this measurer of wind-pressure were shown by Prof. Börnstein, among others that of December 4, a day distinguished by a very low minimum (730 mm.), which passed over Europe from west to east. The observer perceives in this curve a very great rise of the wind's momentum during the day, then at about seven to nine in the evening he sees the curve descend almost to the line of zero, remounting thence in the later hours of the night to its maximum. This showed that the centre of the barometric minimum had passed exactly over Berlin, two periods of intense wind-momentum being separated by a lull of considerable duration.—Dr. König added some supplementary notes to the address recently delivered by him before the Society, setting forth the results of his investigations into the state of the colour-blind (see NATURE, vol. xxix. p. 168). Among other things he read a passage in Goethe's "Theory of Colours," showing that Goethe had already examined a colour-blind person, regarding whom he was of opinion that he was blue-blind, or *akyanoblept*. From Goethe's statements, however, it was plain that the individual in question was red-blind, and it would accordingly appear that this was the first real observation of a case of colour-blindness.

Physiological Society, December 21, 1883.—Prof. Fritsch gave a demonstration of the model of a brain, prepared according to the directions of Prof. Aeby in Zurich, and acquired by the Physiological Institute. By means of differently coloured wires and of coloured balls of different sizes, it shows the situation of the cerebral ganglia, and the course of the nerve-fibres in connection with them. The nerve-cords and the ganglia pertaining to them are without exception of the same colour. The connections between the spine and the separate sections of the cerebrum and cerebellum, the cerebral cavities and fissures, come out very clearly in the skilfully fashioned model.—Dr. Falk spoke of the transference from mother to fœtus of corpuscular and chemical poisons, and brought prominently to notice the different results yielded by observations on man and experiments made on animals with a view to obtaining knowledge on this subject. Infectious diseases, such as small-pox, syphilis, &c., were conveyed from the mother. Other diseases, such as inflammation of the spleen, were not so conveyed. With respect to chemical poisons, the case was likewise various. The statements of different authors respecting the oxide of carbon did not agree. Dr. Falk had quite recently had occasion to dissect a woman who died from the poison of oxide of carbon. Her body displayed all the symptoms characterising this form of death, showing in a singularly perfect manner the bright colour of the skin, of the muscles, and of the blood. The dead fœtus of the deceased woman, which was of eight months' growth, had, on the other hand, normally coloured muscles and dark blood, in which neither chemical reagents nor spectral analysis discovered a trace of the oxide of carbon. A case having, however, been elsewhere observed of the passage of the oxide of carbon into the blood of a fœtus six months old, Dr. Falk conjectured that the age of the embryo, more particularly the greater or less thickness of the partition dividing the mother's system of blood-vessel from that of the child, formed a considerable item in the account This point he would study by experiments on the osmosis o gases.—Dr. Blaschko communicated the results of his investigations into the structure and embryological development of the oute skin in the palm of the hand of man and apes. On the under side of the epidermis he not only found protuberances corresponding with the regular furrows visible on the surface, but, answering to the prominences of the surface, were also found protuberances on the under side connected with the former by transverse swellings. The study of the histological developmen of the outer skin further taught Dr. Blaschko that the epidermis, with its protuberances and depressions, was first fully formed before the cutis came into shape, attaching itself to the epidermis.—Dr. Salomon has endeavoured to fill a gap which was yet perceptible in our knowledge of the urine of domestic mammalia. In particular there existed but four analyses of the urine of the pig, which, as an omnivorous animal, stood specially near to man, and of these four, three were of earlier date than 1845. These four analyses, moreover, all concurred in denying that the urine of swine contained any uric acid, a circumstance very remarkable in face of the fact of the universal diffusion of this substance among all the other higher animals that had yet been examined. Its place was supposed to be supplied in the pig by guanine. As the result of his examinations, Dr. Salomon found that in all cases the urine of swine contained uric acid, and that in no inconsiderable quantities. The proportion of uric acid in the urine was, in swine, as 1 to 150; in man, 1 to 50. Guanine, on the other hand, could not be indisputably proved to be present in the urine of swine; but a crystalline substance, very closely related to guanine, and showing similar reactions, was found; lactic acid, the presence of which in swine had been maintained, could not be discovered, although succinic acid, which comes near to it, was found. Creatine and creatinine, as also other xanthine substances, were likewise searched for in the urine of swine.—In connection with this subject, Dr. A. Baginski stated that in the urine of a diptheritic child suffering from nephritis he had found a substance very nearly related to guanine, as also xanthine, both in perfectly perceptible quantities. Both these substances, however, decreased in quantity with the abatement of the disease.

THE ALPS OF NEW ZEALAND

The High Alps of New Zealand; or, A Trip to the Glaciers of the Antipodes, with an Ascent of Mount Cook. By William Spotswood Green. (Macmillan, 1883.)

THE laborious explorations of Dr. Julius von Haast and his associates, undertaken in 1862 and subsequent years, had, as their results, an excellent sketch map of the New Zealand Alps, and a general knowledge of their topography and geology. It was also made evident that, although the summits did not attain the elevation of many in the Swiss Alps, yet, as they were steep and precipitous, as they rose from valleys comparatively low, and as the snow line descended far below its ordinary level in the Northern Alps, there would be considerable difficulty in scaling the higher peaks. No real attempt on these was made till the year 1881, when Mr. Green decided to try his hand at mountaineering in New Zealand.

It was of course necessary for any one contemplating glacier excursions to take guides from Europe. Mr. Green was fortunate enough to secure the services of Emil Boss and Ulrich Kaufmann, both well known guides from Grindelwald. His narrative shows that he could not have made a better choice—the two men proved to be not only first rate mountaineers, but also pleasant and trustworthy companions, always uncomplaining and unselfish.

Mr. Green must have begun his journey under an unlucky star. Small-pox broke out on board among the forecastle passengers before they reached Table Bay. On arriving in Australia, all were put in quarantine for some three weeks, where, we may add, the arrangements for the reception of the unfortunates appear to have been disgracefully bad. Then, when Mr. Green escaped from this bondage just in time to catch the New Zealand steamer, it happened to be full, so that altogether more than a month of valuable time was lost.

At last, after touching at one or two spots on the western coast of the Southern Island, Mr. Green landed at Christchurch, and, after a brief consultation with Dr. von Haast, hastened to push up the country towards Mount Cook. The physical structure of the Southern Island is comparatively simple. A map of it bears some resemblance, except for the smallness of the scale, and the greater height of the mountains, both relative and absolute, to the southern part of the Scandinavian peninsula. The watershed—that of the Southern Alps—lies comparatively near to the western coast, and runs roughly parallel with it; between these is a mountain land, pierced with beautiful fjords, especially towards the south, and covered with dense and generally impenetrable forest; on the eastern side, between the main range and the sea, is a comparatively level district; a zone of lakes borders the mountain region, similar to that on the southern flank of the European Alps; and the lowlands extend far into the recesses of the peaks. The Tasman valley, for example, which runs up to the glacier of the same name in the very heart of the chain beneath the peak of Mount Cook, is described by Mr. Green as an immense flat, from which the mountains rise as from a shore. The end of the glacier being 2400 feet above the sea, the average fall of the river is about 25 feet to a mile. Mount Cook, which attains an elevation of 12,349 feet above the sea, is the culminating point of the Southern Alps, but there are several fine peaks near it which are not very much lower. A grand group of glaciers descends from these, of the beauty of which Mr. Green speaks in enthusiastic terms.

The mountains of New Zealand are of great interest to the student of physical geography. The latitude of Mount Cook corresponds with that of Florence in the northern hemisphere, but the mean annual temperature of the Southern Island is 10° lower than that of corresponding latitudes in Western Europe. There is, however, much less difference between the extremes. For instance, the mean summer temperature of Dunedin (lat. 45° 50′) is 57°·2, the mean winter 50°·7 F. The rainfall on the eastern coast is much the same as on the English lowlands, being 33 inches at Dunedin and 25 inches at Christchurch; but on the western coast, at Hokitaka, it is 118 inches. Thus the snowfall on the mountains is heavy, and the line of permanent snow is full three thousand feet lower than on the Alps. Hence the glaciers descend far below the level of those in Switzerland, coming down on the western side at one place to within 670 feet of the sea-level, while on the eastern they terminate at about 2000 feet; on this side, however, the limit of perpetual snow is about 750 feet lower than on the western. On the whole the area covered permanently by ice and snow in the Southern Alps is about 160 square miles, or 20 more than that in the Bernese Oberland. The Great Tasman Glacier is eighteen miles long, thus exceeding the Great Aletsch by three miles; further it is two miles wide at the end, while the other does not exceed a mile in any part.

The Southern Alps present another very singular feature. To the south of Mount Cook the chain is severed by a singular flat-topped pass—named after Dr. von Haast—the ill-marked summit of which is only about 1600 feet above the sea; yet to the south of it again the mountains rise rapidly, and attain elevations of full ten thousand feet. Thus a depression of a couple of thousand feet would convert the Southern Island of New Zealand into two mountainous islands, divided by a narrow channel, just as the Raftsund parts Hindö and Vaagö in the Lofotens.

The Alps of New Zealand are more ancient than those of Europe, as they were probably uplifted in Jurassic times. The oldest rocks—granites (or possibly in part granitoid gneisses) appear on the western side; these are overlain by crystalline schists, to which succeed slates, grits, &c., of Silurian and later ages. Probably when this district is fully surveyed the New Zealand Alps will be found to consist of a series of Archæan rocks overlain by sedimentary deposits of considerably later date. The highest rock on Mount Cook appears to be a quartzite, and Mr. Green mentions the occurrence, lower down the mountain, of some volcanic tuffs.

For Mr. Green's adventures during the ascent of Mount Cook we must refer readers to his volume. Suffice it to say that this proved to be no easy task. The difficulties were twofold: those of conveying the necessary supplies of food and covering to a sufficiently elevated bivouac, and those presented by the mountain itself. The former of course will be overcome as the country is opened up, but it is evident that Mount Cook is equal in difficulty to most of the first class Alpine peaks. Mr. Green first attacked it by the southern ridge, but, after reaching a height of 7500 feet, found that route impracticable. An attempt was then made to reach the north-eastern face of the mountain by a route which also had to be abandoned. Mr. Green then mounted by a ridge on the left bank of the Hochstetter Glacier, and, after bivouacking at a height of about 7000 feet, succeeded in attaining the summit by a circuitous and difficult climb near the ridge connecting Mount Cook with Mount Tasman. His usual ill-fortune pursued him. The weather was bad, as it seems often to be in these parts—and the approach of night compelled him to return without actually setting his foot on the very highest point. The ascent however was practically accomplished, only a slight detour to avoid a crevasse and a little more plodding along a snow ridge remained; but even the quarter of an hour or twenty minutes which this would have added to the expedition could not be spared. The summit of Mount Cook is not the place on which to spend a night in bad weather, nor is it a peak which can be descended in the dark. As it was, notwithstanding their utmost exertions, the travellers were compelled to halt for the night at an elevation of some 10,000 feet above the sea, on a ledge so dangerous that they dared not sleep—even one at a time!

Mr. Green afterwards visited the neighbourhood of Mount Earnslaw, a high peak south of Haast Pass, but his usual ill-fortune pursued him, and the weather prevented him from doing more than make a reconnaissance.

We lay down this volume with regret that the Fates were not kinder to Mr. Green in giving him the opportunity of writing a longer tale of adventure. He tells his story so well and pleasantly that we regret he could not carry further his explorations of New Zealand peaks and glaciers. He is evidently a close observer and devoted student of nature, so that without any attempt at book-making he has contrived to incorporate with his narrative many interesting facts relating to the natural history and physiography of these remarkable islands, which raises his work far above the level of an ordinary book of travel.

T. G. BONNEY

DOBSON'S "MONOGRAPH OF THE INSECTIVORA"

A Monograph of the Insectivora, Systematic and Anatomical. By G. E. Dobson, M.A., F.R.S. Parts I. and II. 4to. Pp. 1-172, 22 Plates. (London: Van Voorst, 1882-83.)

THE Insectivora constitute an order of Mammals at the same time but little known and of great scientific interest. Until recently they were not considered an attractive group. Small in size, shy and retiring in habits, difficult of capture, none of them of commercial value or capable of domestication, they have received little notice even from professed zoologists, and to the general public their existence, except in the case of two or three of the commonest species, has been almost unknown. The fact, however, on which Prof. Huxley insisted many years ago, in his lectures at the College of Surgeons, that in this order we find some of the most generalised members of the Eutherian or placental Mammals, little-modified representatives of what appear to be ancestral forms, whose study is an excellent introduction to a knowledge of the more modified or specialised members of the class, has done much to elevate them in the eyes of naturalists who are seeking the key to unlock the history of the evolution of the Mammalia. Mr Dobson, whose excellent work in the Chiroptera is familiar to all zoologists, has done well then to take up the Insectivora, and to give us, for the first time, a thoroughly reliable and exhaustive monograph upon them.

Aided by wisely-bestowed grants from the Government Fund administered by a committee of the Royal Society, and with the assistance of numerous scientific friends, he has been enabled to collect abundant materials, and publish the results of his investigations in a copiously illustrated form. To facilitate comparison and avoid repetition, Mr. Dobson commences with a detailed account of the anatomy, paying especial attention to the myology, of two species, *Gymnura rafflesi* and *Erinaceus europæus*, which have been selected, the former as the nearest representative of an undifferentiated Eutherian, and the latter as being a well-known species, easily obtainable for examination. With these the anatomy of the species subsequently described is compared and contrasted. With regard to the general classification of the group, a knowledge of which can of course only be obtained from a thorough examination of their structure, Mr. Dobson has wisely reserved his views until the work is completed, adopting provisionally that which has been gradually elaborated by Peters, Mivart, and Gill.

The two first parts of the work already issued contain the families *Erinaceidæ*, *Centetidæ*, *Solenodontidæ*, *Potamogalidæ*, *Chrysochloridæ*, and *Talpidæ*, each family, genus, and species being treated of fully, both anatomically and zoologically. The difficult group *Soricidæ*, as well as the *Macroscelidæ*, *Tupaiidæ*, and the aberrant *Galeopithecidæ*, will form the subject of the third and concluding part. If this part should be, as we have every reason to believe it will, equal to its predecessors in thoroughness of detail and beauty of illustration, we shall have a work which will do great credit to its author, and rank among those solid contributions to knowledge which form landmarks in the progress of science.

W. H. FLOWER

OUR BOOK SHELF

Manual of Mathematical Tables. By the Rev. J. A. Galbraith and the Rev. S. Haughton, F.R.S. (London: Cassell, Petter, and Galpin.)

"Now what so pleasing can there be, if a man be mathematically given, as to calculate or peruse Napier's logarithms, or those tables of artificial sines and tangents, not long since set out by mine old collegiate, good friend, and late fellow-student of Christchurch in Oxford, Mr. Edmund Gunter, which will perform that by addition and subtraction only which heretofore Regiomontanus's tables did by multiplication and division?" We shall not take up the cudgels against quaint old Burton, but will simply say that, for those to whom the subject is a "pleasing" one, here is an exceedingly handy and neatly got up manual, whose *raison d'être* is justified by its having reached a fourth edition. If our readers are "philosophers," they will not require an account of what logarithms are (see Mr. Glaisher's excellent description in the "Encyclopædia Britannica," vol. xiv.); if they are not, with Mr. Squeers we say, "Then I am sorry for you, for I sha'n't be able to explain them."

The tables, are in the main, five-figure tables, except that the logarithms of 1001 to 1100 are given to seven places, and in the case of the logarithms of numbers extend to the logarithm of 10000. The other tables are logarithms of sines and tangents to every minute of the quadrant, and Gauss's sum and difference logarithms. Besides, there are a capital introduction, tables of useful constants with their logarithms, and solutions, by trigonometrical tables, of quadratic and cubic ($x^3 \pm px \pm q = 0$) equations. There are no tables of natural sines and tangents. We have no hesitation in commending these tables to a still wider public than they have already reached. R. T.

Principles of Theoretical Chemistry. By Ira Remsen. (Philadelphia: H. C. Lea's Son and Co., 1883.)

UNFORTUNATELY for some years past we have been treated with an immense number of "books" on chemistry in England of a most mechanical type: books in which no reasoning theory is apparent. A dry epitome of facts in a most unpalatable shape, embellished here and there with formulæ of various kinds, graphic, symbolic, empiric, or glyptic, but in very rare cases any attempt at showing the learner, easily, how these ideas of chemical constitution, represented by formulæ, are clearly arrived at. If a student is unable to see, in his mind, how the formula H_2SO_4 represents *a* knowledge of the constitution of sulphuric acid, he had much better only know its percentage composition, as it may otherwise lead him wrongly.

From the style of the present work, and some others we have recently seen from the other side, our cousins are taking up chemistry in a more philosophic manner than ourselves. And it is easy to see whence this view comes. Considering that we own a Dalton it is strange that the development of chemical theories is so lightly treated in English text-books. Are English students so superficial or so under the domination of *Exams.* that a work like Kopp's "Entwickelung" is too much for them?

This very condensed little work, just over 200 pages, is intended for somewhat advanced students who have a basement of facts to build upon. It commences with a general discussion of atoms and molecules, which is continued in a very simple and clear manner, with the exception of a few *newish* words like *chemism*. The chapters on atoms and molecules and on valency are about as clear and simple as they can be made, and the same may be said in regard to the opening chapter on carbon compounds. The author has evidently a reasonable notion of the value and permanence of a chemical theory, and no exception can be taken to the manner of discussion or expression. Speaking, for instance, of Avogadro's hypothesis, the author says: "It is at present almost universally accepted by chemists, some, indeed, going so far as to speak of it as a *law*." It is certainly one of the best additions to the list of *small* chemical books that has been made for some time.

Studies in Micrographic Petrography. (Ady and Hensoldt, 7, Muchell Road, Nunhead, S.E.)

THE growing interest taken in this country in the study of petrography is well shown by the rapidly increasing facilities offered for the prosecution of this branch of science. The most recent of these has just appeared under the foregoing title. It is to consist of the issue of two dozen microscopic slides of characteristic minerals and rocks prepared by Mr. Hensoldt of Wetzlar, with illustrative drawings and descriptive text by Mr. J. E. Ady, who is already favourably known for his microscopic preparations of British rocks. The first number of the "Studies" is devoted to "*Eozoon*, Led Beg, Sutherland." It contains two lithographic plates illustrative of the so-called eozoonal structure of a limestone in the north of Scotland, and four pages of descriptive text. The author gives a brief reference to the literature of the subject, and an account of the microscopic structure of some portions of the limestone in question, which he regards as akin to that of the Canadian *Eozoon*, but as being of inorganic origin. We are afraid his sketch is too slight to have much weight in the controversy regarding *Eozoon*. His effort to extend the opportunities of petrographical investigation, however, and to popularise this fascinating but difficult branch of geology is praiseworthy, and we hope that his "Studies" may meet with such success as may induce him to continue them.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Remarkable Sunsets

THE numbers of NATURE for October, which are the latest to be seen here at this date, contain in the correspondence accounts of the green appearance of the sun in India. Some solar phenomena observable at present and during the whole of the past month are probably related to these, and yet are sufficiently distinct to deserve a separate description. They have, indeed, attracted the attention of everybody here by their novelty and spectacular magnificence, and to some have an ominous significance in connection with recent seismic disturbances.

In November and December we have in this part of Japan a remarkably clear atmosphere, and this year has proved no exception. The great snow-capped mountain, Fujii, some ninety miles away to the west, is beautifully defined to view both at sunrise and sunset on most days, although during the greater part of the year—the warmer part that is—it is rare to catch a glimpse of it.

The phenomena of which I wish to record a description occur every day before and after sunset and sunrise, and serve to materially lengthen our day. In this latitude, although not in the tropics, the shortness of the twilight is very noticeable as compared with that of England, but at present at least an hour and a half elapses between the moment of sunset and that of the disappearance of the last of its rays, and this, with the same time between dawn and sunrise, causes our day to be very appreciably lengthened.

On some days there is round the sun, even while it is still high, a considerable area of silvery glare, 40° to 50° in diameter, and bordered by a lurid reddish-brown or purplish-brown halo. A similar lurid turbidity lies in the horizon, and as the sun descends the halo blends with this below, while above the sun it attenuates and disappears, the silvery glare remaining undiminished. When the sun sets there is still a nearly circular area of this intense glare with a diameter of about 12°. On other days there is before sunset only a thin silvery light round the sun diffusing away from it, and only about and after the setting is the more defined area of strong light strikingly visible, and on these days the horizon also shows little of the dull redness mentioned above. Besides the above peculiarities, the sun preserves its whiteness much more than usual, so as to be only golden orange when setting.

Now follow the more remarkable phenomena. The white glare, or patch of silvery light, gradually sets, spreading out along the horizon as it does so, and passing through the sunset colours until little more than a red line one or two degrees deep remains. This happens at about twenty minutes after sunset. At this moment, on the gray curtain of twilight appears a white luminosity, which rapidly intensifies over the sunset, and shades away over almost half the visible hemisphere. The brightnes over the sunset becomes vividly brilliant, and at the same time delicately coloured. Over a somewhat depressed circular area, about 12° high and 15° broad, it assumes a pale green tint. Above this comes an equally dazzling pale yellow-orange, and again above this a soft rose colour melts away to the zenith. The revival of the light, or return from commencing twilight, is peculiarly striking. Buildings become brilliantly illuminated, and strong shadows are cast. All this outglow occurs in no more than five minutes, and now continues for about a quarter of an hour, but the brilliancy gradually contracts in area and sets with a magnificent display of sunset colours reaching some 120° round the horizon, until, by fifty minutes after sunset, this light has also gone down to a red line of about 2° elevation. I should not have omitted to say that the green light passes to yellow.

By this time night has fairly well come in the eastern half of the heavens, but already another but more delicate silvery whitening begins to show itself on the western curtain, and this also diffuses very rapidly up to the zenith and round to north and south. It also then goes through a process of contracting, intensifying to considerable brightness, and gradually passing through the sunset colours. Night is now full—with or without moonlight, according to date—and from the west, or rather from a point well to the north of it, spreads a delicate but brilliant light, having an almost perfect resemblance to the burning of a vast distant city. The last crimson light of this reflection does not disappear till an hour and a half after sunset.

The phenomena I have attempted to describe cannot possibly, I think, be explained otherwise than as being the effects of reflection, and that from a canopy many miles above the earth's surface. The matter of this canopy is highly transparent, for not only are moon and stars brilliantly clear, but in the crescent moon the dark surface of its sphere was on some nights in both months visible and so distinct as to have been noticed independently by several persons. (It has been suggested that this greater visibility of the dark surface of the moon may be due to a stronger reflection from the present atmosphere of the earth.) The reflecting matter must, I suppose be water, but in what form and under what conditions it is there so high up day after day in varying weather, it is difficult to me to conceive. We have had wet days intervening, cloudy days, and very windy days, but on all occasions, except during rain, the phenomena have been visible with strange uniformity.

Not counting the setting of the silvery glare twenty minutes after sunset, which ought perhaps to be done, there are, it will be seen, two reflected sunsets following the true one. In the morning before sunrise the same phenomena in inverse order are perhaps still more remarkable to see. Indeed the whole phenomena, night and morning, have a most unnatural and magical appearance, very different from those of the ordinary sunset and sunrise.

One other phenomenon, also of reflection, has yet to be mentioned. Rarely with much distinctness, but always to be noticed, there appears high up in the *east*, just after the silvery glare following the sun has set, and lasting only a few minutes, a dim image of the white glare and the western horizon just after sunset. It is of a delicate rosy light, with a grayish central part.

I am informed that somewhat similar appearances are being seen in Shanghai. EDWARD DIVERS

Imperial Japanese College of Engineering, Tokio,
December 12, 1883

IF the red sunsets are to be attributed to smoke and dust in the atmosphere from volcanic eruptions, as seems likely from the contributions in the last number of NATURE at hand (December 20), then it becomes important to take into account other eruptions which may have happened simultaneously with or since that of Krakatoa on August 27, 1883. In any discussion of atmospheric currents as fixing the dates of the appearance of these sunset phenomena at different places this is of special importance, in order that no confusion may arise in trying to reconcile places and dates that may refer to dust and ashes brought from entirely distinct eruptions. For this reason I send you the following extracts.

The first is from the U.S. Signal Service *Monthly Weather Review* for October, 1883, and is as follows :—

"*Unalaska, Alaska, October* 22, 1883.

"*Executive Officer, Signal Service, U.S.A., Washington, D.C.*

"SIR,—I forward by this mail a sample bottle of sand that fell during the storm of October 20, 1883.

"At 2.30 p.m. the air became suddenly darkened like night, and soon after a shower of mixed sand and water fell for about ten minntes, covering the ground with a thin layer. The windows were so covered that it was impossible to see through them.

"This sand is supposed to have come either from the Menkushin or the new volcano adjacent to Bogoslov. The former is at a distance of about nineteen miles south-west, but for years has only issued forth smoke or steam. The latter is a new one, which made its appearance this summer, and burst out from the bottom of Behring Sea. It has been exceedingly active, as it has already formed an island from 800 to 1200 feet high.

"According to the report of Capt. Anderson, the discoverer, who sails one of the company's vessels, and who went within 2000 yards of it, it presents a most magnificent sight. The fire, smoke, and lava are coming out at many crevices, even under the water line. Large boulders are shot high in the air, which, striking the water, send forth steam and a hissing sound.

"Bogoslov is about sixty miles from here, in a westerly direction. The new volcano is about one-eighth of a mile north-west of it. "I am, Sir, very respectfully,

"S. APPLEGATE,
"Sergt. Sig. Corps, U.S.A."

The other extract is from a recent paper as follows :—

"*San Francisco, Cal., December* 28, 1883

"Prof. Davidson received from Alaska to-day the particulars of the volcanic disturbances there in October last, near the entrance to Cook's Inlet. On the morning of October 6 a settlement of fishermen on English Bay heard a heavy report, and, looking in the direction from whence the sound came, immense volumes of smoke and flame were seen to burst forth from the summit of Mount Augustine. The sky became obscured, and a few hours later great quantities of pumice dust began to fall, some of it being fine and smooth, and some gritty. At half-past three o'clock on the same day an earthquake wave thirty feet high came rushing in over the hamlet, sweeping away all the boats and deluging the houses. The tide at the time being low saved the settlement from utter destruction. This wave was followed by two other waves eighteen feet high, which were succeeded at irregular intervals by others. The pumice ashes fell to a depth of five inches, making the day so dark that lamps had to be lit. At night the surrounding country was illuminated by flames from the crater. Ordinarily Mount Augustine is covered with snow, but this year it is completely bare. Upon examination after the disturbances had subsided, it was found that the mountain had been split in two from base to summit, and that the northern slope had fallen to the level of the surrounding cliffs. Simultaneously with the eruption, a new island made its appearance in the passage between Chernaboura Island and the mainland. It was seventy-five feet high, and a mile and a half long. So violent was the volcanic action that two extinct volcanoes of the Peninsula of Alaska, lying to the westward of the active volcano Iliamua, 12,000 feet high, burst into activity, and emitted immense quantities of smoke and dust. Flames were visible at night. It is stated that the wives of a party of Aleut Indians, who were engaged in otter-hunting in that locality, became afraid of the subterranean noises, and refused to stay, returning to their homes. None of those who remained can be found."

The approximate positions of some of the points mentioned in these reports are as follows :—

	Lat.	Long.
Iliamua	60·1 N.	153·1 W.
Mount Augustine	59·5 N.	153·5 W.
Unalaska	53·9 N.	166·5 W.
Bogoslov	54·0 N.	168·0 W.

Here we have the record of (1) a new volcano which appeared near Bogoslov some time during the summer, and had been continuously active and thrown up an island 1000 feet high up to some time in October; (2) an explosive eruption of Mount Augustine on October 6, which split off the whole side of the volcano and distributed ashes to a depth of five inches many miles away, and started a wave in the ocean about thirty feet high; and (3) of a shower of sand and water on October 20 at Unalaska, which probably arose from some fresh or renewed eruption of a neighbouring volcano.

Many of these phenomena resemble those reported from Krakatoa, though on a smaller scale. It is not necessary to point out that a continuous eruption of a new volcano for weeks or months would probably eject as much or more dust and ashes than accompanied the Krakatoa convulsion, though not to so great a height. If, however, Mr. Preece's theory of electric repulsion of the dust particles be true, then the finest of them, if highly electrified, might rise to great heights, independent of the force of ejectment from the volcano.

In this connection it is well to remember that there may have been many other volcanic outbursts during the last few months, of which we have not yet heard, and perhaps never may. The whole chain of islands from Java to Alaska, including the Philippines and Japan, is full of volcanoes, and seems to be a sensitive seam in the earth's crust. A convulsion like that of Krakatoa is likely to be accompanied or followed by others along this line, the northern portion of which is only visited by otter-hunters.

Without presuming to question the theory as to the rapid transmission of Krakatoa dust by the upper currents of the atmosphere until we see the evidence on which it rests, it occurred to me that the above considerations might possibly modify or supplement it in some degree.

Referring to the remarkable results deduced by General Strachey, showing an atmospheric wave travelling three times round the globe from the Krakatoa eruption, which seems to be of even more scientific interest from a physical point of view than the transmission of the dust and ashes, and which deserves a thorough and careful re-examination when the data are in from all available barometric records, I would say that I have been kindly allowed to examine the barometric records of the Signal Office here at Washington, and I find no trace of any such disturbance following the reported Alaskan eruptions of October 6 and October 20. In connection with the record of the waves following the Krakatoa catastrophe there are some interesting points which I wish to examine more carefully before discussing them.

H. M. Paul

Washington, January 8

Referring to Mr. Burder's letter in Nature of January 10 (p. 251), is it so certain that, if there be no resisting medium in interplanetary space, the whole of the earth's atmosphere must "rotate with the earth as if it were part and parcel of it"? Take a stratum of the atmosphere at, say, forty-five miles in altitude at the equator. According to the received theory, this ought of course to move with a velocity greater than that of the surface of the earth immediately below. But each successive inferior stratum moves with less velocity. And thus they must tend to retard the superior strata with which they may be assumed to be in contact. Of course the merging of stratum into stratum is gradual, but this does not affect the amount of friction and retardation.

In like manner, imagine a section of the atmosphere taken along the equator. Sections taken along successive parallels of declination north and south would tend to retard the velocity of this central layer.

These two causes combined might have a considerable effect in retarding the velocity of the upper atmosphere in equatorial regions. And it seems to me doubtful whether the upper atmosphere near the poles would be actually carried round with each terrestrial rotation. The rarity of the upper regions of the atmosphere and the lessened force of gravity would both help towards the result indicated, inasmuch as they would tend to make the atmosphere less rigid.

As I am writing, I venture to make another suggestion. Gilbert White mentions that in the summer of 1783, when, as at present, the atmosphere was filled with dust consequent on volcanic eruptions, and "a peculiar haze or smoky fog prevailed for many weeks in this island and in every part of Europe, and even beyond its limits," "all the time the heat was so intense that butchers' meat could hardly be eaten the day after it was killed, and the flies swarmed so in the lanes and hedges that they rendered the horses half frantic, and riding irksome." May not the present May-like weather be due to a like cause? Sweet violets, primroses, wallflowers, roses, and several other flowers are now blooming in my garden under the Cleveland Hills.

Had the halos round the moon seen here last and the previous night any possible connection with the dust in the atmosphere? I computed the diameter of the inner dirty white to be twice, the dirty orange one and three-quarters, and the outer green three and a quarter times the moon's apparent diameter.

John Hawell

Ingleby Greenhow Vicarage, Yorks, January 15

I think a few notes relating to the recent sunsets may still have an interest for some readers of Nature. Notwithstanding the length of time these remarkable phenomena have been apparent, the sunsets of January 11 and 12 were as brilliant as regards the *second* after-glow as any that have preceded them, the final glow having lasted on the 12th till 5.55; while the sun set that evening at 4.12.

The pink halo so often seen of late could not be discerned that day though the sky was cloudless; but it has been often visible when clouds partly obscured the sun, or portions of the sky, and could then be recognised between them, separating the blue of the remoter sky from the whitish light surrounding the sun, as a ring-formed glow of a strong pink colour.

These broad pink halos have been less commented on than the splendid sunsets which have invariably succeeded them, but they have been nearly as persistent in their presence. You have had so many accounts of the succession of colours and effects of the two after-glows, that I will not allude further to them here; but as I have retained a record of many remarkable sunsets and sunrises which I observed in Wales in former days (possibly the very same mentioned by Prof. Piazzi Smyth in Nature, December 13, 1883, p. 149, as observed by him thirty years ago), and as I carefully noted in them the time and hour of the changes in the sky down to that of the complete extinction of the after light, it may interest others than myself to compare displays of that date with those of this winter.

What is worthy of especial interest is the great difference between the periods of prolongation then and now of the illumination of the western sky, showing that the second after-glow of recent sunsets is a phenomenon distinct from and additional to those belonging to normal sunsets.

The following table exhibits the two series of observations made in 1855, 1856, 1857, and in 1883–84 respectively:—

Date	Sunset at	First after-glow or cone of pink light				Second after-glow in 1883-84, which begins as the first after-glow sets
		Appears as sunset colours are fading	Brightest at	Sets		
				1st series, 1855-56-57	2nd series, 1883-84	
Nov. 11, 1856 ...	4.13	4.50	4.57	5.10		
,, 12, ,, ...	4.14					
,, 23, 1855 ...	...	...	...	4.55		
Dec. 7, ,, ...	3.50	...	...	4.20		
,, 8, ,, ...	...	...	...	4.20		
,, 10, ,, ...	...	...	...	4.20		
,, 11, 1883 ...	...	...	...	...	about 4.45	5.45
,, 14, ,, ...	...	...	...	...	...	5.45
,, 15, 1856 ...	...	4.15	4.21	4.35		
,, 18, ,, ...	...	...	4.20	4.30		
,, 19, ,, ...	3.50	...	...	4.30		
,, 24, 1883 ...	3.53	...	...	...	about 5.0	5.45
Jan. 11, 1884 ...	4.13	...	...	...	,, 5.0	5.40
,, 12, ,, ...	...	...	...	...	,, 5.0	5.55
,, 15, 1857 ...	...	...	...	4.55		
,, 16, ,, ...	...	4.50	...	5.0		
,, 19, ,, ...	...	...	5.10	5.18		
,, 26, ,, ...	...	...	5.20	5.25		
Feb. 8, ,, ...	5	...	...	...		

The colours associated with the actual sunset are quite in accord in both.

The first after-glow, or pink cone or dome of light appearing after the sunset colours have nearly faded, is also similar in both series, but its time of setting has been apparently somewhat prolonged in the recent observations.

It is the 1883-84 series alone, however, that shows the *second* after-glow, and the duration of this strange phenomenon, which I have the advantage of observing over a wide bird's-eye view in North Wiltshire, has extended on evenings when it could be well observed to about one hour after the first after-glow had disappeared below the horizon. The exact moment of this disappearance has been more difficult to determine than in the earlier observations where darkness followed; as recently the heavens and the earth have been reilluminated just as the natural night would have begun. T. STORY-MASKELYNE

Salthrop, January 13

As the "halo" exactly opposite the sun, reported by Mr. T. W. Backhouse in NATURE, January 10 (p. 251) may prove to be of considerable importance, I beg to add my observations of it on the 12th. I had noticed a mass of ruddy colour under the given conditions, previously, but had not detected its strange nature. The sunset on the 11th was very fine. The 12th, until after sunset, was cloudless, except for the hazy masses which seem to precede every sunrise, and, more especially, sunset, at present. Our sunshine record is an unbroken scorch from 9.15 a.m. to 2.52 p.m. (sun seen clear of horizon at 8.26, and touched at 4.0); I doubt if, previously, we have recorded even five hours in early January. At 7.45 a.m. on the 12th (sun rose at 8.22) the cloud-glow had turned to silvery green below, and rose from 15° to 30° in the south-east. At 7.47 the rose reached 60°, but was fainter. I first noticed the "halo" at 7.52. It was then so well defined that, calling a lady's attention by asking what she saw there, she spoke of it as "a broad rainbow." Position, by compass, 30° north of west. It was a semicircle situated 10° above the horizon, standing on the dark gray arch of dawn, Jupiter being on a line with the base of the left end of the rosy arch. The inner arc of this measured 10°, and the outer 24° in radius, but it spread out to 30° at the base. The centre was of the same blue as the sky to the right and left of the rosy semicircle, above the gray. The base, sinking faster than Jupiter, spread out so that, at 8 o'clock, the arch having now broken above, its outline was rather like a railway chair. The base now reached from west-north-west to north-north-west by north. After sunset there were signs of a similar phenomenon, but clouds prevented certainty.

Is not *fifty* miles an underestimate for the altitudes of the light-reflecting material? If Mr. Symons is nearer the mark in his suggestion (100 to 200 miles), then more than half of the eastward velocity of the original erupted dust is accounted for by retardation, due to matter having velocity belonging to an earth radius of 4000 miles, revolving in a circle of 4100 to 4200 miles radius. Would it need an eruptive force of more than two to four miles per second (six to twelve times greater than a cannon ball) to attain such altitudes? The constant uprush would minimise the air-resistance enormously.

York, January 14 J. EDMUND CLARK

P.S.—January 15.—This morning, at 7.47, the "halo" began to form, but was not nearly as perfect as on the 12th. The arch (upper part only) was *rayed*, as if it were the opposite point of sight for rays from the sun. All over before 8, or fully twenty minutes before sunrise.—J. E. C.

WITH reference to Herr Wetterhan's inquiry as to the absence of the sky-glow in a clear sky at other places than Freiburg on the morning of January 11, I find that at San Remo, in Northern Italy, where I spent the week ending on that day, a similar falling off of effect occurred at the same time. The sunrise was "very fine, but nothing to compare with the sunset of yesterday," and "the filmy streaks were very thin, and stretched this morning from south-west by south to north-east by north." Nevertheless there was the strange bluish-white glare above the eastern horizon, casting shadows, and a thin pink film up to about 75° at 28 min. before sunrise. The sunset glow of this day and of the day before was magnificent, the procession of colours beginning about 15 min. after sunset, and lasting a full hour. I see that your Constantinople correspondent also mentions the sunset of the 11th as a remarkably fine one. The air on the 10th, not the 11th, as at Freiburg, was wonderfully transparent at San Remo, the whole range of Corsican mountains, over eighty miles distant, standing out sharply for 15 min. before and after sunrise, and the sun himself bursting forth in great splendour from below the sea line.

London, January 19 F. A. R. RUSSELL

Unconscious Bias in Walking

SOME ten or twelve years ago I made some experiments upon the subject of Mr. Larden's letter in NATURE (Jan. 17, p. 262), namely, unconscious bias in walking. The experiments were not numerous, but they left no doubt in my mind as to the cause of divergence from a straight path. My notes were sent, at my father's suggestion, to the late Mr. Douglas Spalding, who was about to undertake experiments on the curious power which animals have of finding their way. I rather think he made some trials with pigs, but I believe he never published anything on the subject. In stating my results I am compelled therefore to rely on memory only.

I began with walking myself, and getting various friends to walk, with eyes shut in a grass field. We all walked with amazing crookedness in paths which were not far removed from circles. I myself and Mr. Galton on the first trial described circles of not more than fifty yards in diameter, although we thought we were going straight, and afterwards I was generally unable to impose a sufficiently strong conscious bias in one direction to annul the unconscious bias in the other. I believe we all diverged to the right excepting one of us who was strongly left-handed.

I then got eight village schoolboys, from ten to twelve years of age, and offered a shilling to the boy who should walk straightest blindfold. Before the contest, however, I dusted some sawdust on the ground, and after making each of the boys walk over it, measured their strides from right to left and left to right. They were also made to hop, and the foot on which they hopped was noted; they were then made to jump over a stick, and the foot from which they sprang was entered; lastly, they were instructed to throw a stone, and the hand with which they threw was noted. Each of these tests was applied twice over.

I think they were all right-handed in throwing a stone, but I believe that two of them exhibited some mark of being partly left-handed. The six who were totally right-handed strode longer from left to right than from right to left, hopped on the left leg, and rose in jumping from that leg. One boy pursued the opposite course, and the last walked irregularly, but with no average difference between his strides. When told to hop, he hopped on one leg, and in the repetition on the other, and I could not clearly make up my mind which leg he used most in jumping. When I took them into the field, I made the boys successively take a good look at a stick at about forty yards distance, and then blindfolded them, and started them to walk, guiding them straight for the first three or four paces. The result was that the left-legged boys all diverged to the right, the right-legged boys diverged to the left, and the one who would not reveal himself won the prize. The trial was repeated a second time with closely similar results, although the prize-winner did not walk nearly so straight on a second trial.

I also measured the strides of myself and of some of my friends, and found the same connection between divergence and comparative length of stride. My own step from left to right is about a quarter of an inch longer than from right to left, and I am strongly right-handed.

Comment on these experiments seems needless, and they entirely confirm Mr. Larden in his view.

It seems to be generally held that right-leggedness is commoner than the reverse; this I maintain to be incorrect. I believe that nine out of ten strongly right-handed persons are left-legged. Every active effort with the right hand is almost necessarily accompanied by an effort with the left leg, and a right-handed man is almost compelled to use his left leg more than the other. I believe that Sir Charles Bell considered that men were generally right-legged, and sought to derive the custom of mounting a horse from the left side from the fact that the right leg is stronger than the other. I suggest as almost certain that we mount on that side because the long sword is necessarily worn on the left, and would get between our legs if we went to the off-side of the horse. Some of your readers may perhaps be able to tell us whether the Chinese do not wear their short swords on the right and mount their horses from the right.

I will not hazard a conjecture as to why the rule of the road in Great Britain, and inside of the towns of Florence and of Salzburg (?), is different from that adopted by the rest of the world. For an armed horseman the English rule is, I presume, more advantageous, both for attack and defence.

January 20 G. H. DARWIN

THE question whether a man will walk to the right or left in a mist, in darkness, or if blindfolded, has led to no little controversy and dispute. Almost every conceivable reason has had its advocates for the fact that some men persistently turn to the left, and others to the right, when walking without the aid of sight. I am familiar with some ambidextrous men, and about the same number of left-handed men, but I cannot recall a single instance of a left-legged man, and think they must be somewhat rare. In the present question it might, perhaps, be well to put aside peculiarities of the arms—as occupation and education enter very largely into the method of their use—and confine observations to the legs alone. Mr. Larden has, I think, very nearly arrived at the solution of the problem with his definition of right or left strong-legged men circling to the right or left respectively. I take exception, however, to his referring the peculiarity to the *strength* of the limb, and think the following suggestion may afford help in the matter, being founded upon observations, and providing a reason for circling in walking in either right- or left-legged men :—It has been frequently remarked of late years that short-leggedness on one side or the other is of common occurrence—the cause is doubtless attributable to a retardation in the growth of the limb caused by one or more of the many illnesses to which we are subject in the earlier years of our life. Excepting when the retardation in the growth of the limb is considerable, it produces no inconvenience, and the possessor of a limb shorter than its fellow by some tenths of an inch may never be aware of the deficiency. To apply this fact to the question (it is another matter why the left leg is more frequently the short one), Mr. Larden's strong leg should correspond to my long leg. The long leg makes a longer step in proportion to the difference in its length over its fellow. If the right be the longer leg, as is oftener the case, the walker will circle to the left, and *vice versâ*. In my experiments I fixed a drawing-pin into the sole of each boot, selected a hard, level, untrodden piece of sand on the sea-shore, about 250 yards in length, and used a measuring-tape which would take ten or twenty paces in one measurement for obtaining the difference in length of the paces; the drawing-pins afford a definite and precise mark in the sand. To insure a good and regular start I always allowed my man a few yards start with his eyes open and fixed on the distant mark. He then, without stopping, put over his head and face a cardboard cylinder open at the top. This allows the eyes to be open, whilst effectually preventing any lateral vision. I think this, small detail as it is, important, as a bandage tied round the head across the eyes is sometimes unpleasant and often confusing.

97, Adelaide Road THOS. HAWKSLEY

Diffusion of Scientific Memoirs

PROF. TAIT's letter in your issue of December 27 (p. 196) raises two questions of interest to the Cambridge Philosophical Society. Prof. Tait states that during the last thirty years he has received very few of the publications of the Society. I cannot find from the records of the Society that Prof. Tait has ever expressed the wish to have the publications sent to him. The Cambridge Philosophical Society, like the Royal Society of London, the Royal Astronomical Society, and, I believe, other scientific societies, sends its publications to all Fellows who claim them within a reasonable time from the date of issue. Any Fellow requesting that *all publications* may in the future be sent to him receives them as they appear. The second point is the free distribution of copies. I find that at the present date the *Transactions* or *Proceedings* of the Society, or both, are sent either gratis or in exchange for other publications to the following number of centres:—

Home		Foreign	
London	16	Germany	22
Rest of England	16	France	9
Scotland	8	United States	12
Ireland	6	British Colonies	8
		Other foreign countries	23
Total	46	Total	74

Honorary Fellows... ... ... about 40
Total number distributed ... ... ,, 160

Of this 160 about 40 have been added since the year 1869.

In Edinburgh at present there are three centres receiving the publications of the Society. I doubt very greatly if there are many societies which do as much as the Cambridge Philosophical Society towards spreading their publications.

R. T. GLAZEBROOK,
Secretary Cambridge Philosophical Society

Cambridge, January 19

Recent Low Temperatures in America

ON or about December 19 some very low temperatures are reported to have been registered in Manitoba. At Emerson, in lat. 49°, a cold of 46° below zero, and in Dakota (United States) −49° are recorded.

I do not presume to say that these temperatures are incorrectly given, but they must be received with some distrust, arising from possible, I may almost say probable, defect in the thermometers used.

These sources of error are two, and by no means uncommon. First, the construction of the instrument may be defective. Second, it is not unusual during the heat of summer for a portion of the spirit to become vaporised, and afterwards condensed in the upper end of the tube. If the spirit is colourless, and if the detached fluid extends down to the metal band which keeps the tube in its place, the error, which may amount to 8° or more, is not readily noticed, unless specially looked for. I had several examples of this error in thermometers used by me in Canada, and one not long ago at the house of an English gentleman, who had perfect faith in the correctness of his thermometer.

Of the errors arising from defective construction there were two notable examples among some twenty thermometers which were tested by freezing mercury at Great Bear Lake in the winter of 1848–49. Eighteen of these thermometers agreed very closely with each other, indicating −36°·5, or about 2° too high. Two others, beautifully finished, and made by a London maker of high repute, showed at the same time, and under similar circumstances, 57° below zero, or about 19° of error.

JOHN RAE

Meteors—Unpublished Notes of November 30, &c.

ON November 30, at 8.27 p.m., a large meteor passed from Dubhe, in the Plough, through the lower part of Auriga, exploding in sparkling reddish light; and at 9 another described nearly the same line, but without explosion. The latter left a very vivid bluish light in its path, which lasted about ten seconds. At 10.55 a very large meteor dropped right down from Psi Ursæ Majoris, and disappeared in a black cloud a few degrees above the horizon. At 11.10 one sped rapidly from Beta Ursæ Minoris through between Epsilon and Zeta (Mizar) Ursæ Majoris, and exploded in very brilliant white light. At 11.20 one proceeded from a point about 1° below Benetnasch, and disappeared in the right shoulder of Hercules without explosion. At 11.25 one blazed out from a point 2° above Etanin, and disappeared near Beta Cygni. At 11.30 a large and brilliant but a transient meteor went from Omicron Ursæ Majoris, and disappeared in the tail of the Dragon. At 11.35 one dashed out from a point about 1° above Pi Ursæ Majoris, and I thought that it would go through Merak, but just before it reached Merak it curved suddenly from it and exploded. About 12 a number of small ones were seen. December 1—Meteors seen at 0·13 a.m., 0.18, 1.12, 1.23, 1.45, 3.30, 3.40, 4, 4.23, 4.40, 4.55, 5.7, 5.10, 5.18. December 4—At 2.15 a.m., 2.20, 2.25, 2.28; and a number of meteors were observed between 5 and 6 p.m. December 5—A goodly number of meteors seen from 1 a.m. to 6, and from 8 p.m. to 10. December 6—1.12 a.m., 1.15, 1.22, 2.10, 2.30, 3.40, 5.21, 5.25. December 7—Three meteors seen. December 8, 9, 10, and 12—Only a few meteors were observed here; and from the unfavourable state of the weather, not a meteor could I manage to see since. I have ascertained the paths of all the above meteors, but to give them all would encroach too much on your space. I will supply particulars if required. On November 30 and December 1 last there was a brilliant display of meteors. A few Leonids, Leo Minorids, Taurids, and Geminids were seen. Six Andromedes made their appearance from December 4 to 8. On December 8 a beautiful bolide rushed through the clouds from south-west to south-east, at 6 p.m. Not a star in that part of the heavens could be seen at the time, but the moon shone dimly a little to the left of it. The point at which it appeared was a few degrees higher than the moon, and it disappeared a few degrees above the earth. It blazed in and out three different times on its way through the black clouds, and a little before the end of its journey it swelled out into a huge magnificent ball of red fire, and by its explosion it illumined the western heavens and earth with its bright crimson light. A few of the spectators were alarmed at the unusual apparition. No intonation. Left in its wake a red belt of fire. The light of most of the meteors was blue, or the colour of electric light. A number of the meteors curved suddenly round just before disappearing. Numbers of meteors were seen dropping into black clouds, others seen dropping out of them down to the horizon.

Mossvale, Paisley, January 14 DONALD CAMERON

BRITISH APHIDES[1]

ENTOMOLOGISTS are fond of attaching themselves to some special group of insects—bees, beetles, or butterflies; but there are very few, we believe, who take an interest in collecting the winged or wingless forms of the Aphides. One is very apt to overlook the value of the work of a mere collector, but it comes home to us when amid a group so large, and so important from an economic point of view, as this of the plant lice is, we find only some half a dozen of our British naturalists collecting specimens of the species or making observations on the marvellously strange habits of their heterogeneous forms. Under these circumstances it was most fortunate that a society like the Ray Society was in existence, for the number of those interested in the subject of the history of British Aphides would have been too miserably small to have justified any publisher, no matter how energetic, from publishing an account of these insects; but, thanks to the Ray Society, we have, as the works published by them for their subscribers for the years 1875, 1877, 1880, and 1883, four handsome octavo volumes by Mr. G. Bowdler Buckton, F.R.S., which seem well entitled to their designation of a "Monograph of the British Aphides." These volumes, besides the text, contain over 140 plates, of which ten are devoted to anatomical details, and the rest to coloured portraits of the species both in their immature and various mature forms, and in some few instances there are representations of the various parasites which feed on them. It is to be specially noted that these figures are both drawn and lithographed by the author, and certainly a more interesting series of life-like figures of Aphides is nowhere to be found.

While it seems true that the Aphides are not general favourites of the collector, it is also true that no group of insects has attracted more attention. For nearly a century and a half the mysteries of their growth and development have been laboriously inquired into, and the researches of Réaumur and Charles Bonnet in the eighteenth, and those of Huxley in this our nineteeth century, have not exhausted all the marvels of these strange forms. Their history makes them in many ways attractive. Thus, to those interested in the details of embryology, these Aphides present questions for solution of the greatest importance, and concerning which there is still no absolutely settled opinion. Even the brilliant investigations as to this branch of the subject by Huxley still left work to be done. To the general naturalist they present a source for abundant study—not only their varied and often strange forms, but their curious habitations and the defences which they seem to have against hosts of different insect foes; while to the practical economist they have an immense interest when he thinks that by their success in the struggle for life they cause distress to human nations, often bringing about decrease in the amount of our food material and an increase in the amount of our taxation. To name the Hop Fly or the Vine Aphis is to at once illustrate our meaning.

It is not our intention to write a criticism on Mr. Buckton's learned monograph; it pleases us better to introduce it to our readers as a scientific work full of many easily read and wonderful histories of our native species of plant lice—one that the reader will not lay down in a hurry when he once takes it up; one in which, open where he will, he shall find something in it to interest and attract him. In order that we may in some measure prove this we will give a brief sketch of the chief subject-matter of these volumes. Passing over the disquisition as to the origin and meaning of the word "aphis," we have a general history of the group; included under this heading we find a sketch of their anatomy, an account of the most noteworthy contributions to their history by the early writers, and a sketch of what is known as to their metamorphoses and their very strange reproduction. This is followed by the classificatory portion, in which full diagnoses are given of the genera and species.

Mr. Buckton would account for the want of activity in our entomologists in their study of this group by the confusion into which the group has fallen with reference to its synonomy. One species of Aphis possesses no less than thirty synonyms, while in another case the same name has been given to no less than six different species of the group. There is this further difficulty in their study, that the distinctive characters are far less marked than in most other insects. As to colour, not only are the young sometimes in this respect quite unlike their parents, but their hues vary with the hour, and even the adult forms may undergo as great a change in their tints as the autumn leaves amongst which they nestle.

The family itself belongs to the order of the Hemiptera and to the sub-order Homoptera, where it is located between the families Coccidæ and Psyllidæ. Among the anatomical peculiarities it may be noted that the winged forms are provided with no less than three different kinds of eyes—ocelli, compound eyes, and supplementary eyes. The larvæ of some have eyes; in others the eyes are quite rudimentary; while in some subterranean forms they are absent. Though all the winged forms have ocelli, yet their nocturnal habits are not marked. All the Aphides are suctorial in their habits; as the source of their food varies so does the structure of the mouth parts, especially the rostrum and setæ. In *Stomaphis quercis*, feeding in the alburnum of the oak, the rostrum is nearly twice the length of the insect, and the setæ are much longer; and in the genera Lachnus and Schizoneura, in the young forms, the rostrum projects beyond the end of the abdomen, and is carried as if it were the tail of the insect; while in the young of *Chermes laricis* the lông and delicate setæ are coiled into a spiral, which would seem to act as a kind of spring cable by which the insect moors itself so to its feeding ground that it is not easily dislodged by the rough winds of early spring as they play among the larch branches. The punctures are not made by the rostrum, which seems only to act as a sheath, but by the setæ, which can be seen to lance open a number of the parenchymatous cells, and so cause a plentiful flow of cell-contents.

On the question as to the function of the cornicles, the author does not agree with Kaltenbach that they are organs connected with the respiratory apparatus, but rather regards them as the external terminations of excretory ducts. As to honey-dew, the remarks of Kirby and Spence, ascribing it to a secretion of Aphides, is accepted as true by almost all who have written on the subject—including the author—though others, among whom may be mentioned Liebig, Sir J. Hooker (1873), Boussingault (1872), still combat this view.

The chapter on the bibliography begins by alluding to the work of the celebrated anatomist and philosophical lens grinder, Leuwenhoek, in 1690, glances at that of Réaumur (1737), Charles Bonnet (1779), De Geer (1778); the more modern writings of Schrank, Hausmann, Burmeister, Harting, Kaltenbach, Kyber, Morren, Leuckart, von Siebold, Ratzeburg, and Koch among the Germans; Passerini among the Italians; Signoret, Balbiani and Claparède among the French writers; Newport, F. Walker, Haliday, and Huxley among the English writers on the subject.

Aphides are to be found almost everywhere throughout Britain. Some are hardy enough to thrive on the stony heaths of Scotland and Northumberland, whilst others will live almost in the reach of the spray on the sea-shore; terrestrial and aquatic plants are alike subject to their attacks. Some feed on succulent herbs, others on hard timber trees; others again on the roots of flowering plants. Sometimes the white water lily (*Nymphæa alba*) is almost destroyed by the myriads of *Rhopalosiphum nymphææ* which crowd on its leaves and flowers. While certain trees and shrubs appear to be attacked exclusively by their own peculiar Aphis, other trees give nourishment indiscriminately to numerous species. Thus the oak is attacked by at least six, the willow and birch by eight, and the conifers by the same number. Some families of plants are free or almost free from them, such as the Gentian and Irid families. But one species of the large group of the ferns is as yet known to be attacked by them; indeed the cryptogams are as a general rule very free from Aphides; but we have known a species of Marsilea to swarm with them.

---

[1] "Monograph of the British Aphides." By George Bowdler Buckton, F.R.S., &c. Four volumes; being the volumes issued by the Ray Society of London to their subscribers for the years 1875, 1877, 1880 and 1883.

The migration of the Aphides is still involved in some mystery, and we seem to have as yet no certain knowledge of the winter habitats of numerous species which seem to occur only during a few weeks of midsummer, such as *Siphonophora millefolii*, which may be found from July to September, and then entirely eludes our notice for the rest of the year.

The peculiar habits of the species opens an immensely interesting subject: some are almost sedentary, others are fairly active; some form receptacles which strangely mimic fruits; some if disturbed drop to the ground, others run to the opposite side of a leaf or twig; some throw up their hind legs when alarmed, which action gives a signal to the rest of the colony, which responds by going through the same performance; some assimilate their colours to their food plants, so as to be difficult to perceive. An interesting phenomenon in connection with these insects is their dimorphism. Thus the early spring form of *Chermes laricis* is different from that of all her progeny till the last, and the same is the case with *Aphis mali*. These variations often relate to size and colour, but often also to considerable change in form and modification of parts. The most extraordinary instance occurs in *Chaitophorus aceris*, "the early spring forms of which occasionally are so diverse that they have been described as belonging to not only different genera but even to distinct families. Thus Mr. Thornton, the original discoverer of this strange insect, gives it the name of *Phyllophorus testudinatus*; afterwards Mr. L. Clark called it *Chelymorpha testudo*, placing it between the Aphididæ and the Coccidæ." But a nearly equally striking example occurs in the dreaded *Phylloxera vitis*, which has two entirely different habits of life and form. In one it is active and winged; in the other it is apterous and subterranean.

We would have liked more ample information as to the geographical distribution of the group. We read that "it is confined to the more temperate regions of the globe," and "that as we approach the tropics it appears to give way to such forms as Coccus." Over the whole continent of Europe they are spread, and across Europe into the Amur district of China. They abound in North America; seem not to be indigenous in New Zealand, though in this country, according to Prof. Hutton, imported species were often very destructive to the crops; and nothing is said as to their occurrence in Australia or the Cape of Good Hope district.

Mr. Buckton divides the family into four sub-families: Aphidinæ, Schizoneurinæ, Pemphaginæ, and Chermesinæ.

Volume i. is taken up with an account of the first half-dozen genera of the first sub-family, and is illustrated with three plates of anatomical details, and forty-two coloured plates of species. Among the more familiar species whose life-histories are given are the Rose Aphis (*Siphonophora rosæ*), the Wheat Aphis (*S. granaria*), the destructive Hop Fly (*Phorodon humuli*), the Cherry Aphis (*Myzus cerasi*), and the Peach Aphis (*M. persicæ*), this last one of the most beautifully coloured of our native species.

Volume ii., with forty-eight plates, concludes the descriptive details of the genera and species of the sub-family Aphidinæ with seven-jointed antennæ, including the type-genus Aphis. Full details are given of that troublesome insect *Rhopalosiphum dianthe*, the *Aphis vastator* of Smee, which feeds on almost every cultivated plant, often swarming on the potato, turnips, pinks, not to mention hyacinths, tulips, and oleanders, but which the author agrees has nothing to do with the production of either the potato disease or clubbing in crucifers. Forty-five species of the genus Aphis are enumerated, and a very useful analytical table of these is appended. No less than seven synonyms are quoted to *A. rumicis*, Lin., which commits such destruction often on the bean and turnip crop, and which is not very particular as to its food plants. Seven species of the genus Chaitophorus are described, and a full account is given of the very extraordinary dimorphism existing in *C. aceris*. In this volume we have accounts of the aphidivorous Hemerobiidæ and Hymenoptera.

Volume iii., with twenty-seven plates, contains the description of the forms of the sub-family Aphidinæ with six-jointed antennæ, of the sub-family Schizoneurinæ, and of some of the forms of the sub-family Pemphiginæ. Among the more familiar species we have here the Aphis (*Pterocallis tiliæ*) which abounds on the lime tree, and so bedews it with its sweet secretion; the Beech Aphis (*Phyllaphis fagi*), so well known as often covering the leaves of the beech tree with its white cottony or rather waxy fluff; the Sallow Aphis (*Lachnus viminalis*), which sometimes swarms on our willows. The "Amerieau blight" (*Schizoneura lanigera*) on our apple trees is an introduced species, apparently from America. It appears that they descend into the soil in winter and attack the roots of the apple trees. *S. lanuginosa* is the aphis which produces the wonderful fig-like galls on the elm tree. These galls are about the size of small green figs, with a small opening at their summits; they contain thousands of the plant lice. In 1866 Mr. McLachlan, travelling in the south of France, gathered a number of these galls, which were in extreme profusion—elm trees twenty feet high being one mass of galls—with the intention of bringing them home; but they made such an awful mess from the viscid liquid in the galls, that he was compelled at last to throw them away. *Pemphigus lactucarius* is the species found living in little earth cavities in the vicinity of the roots of various plants. If a stump of lettuce be pulled up in spring, these "downy flocks" will be very often detected.

The last volume, with twenty-four plates, concludes the account of the species of Pemphiginæ, and gives descriptions of those of the sub-families Chermesinæ and Rhizobiinæ. Mr. Buckton agrees with Passerini, and retains Chermes among the Aphididæ. The Greek verse on the title-page of this volume having caught our eye, we are reminded how little the families treated of in it are the subjects of parasitism; the reason why seems obscure: with these forms the big and little fleas seem to lie down together, not causing each the other any alarm. The Fir Aphis (*Chermes abietis*) is the maker of the curious cone-like galls of the spruce, and a closely related species is often very destructive to larch plantations. Of the genus Phylloxera two native species are described, and a full account of the Vine Aphis (*P. vitis*) now introduced into our hothouses is also given. In this account we have a very interesting and important communication from that eminent entomologist, Jules Lichtenstein, in which he gives a summary of his views on the metamorphoses of the plant lice. This volume has appended to it chapters on Aphides in their economical relations to ants; on the reproduction of Aphides; on the biology and morphology of Aphides; on the antiquity of the Hemiptera, and particularly with regard to the Aphidinæ as represented in the sedimentary rocks and in amber; diagnoses of the Aphides found in amber are given, with figures; and we have also an account of those known to occur in a fossil state in America. Directions for the mounting and preservation of Aphides are given, and we find a very complete bibliography of authors who have treated about Aphides, and a very excellent general index.

In conclusion it only remains for us to congratulate the author on the very successful accomplishment of this important work, which is certain to excite an interest in this marvellous group of insects, and the Ray Society on being the medium of publishing the most beautifully illustrated work on the Aphides that has as yet appeared.

EARTHQUAKES AND BUILDINGS

A COMPLETE discussion of the effects which earthquakes produce upon buildings would form a treatise as useful as it would be interesting. Not only would it involve a discussion of the practical lessons to be derived from the actual effects of earthquakes, but it would include deductions based on our present knowledge of the nature of earthquake motion. Such knowledge is obtained from the records of seismographs.

In the following few notes I intentionally overlook this latter portion of the subject, and confine myself to a few of the more important practical conclusions respecting the effect of earthquakes on buildings, which may be of value to those whose mission it is to erect buildings in earthquake countries.

With regard to the situation of a building, it is sometimes observed that after an earthquake it is the portion of a town situated on low ground which has principally suffered, whilst adjoining portions on hills may have practically withstood the disturbance. In 1855 this was the rule governing the distribution of ruin in Tokio. The reverse, however, has been the rule in Yokohama. Speaking generally on this point it may be said that there is no universal rule,—each small area in an earthquake region having its special rule. As a site for a building, theory seems to indicate that soft earth or marshy ground, which would absorb much of the momentum communicated to it, and therefore act as a buffer between a building and a shock approaching through other strata, would prove a safe foundation. This seems also to have been an old opinion, for we read that the temple of Diana was built on the edge of a marsh to ward off the effects of earthquakes, but experience has repeatedly shown us, as in the case of Tokio and Manila, that swamp-like ground, as an earthquake palliative, has but little effect. On the other hand, hard rocky strata, where the amplitude of motion is small, but the period quick as compared with the motion in the inelastic material of the plains, has, as was markedly illustrated in 1755 at Lisbon, and in 1692 at Jamaica, proved the better foundation. Places to be avoided are the edges of cliffs, scarps, and cuttings. For emergent waves, these are free surfaces, and from their faces materials are invariably shot off, much in the same way that the last car in an uncoupled train of carriages may be shot forward by an engine bumping at the opposite end.

As foundations for a building there are two types. In one, which is the European method of building, the structure is firmly attached to the ground by beds of concrete, brick, and stone. In the other, which is illustrated in the Japanese system of building, the structure rests loosely on the upper surface of stones or boulders. As an indication of the relative value of these two forms of building, it may be mentioned that in Yokohama, in 1880, many of the European buildings were more or less shattered, whilst in the Japanese portion of the town there was no evidence of disturbance.

The houses, like the foundations, are also of two types. In the European house built to withstand earthquakes, of which there are examples in Tokio and San Francisco, and for which in America patents have been granted, we have a building of brick and cement bound together with hoop iron and numerous tie rods. A building like this, which from time to time is jerked backwards and forwards by the moving earth, to which it is secured by the firmest of foundations, is expected to resist the suddenly-applied and varying stresses to which it is exposed by the strength of its parts. This type of structure may be compared to a steel box, and if its construction involves any principle, we should call it that of strength opposing strength. Some of the buildings in Caraccas, which are low, slightly pyramidal, have flat roofs, and which are bound along their faces with iron, belong to this order. These so-called earthquake-proof buildings, with the exception of their chimneys, have certainly satisfactorily withstood small earthquakes in Japan. As to how they would withstand a disturbance like that at Casamicciola is yet problematical. Unfortunately these structures are very expensive.

The second type of building may be compared to a wicker basket. This is certainly as difficult to shake asunder as the steel box type, and at the same time is not so expensive. The Japanese house belongs to this type. It is largely used on the west coast of South America; and in Manila, since the disaster of 1880, it has rapidly been replacing the heavy stone form of structure. Briefly, it is a frame house with a light roof of shingle, felt, or iron. As put up in Japan, its stability chiefly appears to depend on the fact that it is *not* firmly attached to the earth on which it rests, and that its numerous joints admit of considerable yielding. The consequence is that, whilst the ground is rapidly moving backwards and forwards, the main portions of the building, by their inertia and the viscous yielding of their joints, remain comparatively at rest.

A house that my experience suggests as being aseismic, and at the same time cheap, would be a low frame building, with iron roof and chimneys supported by a number of slightly concave surfaces resting on segments of stone or metal spheres, these latter being in connection with the ground. Earthquake lamps, which are extinguished on being overturned, would lessen the risk of fire, while strong tables and bedsteads would form a refuge in case of sudden disturbances.

In earthquake towns the streets ought to be wide, and open spaces should be left, so that the inhabitants might readily find a refuge from falling buildings. Brick chimneys running through a wooden building, unless they have considerable play and are free from the various portions of the building, are exceedingly dangerous. In consequence of the vibrational period of the house not coinciding with that of the chimney, the former by its sudden contact with the latter when in an opposite phase of motion almost invariably causes an overthrow. In 1880 nearly every chimney in the foreign settlement in Yokohama was overthrown in this manner, and the first alarm inside the houses was created by a shower of bricks falling on beds and tables. Since this occurrence the chimneys in Yokohama have had more or less play given to them where they pass through the roofs.

Chimneys with heavy tops, like heavy roofs, must be avoided. Another point requiring attention is the pitch of a roof. If this is too great, tiles or slates will be readily shot off. Archways over openings should curve into their abutments, otherwise, if they meet them at an angle, fractures are likely to be produced.

If for architectural reasons, or as a precaution against fire, it is necessary to have buildings which are substantial, their upper portions ought to be as light as is consistent with the requisite strength. Hollow bricks, light tiles, with *papier-maché* for internal decorations, have been recommended as materials suitable for superstructures. At the present time the city of Manila, partly through Government interference, and partly through the desire of the inhabitants to reduce the chances of farther disasters, presents a singular appearance of light superstructures rising from old foundations. Iron roofs are visible in all directions, whilst on the massive basements of old cathedrals and churches upper stories of wood, with cupolas and spires of corrugated iron, have been erected.

Although the suggestions embodied in the above notes are few in number, it is hoped that they may be of some practical value. Without extending them, they show us that, even though we may not be in the position to escape from earthquakes by forewarning ourselves of their approach, we can at least mitigate the effects of these disasters by proper construction. JOHN MILNE

Tokio

THE LATE ERUPTION OF VESUVIUS

OUR visit to the crater of Vesuvius on January 11, 1884, was a most interesting one. In my former letter I gave the rough details of this new eruption as well as could be ascertained from the base of the cone. The lava that issued on Tuesday night continued to flow till Wednesday evening, but seemed to have arrested its progress about 10 o'clock that night, when I was in the Atrio del Cavallo. This stream proved to have welled out at the base of the little cone of eruption and to have flowed across the solid lava plain in the crater of 1872, and then to have poured down the north-north-west slope of the cone till it reached the Atrio, across which it extended but little. Within the crater of 1872 we have a somewhat convex plain of lava, which is continuous with, or, more properly, overlaps, the crater edges, except for a short distance on the south-south-west side. The north-east part of this is covered by the remnants of the crater of January, 1882. Within this were a series of crater rings that have since filled up to a certain extent the cavity of 1882. For some time the vent has travelled south, so that the present cone of eruption overlaps the crater ring of January, 1882, on its south side, whereas there is a deep crescentic fossa between the present cone and the north crater ring of two years since. The vent was giving forth great volumes of vapour, and there was an almost continuous fountain of fragments of molten lava, which often attained the height of one or two hundred yards. As a consequence much filamentous lava, often as fine as cotton, was raining around the crater, and as we sat there eating our lunch, it was so covered with these rock fragments, that it required a long climb on foot to make such a gritty meal palatable. The ejectamenta are composed solely of lava in detached pieces, ejected in a plastic state with a few bombs, consisting of older solid lava fragments partially fused and rounded on the surface, which is varnished irregularly by the fluid magma that enveloped them. This indicates that the lava is very near the top of the chimney, which must be full, as it has been for some time. Photography was no easy matter amidst this fiery bombardment, for such was the abundance of the ejectamenta that we could see how rapidly the cone of the eruption was growing. I made a rough calculation of the quantity of new material expelled, and I think six cartloads in four seconds as quite a fair estimate. The lava that had flowed was solid and cold enough to allow my dog to cross it with ease, though through a few cracks it was seen to be still incandescent, and a green staff thrust in immediately blazed. The lava that was flowing in the direction of Pompeii is still doing so in one or two points, apparently at the same rate and place as two weeks since.

Altogether this eruption seems to be of very little importance, and during the last four years there have been many similar ones. Prof. Palmieri, in the *Corriere del Mattino* of January 11, prophesies a great eruption, but on what grounds it seems difficult to make out. No one would deny that such could occur and is not improbable; but there seems to be no more reason now than two months since.

The smoke or vapour yesterday had, when seen by reflected light, the same colour as usual, namely, a salmon tint. The sky was very clear, and I looked at the sun through this vapour, bearing in mind the recent remarkable sunsets and green suns. The transmitted light ranged from a *burnt sienna* brown to a dirty orange, having much the same colour as when we look through a dark London fog. I noticed that the light that traversed the vapour column and fell on the opposite escarpment of Monte Somma was of a colour that would be obtained by mixing a mauve with about equal quantities of brown.

Naples, January 13 H. J. JOHNSTON-LAVIS

THE EGYPTIAN SUDAN AND ITS INHABITANTS

AS some degree of vagueness seems still attached to the term Sudan, it may be well to state at once that it is simply the Arabic equivalent of the older and more intelligible expressions, Nigritia, Negroland, which have in recent times somewhat unaccountably dropped out of use. In its widest sense it comprises the more or less fertile zone lying between the Atlantic on the one hand and the Red Sea and Abyssinian Highlands on the other, and stretching from the Sahara and Egypt Proper southwards to the Gulf of Guinea, the still unexplored Central Equatorial regions, and further east to Lakes Albert and Victoria Nyanza. This vast tract, which may on the whole be regarded as the true domain of the African Negro race, is commonly and conveniently divided into three great sections:—(1) *Western Sudan*, comprising roughly the basins of the Senegal and Quorra-Binue (Niger) with all the intervening lands draining to the Atlantic; (2) *Central Sudan*, comprising the basins of the Komadugu and Shari with all the lands (Kanem, Bornu, Baghirmi, Wadai) draining to Lake Chad; (3) *Eastern Sudan*, comprising everything east of Wadai, that is mainly the Upper and Middle Nile basin.

Politically, this third section, with which alone we are here concerned, has for some years formed part of the Khedive's possessions, hence is now more generally known as *Egyptian Sudan*. Until 1882 it formed a single administrative division under a Governor-General resident at Khartum. But in that year a sort of Colonial Office was created for this region, which was placed under a Cabinet Minister and broken up into four separate departments or divisions, each under a Hukumdar, or Governor-General, directly responsible to the Minister for Sudan at Cairo. The various provinces hitherto forming the single administration of Egyptian Sudan thus became distributed as under:—

WEST SUDAN, comprising Darfur, Kordofan, Bahr-el-Ghazal, and Dongola, with capital Fasher.

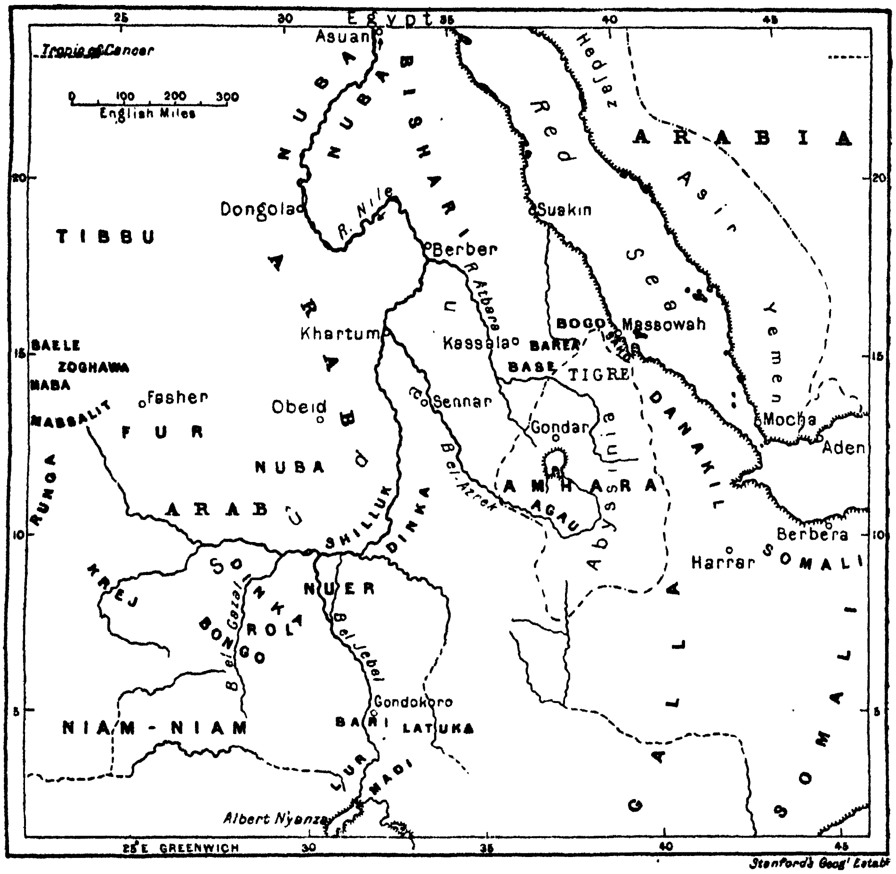
CENTRAL SUDAN, comprising Khartum, Senaar, Berber, Fashoda, and the Equator (Hat-el-Istwa), with capital Khartum.

EAST SUDAN, comprising Taka, Suakin, and Massowah, with capital Massowah.

HARRAR, comprising Zeyla, Berbera, and Harrar, with capital Harrar.

The complete development of this scheme has been somewhat rudely interrupted by the successful revolt of the "Mahdi," who has for the moment wrested the greater part of the country from Egyptian control. But should this arrangement be carried out after the restoration of order, a further element of confusion will be introduced into African geographical nomenclature, for we shall then have three political subdivisions of Egyptian Sudan bearing the same names as the three above described physical subdivisions of the whole region.

These however are matters of detail, with which statesmen do not usually concern themselves, and apart from the terminology the projected arrangement in this instance really recommends itself both on geographical and ethnological grounds. Thus the provinces of Darfur, Kordofan, and Dongola, forming the bulk of "Central Sudan," present a certain physical uniformity in the somewhat steppe-like character of the land, destitute of forest timber and covered mostly with prickly grass, scrub, gum trees, mimosas, and other thorny plants. It is intersected by no large streams, and generally open except towards the west, where the Marrah range forms a water-parting between the few rivers and intermittent torrents flowing south-east to the Nile and south-west through the Bahr-es-Salamat to the Shari. The inhabitants also are of a somewhat homogeneous character, the aborigines belonging mainly to the old Nuba stock almost everywhere interspersed with nomad and slave-hunting Arab tribes. This region communicates with the Nile through two historical caravan routes, one running from El Obeid north-north-east to Khartum, the other from Fasher north-east to El Dabbeh above Old Dongola. Through these outlets the produce of the land—gums, ivory, ostrich-feathers, and slaves—have for ages been forwarded down the Nile to Egypt, the natural emporium of East Central Africa.



Stanford's Geog' Estabt

Ethnological Map of the Eastern Sudan.

The Nile itself imparts a distinct geographical unity to the more fertile and better watered provinces of Khartum, Senaar, Berber, Fashoda, and the Equator, forming the second division of "Central Sudan." Here the great artery forms a broad, somewhat sluggish stream, often choked with "sudd," or floating masses of tangled vegetable matter, but nevertheless generally navigable from the confluence of the White and Blue Niles at Khartum nearly to Lake Albert Nyanza. The Bahr-el-Jebel, as its upper course is called from the lake to the Sobat junction, is thickly peopled on both sides and along the tributary valleys by numerous tribes and even great nations (Dinka, Shilluk, Mittu, &c.) of pure Negro and Negroid stock. Lower down the White Nile, that is, the section from the Sobat to the Azrek confluence, is held mainly by intruding "Baggara" and other cattle-breeding Arab tribes, interspersed with isolated groups of Nuba, Funj, and other peoples now mostly assimilated to them in speech, usages, and religion.

Although more varied in aspect, the third division of "Eastern Sudan" enjoys a certain unity at least in its outlines, its three provinces of Suakin, Taka, and Massowah being comprised between the middle course of the Nile and the Red Sea, and stretching from the Egyptian frontier southwards to Abyssinia. Here the main stream from Khartum to Asuan (Syene), where it enters Egypt, is essentially a mountain torrent, describing great bends to the right and left while forcing its way over six cataracts and other obstacles through the sandstone and granitic ridges intersecting the Nubian wilderness on the

RACE	MAIN DIVISIONS	LOCALITY	REMARKS
HAMITE	*Tibbu*: Baele; Zoghawa; Wanyanga	N. and N.W. Darfur	*Hamite* is here equivalent to the *Kushite* of some writers; but is taken in a wider sense, answering to the African Division of the Mediterranean or Caucasic anthropological type of mankind. For the removal of the Tibbu from the Negro to this connection, see NATURE, March 1, 1883 ("North African Ethnology"). Most of these are zealous Muhammadans.
	Bishari (Beja) Hadendoa; Hallenga; Ababdeh; Beni-Amer	Between Red Sea and Nile, 15°–25° N.	
	Danakil: Adaiel; Dahimela, &c.	Between Abyssinia and the coast, 10°–15° N.	
	Saho; Bogos; Habab	Massowah district	
	Somali: Idur; Isa; Mijarten, &c.	Gulf of Aden Coast	
	Galla (Orma) Yeju; Wollo; Mecha, &c.	E. and S. of Gojam	
SEMITE	*Arab* Kababish; Sheygieh; Robabat, &c.	W. from Nile between Dongola and Khartum	The *Arab Semites* are recent intruders, mainly *viâ* Isthmus of Suez and Egypt; the *Himyarites* are intruders from prehistoric times from South Arabia *viâ* Strait of Bab-el-Mandeb. The former are all fierce Muhammadans, the latter mostly monophysite Christians.
	Homran; Rekhabin; Alawin	Senaar	
	Homran; Hamr, El-Homr; Habanieh, &c.	Kordofan and Darfur	
	Ziaieh; Bahemid	N. Darfur	
	Himyaritic Tigré; Dembela; Lasta	N. and E. Abyssinia	
	Harrari	E. from Shoa	
NUBA	*Barabra* (mixed) Kenus; Mahasi; Dongolawi	Nile Valley from Egypt to Old Dongola	The Nubas hold an intermediate position between the Negro and Hamite; but the speech is distinctly Negro, and has no connection with the Fulah of West Sudan, as has been supposed by Fr. Müller and others. The Kordofan Nubas represent the original stock and are mainly pagans; those of the Nile are Negroid and a historical people, Christians from the sixth to the fourteenth century, since then Muhammadans of a mild type. They represent the Uaua of the Old Egyptian records, the *Nubæ* of Strabo, and the *Nubatæ* of later times.
	True Nuba Kargo; Kulfan; Kolaji Jebel Nuba; Tumali	Kordofan	
	Fur: Fur; Konjara; Fongoro, &c.	Darfur	
	Sub-Nuba Takruri	Gallibat	
	Barea; Basé (Kunama)	Taka (Mareb Valley)	
	Funj; Hamagh	Senaar	
NEGRO	*Sudanese*: Birkit; Masalit; Abu-Sarib, &c.	Darfur	Most of these Negroes have been reduced in recent years, and are still virtually pagans. Some, such as the Mittu, Krej, and Bongo, are of a red-brown rather than a black complexion, but the type is Negro, although the speech of all except the Dinka shows grammatical gender. They are very brave and fierce, but easily controlled by firmness and kindness.
	Nilotic Shilluk; Dinka; Nuer	White Nile and B. el Arab	
	Fallaugh; Kumkung; Ninak, &c.	Sobat basin	
	Krej; Bongo (Dor); Mittu (Moro)	About W. tributaries White Nile	
	Bari; Madi; Lur; Latuka	B. el Jebel, N. of Lake Albert Nyanza	
BANTU	Waganda; Wanyoro; Wasoga; Wagamba	Extreme S. frontier, N. side Lake Victoria Nyanza	The Bantus have not been reduced, although included in the Moudirié de l'Equateur of Messedaglia's official "Carte du Sudan" (Khartum, 1883).

east and the Libyan desert on the west. It is thus practically useless for navigation, and the communications with the upper provinces have to be maintained by difficult caravan routes subtended like arcs to the curves of the stream, or radiating from Berber near the Atbara confluence to Suakin on the Red Sea. But south of these dreary solitudes the Atbara basin itself, comprising parts of the Berber and Taka provinces, is a magnificent subtropical land, the flower of the Khedive's possessions, diversified with a varied succession of dense woodlands, rich pastures, and well-watered arable tracts. Hence the route traversing this region from the Nile, through Kassala to the Red Sea at Massowah, although much longer, will be found far more practicable than the more northern highway to Suakin. Like the land itself, the inhabitants of this division present a great diversity of type, the narrow valley of the Nile being occupied by Nubas from the Egyptian frontier to the Old Dongola, and thence on the left bank by Kababish Arabs to Khartum, while the whole region between the Nile and Red Sea, and from Egypt southwards to Abyssinia, is the almost exclusive domain of the great Hamitic Bishari nation. Along the northern frontier of Abyssinia these come in contact at various points with Arab, Amhara, and Tigré peoples, and in one instance even with an isolated Negroid or Nuba tribe, the Basé (Kunama) of the Khor-el-Gash (Mareb) Valley.

The fourth division of Harrar, with its three provinces of Zeyla, Berbera, and Harrar stretching along the northern verge of Somaliland eastwards to Cape Gardafui, is practically separated from the rest of Egyptian Sudan by the intervening "Empire" of Abyssinia, and will be totally severed whenever that state resumes possession of its natural outport of Massowah. It is mainly an arid strip of coastlands fringing the Red Sea and Gulf of Aden, and inclosing the recently-founded Italian and French settlements on Assab Bay and at Obokh on the Gulf of Tajurrah. With the exception of the small Amharic inclave at Harrar, the whole of this division is inhabited by peoples of Hamitic stock and speech—Saho and Danakil, between the Red Sea and Abyssinia, Idur, and other Somali tribes along the Gulf of Aden.

Egyptian Sudan thus stretches north and south across nearly twenty-four degrees of latitude from Egypt to the equator, or about 1650 miles, and west and east across twenty-two degrees of longitude from Wadai to the Red Sea at Massowah, or from 1200 to 1400. Within these limits it has a total area of at least 2,500,000 square miles, with a population that cannot be estimated at less than 12,000,000. Of these probably three-fourths are of pure or mixed Negro descent, and mostly pagans or nominal Muhammadans. The rest belong to various branches of the Semitic and Hamitic stocks, and are nearly all Muhammadans of a more or less fanatical type. In his valuable "Report on the Sudan for 1883" Lieut.-Col. Stewart remarks: "Besides the main division of the people into Arab and Negro, they are again subdivided into a number of tribes and sub-tribes, some sedentary and others nomad. Of the Negro tribes all are sedentary and cultivators, but the Arabs are for the most part nomads or wanderers, each tribe within certain well-known limits. All these Arab tribes are large owners of cattle, camels, horses, and slaves. These last, along with the Arab women, generally cultivate some fields of doora (a kind of millet) or corn, sufficient for the wants of the tribe. The Arab himself would consider it a disgrace to practise any manual labour. He is essentially a hunter, a robber, and a warrior, and, after caring for his cattle, devotes all his energies to slave-hunting and war" (p. 8).

This presents a fairly accurate picture of the natural relations of the people in all respects except as regards the main division into two ethnical groups—Arab and Negro. From what has been already stated it is obvious that this is a totally inadequate distribution. It is another and signal instance of that official ignorance or disregard of the racial conditions that has ever been such a fruitful source of political troubles and disasters in lands governed or controlled by foreign administrators. As a matter of fact, Egyptian Sudan is a region of great ethnical complexity, and so far from being occupied by Arabs and Negroes alone, there are scarcely any Arabs or Negroes at all anywhere east of the Nile between Khartum and Egypt. To designate as Arabs the tribes at present blocking the Suakin-Berber route, as is currently done, betrays a depth of ethnological ignorance analogous to that of the writer who should group Basques, for instance, and Slavs in the same category. The Arabs themselves are comparatively recent intruders, although it is possible that some, such as the Beni-Omr, now fused with the Funj and Hamagh Negroid peoples of Senaar, may have found their way across the Red Sea into the Nile basin in pre-Muhammadan times. But the Bishari tribes about Suakin are the true autochthonous element, lineal descendants of the Blemmyes and other historic peoples whose names are enrolled in Greek, Roman, and Axumite records. But these and other points will be made clear by the above synoptical table, with accompanying map, of the East Sudanese races and tribes.

Khartum, the centre of administration for all these discordant elements, has been brought within the sphere of civilisation since 1819, when it was occupied by the Egyptian troops under Ismael Pasha. At that time it was a mere outpost of the Hamagh kingdom, Senaar; but, thanks to its convenient position at the confluence of the two Niles midway between the Mediterranean and the equator, it soon rose to importance under the strong government of Mehemet Ali. Under Khurshid Pasha (1826–37) its skin and reed hovels were replaced by substantial brick houses, and at present it is by far the largest and most flourishing place in Central Africa, with a motley population of over 40,000, including the garrison troops. Here considerable quantities of goods in transit are always in deposit; here are resident many Europeans interested in the African trade, and in the more philanthropic work of African culture and exploration. Khartum has thus become inseparably associated with all the work done during the last half century towards developing the material resources of the land and raising the moral status of its inhabitants. At its mention, the names of Petherick, Beltrami, Schweinfurth, Baker, Gordon, Marno, Junker, Linant de Bellefonds, Emin Bey, Gessi, and many other heroic pioneers in the cause of African progress, are irresistibly conjured up. Such names plead silently but eloquently for its preservation to civilisation in the better sense of the word, and make us feel how great a crime against humanity would be its abandonment to barbarism and the villainous Arab slave-dealers of Central Africa.

A. H. KEANE

NOTES

WE understand that subscriptions to a memorial to the late Mr. F. Hatton are being asked for in a paper in which the name of Prof. Huxley is mentioned as one of the committee and an intending subscriber. We are authorised to state that the name of Prof. Huxley has been employed without his knowledge.

WE have received the following subscriptions on behalf of the Hermann Müller Fund:—Prof. W. H. Flower, F.R.S., 1*l.*; Mr. W. E. Hart, 1*l.*; K., 10*s*.

MR. FRANK E. BEDDARD, M.A., of the University of Oxford, Naturalist to the *Challenger* Commission, has been selected out of thirteen candidates for the post of Prosector to the Zoological Society of London, in succession to the late Mr. W. A. Forbes. Mr. Beddard was a pupil of the late Prof. Rolleston, and for the past year has been employed on editorial and other work connected with the issue of the official reports on the scientific results of the *Challenger* Expedition. He has also been intrusted with the examination and description of the *Isopoda* collected by the Expedition, and has the reputation of being a most promising and enthusiastic naturalist.

AMONG other legacies in the will of the late Sir William Siemens are 1000*l.* each to the Scientific Relief Fund of the Royal Society and the Benevolent Fund of the Institution of Civil Engineers.

THE Cunningham Medal of the Royal Irish Society was presented on the 15th inst. to Mr. John Birmingham of Tuam, for his "Contributions to the Advancement of Knowledge in Astronomy."

MR. ARCHIBALD GEIKIE, F.R.S., Director-General of the Geological Survey of the United Kingdom, will give the first of a course of five lectures on the Origin of the Scenery of the British Isles, on Tuesday next (January 29), at the Royal Institution of Great Britain.

IN January, 1883, one of the officers of the Geological Survey of Ireland, Mr. E. T. Hardman, was selected to proceed to Western Australia for the purpose of taking part in an exploration of the Kimberley district of that colony. He took the field in April last, and continued on active service in the bush until near the end of September, having in this interval travelled at least 1500 miles, and having obtained materials for a first geological sketch-map of about 12,800 square miles of country. He has determined the sequence of formations which begin with certain quartzites, schists, and other metamorphic rocks, which he classes provisionally as altered Lower Silurian, but which may be of Archæan age. These are succeeded by limestones and sandstones with gypsum, &c., which are referred to Upper Carboniferous horizons. Certain basalts and felstones occur, the age of which is uncertain. The youngest deposits are Pliocene sands, gravels, conglomerates, and marly limestones ("pindar" of the natives) overlaid by river gravels, extensive plains of alluvium, and, along the sea-coast, by raised beaches.

MR. BARNUM's so-called white elephant arrived safely last week at the Zoological Gardens from Burmah, and has already attracted many visitors. Prof. Flower, writing to the *Times*, says:—"The Burmese elephant now deposited in the Zoological

Society's Gardens, Regent's Park, is apparently not quite full grown, being between 7 feet and 8 feet in height, and has a well-formed pair of tusks about 18 inches in length. It has a remarkably long tail, the stiff bristly hairs at the end of which almost touch the ground. The ears are somewhat larger than in the ordinary Indian elephant, and are curiously jagged or festooned at the edges, whether as a natural formation or the result of early injuries it is difficult to say. It is chiefly remarkable, however, for a peculiarity of coloration which is quite unlike that of any elephant hitherto brought to this country. In this elephant the general surface of the integument is quite as dark as, if not darker than, that usually seen in its kind, being, perhaps, of rather a more bluish or slaty hue. There are, however, certain definite patches, disposed with perfect bilateral symmetry, in which the pigment is entirely absent, and the skin is of a pale reddish brown or 'flesh colour.' These patches are of various sizes, sometimes minute and clustered together, producing only an indistinct mottling of the surface, sometimes in large clear spaces, but which are mostly, especially at their edges, dotted over with circular pigmented spots of the prevailing dark colour about half an inch or more in diameter, which give a remarkable and even beautiful effect. The largest and clearest light-coloured tract is on the face, extending from the level of the eyes to the base of the trunk. . . . The animal is not a pale variety of the ordinary elephant, as some have supposed the so-called 'White Elephant' to be, but one characterised by a local deficiency of the epidermic pigment, in symmetrically disposed patches, and chiefly affecting the head and anterior parts of the body. It does not result from any disease of the skin, as has been suggested, but is doubtless an individual congenital condition or defect."

In *Cosmos les Mondes* for January 19 Prof. P. Guy describes the remarkable sunrise witnessed by him at Perpignan on January 8. From his bedroom window, looking southwards, he noticed a sudden flash, which lit up the whole room, and which was followed by a lovely pale light diffused throughout the southern sky from horizon to zenith. This was at 4 a.m., and consequently could not have been produced by the clouds reflecting the light of the moon, which had set at 2.42 a.m. The luminous matter presented a milk-white appearance, not unlike that of the Milky Way, and scarcely more intense. So transparent was it that the stars remained perfectly visible without any diminution of their brightness through the vapours which seemed to cause the effulgence. Mars and Jupiter, visible near the zenith, were encircled by a halo like that often visible round the moon. Along the southern horizon there stretched a dark band formed by clouds at an elevation of about 15°, the upper edge of which was lit up intermittently by the action of successive waves of light resembling the sheet lightning so often seen in summer. About 4.45 a.m. the light gradually faded away, after which the sky became overcast and quite dark. The local and intermittent light, Prof. Guy thinks, was obviously due to electricity, to which with less certainty may also be attributed the more general manifestation. The upper regions of the atmosphere contain a large quantity of electricity, as shown by the potential increasing with the increased altitude. To its presence are probably due such faint and phosphorescent diffusions of light as are here described, and have often been observed elsewhere.

After more than a fortnight's working without the slightest hitch of any kind, the experiment of the direct electric lighting of one of the District Railway trains between Kensington and Putney may, it is stated, be fairly looked upon as a distinct success. The fitting of the Putney train is of a rather heterogeneous character, being a collection of plant procurable without special manufacture, the whole consisting of a launch boiler, a small Willan's three-cylinder steam-engine, running at 500 revolutions, and driving direct off its own shaft, a Siemens' shunt-wound dynamo supplying current for 50 Swan 20-candle power incandescent lights. In addition there are two water-tanks, and a coal-box, the whole being placed in a separate van, and this tentative arrangement has this advantage—that by the removal of the van to other lines more extended trials can be made on longer trains, as in the present case only 30 of the lamps are employed for the actual service of the train, the remaining 20 being kept lighted in the van itself. The effect on the train is very brilliant, although the arrangements are not what are ultimately proposed—namely, to place a small high-speed engine and the dynamo on the tender and take steam from the locomotive itself, and so dispense with the attendant now required in the special van.

The fiftieth anniversary of the birth of Philipp Reis, the inventor of the telephone which bears his name, was celebrated by the Elektrotechnische Gesellschaft of Frankfort on January 7 by a special meeting in the afternoon, followed by a banquet, to which the son of the deceased inventor and a number of his surviving scientific friends and comrades were invited. A memorial discourse was pronounced by Herr Postrath Grawinkel, dwelling on the inventions of Reis and his now generally admitted claims. At the banquet a speech was made by Dr. Petersen, president of the Physical Society of Frankfort, on behalf of that body, at whose session in 1861 the telephone first saw the light. The speeches and toasts lasted till after midnight.

We mentioned last week that the Scottish Fishery Board on the recommendation of Prof. Cossar Ewart had taken steps to utilise the abundant machinery at their disposal for collecting material that will assist in solving some of the important fish problems. As a firstfruit of this organisation a splendid specimen of a torpedo was forwarded to the University of Edinburgh by the fishery officer at Wick on Saturday last. Prof. Ewart exhibited this, apparently the only torpedo ever found off the Scottish coast, at the last meeting of the Royal Physical Society of Edinburgh (January 16). After giving a short account of the torpedo group, Prof. Ewart mentioned that the specimen exhibited was taken about five miles off Lybster, that it was 28 inches in length and 19½ inches across the pectoral fins, and that it belonged to the species *hebetans*, several specimens of which have been found in the English Channel. This torpedo will in all probability be presented by the Fishery Board to the Edinburgh Museum of Science and Art.

The members of several scientific societies in the east of Scotland having had under consideration the advantages that would result from a federation of the various societies, believing that thereby the value of their scientific work would be greatly increased and their objects promoted, have determined to call a meeting of delegates from the various scientific bodies in the east of Scotland, to be held at the Perthshire Natural History Museum, Perth, on Saturday, February 9 next. At this meeting it is purposed to consider the question of federation, and how it may best be carried out, and also to adopt a constitution, and to arrange for a first general meeting. Some of the advantages of such an association are thus briefly stated:—(1) Increased value of work by having an aim in common; (2) Increased zeal amongst members by definite work being put before them; (3) Improvements in method of carrying out excursions; (4) Increased facilities for intercourse amongst members of the different societies. The idea of a federation of societies is not a new one. In England the societies of three large districts have formed associations, with excellent results; and though in Scotland no unions of a similar nature have yet been formed, the joint meetings (inaugurated by the Inverness Scientific Society) of some of the northern societies, which have taken place annually during the past two or three years, have been a step in the same direction.

THE Geographical Society at Antwerp has given a reception to the distinguished geographer, Dr. Chavanne, editor of the *Mittheilungen* of the Vienna Geographical Society. He has undertaken the task of drawing up a complete map of the Congo territory, showing the stations of the African Association. He will leave for the Congo at the beginning of next month.

THE first maps of the Algerian survey have been published and presented to the Paris Academy by Col. Perrier.

THE largest ice cavern in Carniola has lately been discovered by Prof. Linhart of Laibach, having hitherto been known only to a small circle of woodcutters and hunters. It is now called the Friedrichstein Cavern, and can be reached in about two to three hours from Gottschee. The upper aperture is large and rectangular, the back is formed by a limestone rock rising some 80 metres perpendicularly; there is also a colossal gate fringed by icicles some metres in length. The sides are very steep. The area of the cave is about 450 square metres, nearly circular in shape, the level ground being covered with ice several feet deep. Altogether the cave seems to offer one of the grandest aspects imaginable.

NEWS about the Russian expedition to Western Africa under Herr Schulz von Rogosinski was communicated at a recent meeting of the Berlin Geographical Society. The expedition has investigated the district north and east of the Cameroon Mountains, and discovered a large native settlement or town, Kumba by name, on the Mungo River east of the mountains mentioned. They intend to penetrate still further to the east. Dr. Pauli and Dr. Passavant of Basle have started also for the same districts on an exploring tour. A letter was also read, dated Ibi, September 30, in which Robert Flegel makes some official business communications.

THE additions to the Zoological Society's Gardens during the past week include a Black-handed Spider Monkey (*Ateles geoffroyi*) from Central America, presented by Mr. Colin Wm. Scott; two Yellow-bellied Liothrix (*Liothrix luteus*) from India, a Goldfinch (*Carduelis elegans*), British, presented by Mrs. Edwards; an Indian Elephant (Mottled Variety) (*Elephas indicus* ♂) from Burmah, a Slow Loris (*Nycticebus tardigradus*) from Sumatra, a Gray Ichneumon (*Herpestes griseus*) from India, deposited; a Rufous-necked Wallaby (*Halmaturus ruficollis*) from New South Wales, a Brush Bronze-wing Pigeon (*Phaps elegans*) from Australia, received on approval; an Axis Deer (*Cervus axis*), three Brown-tailed Gerbilles (*Gerbillus erythrurus*), a Babirussa (*Babirussa alfurus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

A SOUTHERN COMET.—A telegram from Melbourne addressed to Prof. Krueger of Kiel, editor of the *Astronomische Nachrichten*, notifies the discovery of a small comet on January 12 in R.A. 22h. 40m., and N.P.D. 130° 8′, and consequently in the constellation Grus. It is stated to be moving quickly to the south-east.

Possibly this comet may add to the very small number of cases where one of these bodies has been telescopically discovered in the other hemisphere, and the elements of the orbit have wholly depended upon southern observations. We can call to mind only two such instances: (1) the comet of 1824 detected by the late Carl Rümker at Parramatta, and observed there by him and by Sir Thomas Brisbane, the founder of that observatory, and Governor of the Colony. The orbit was first calculated by Rümker, and has lately been more completely investigated from the Parramatta observations by Dr. Doberck; (2) the comet of 1833, discovered by Dunlop (Rümker's successor) at Parramatta at the end of September, and observed there from October 1 to 16; orbits by Henderson, Peters, and Hartwig.

PONS' COMET.—For the convenience of readers who are observing in the southern hemisphere we subjoin an ephemeris of this comet, deduced from the provisionally corrected ellipse of MM. Schulhof and Bossert. The positions are for Greenwich mean noon:—

1884		R.A. h.	m.	s.	Decl. °	′	Log. distance from Earth	Sun

The theoretical intensity of light on February 5 is sixty-nine times that on the day of discovery; on April 17 only six times the same. Probably the comet may be discernible with the naked eye until the end of February.

Dr. G. Müller of the Astro-physical Observatory at Potsdam records a second remarkably sudden increase in the brightness of this comet. On January 1 at 5h. 47m. M.T. its appearance was very similar to that of the preceding days, the nucleus large and diffused; photometric comparisons showed that it was following pretty nearly in the calculated light-curve, and harmonised with the measures on December 29 and 30. At 7h. 20m. he was astonished at the altered aspect of the comet. In place of the previously diffused nucleus, there was now an almost stellar point, equal in brightness to a star of the seventh magnitude, so that he was at first under the impression that a bright star was seen through the comet. By comparisons with two neighbouring stars, estimated in the *Durchmusterung* 7·0 and 6·8, the following magnitudes were determined:—

	h. m.			h. m.	
At	7 28	7·53 m.	At	8 27	7·03 m.
	7 41	7·35		8 38	7·00
	7 58	6·97		9 0	7·13
	8 7	6·89		9 7	7·33

With the help of a curve the observations appeared to fix the maximum of the development of light to 8h. 12m. M.T. at Potsdam corresponding to 7h. 20m. Greenwich M.T. At 9h. 30m. the comet's aspect had again changed and resembled that presented at the previous day's observations. The whole variation amounted to about 1·3 mag. On that evening the comet's distance from the sun was 0·90, and that from the earth 0·665.

Attention will be no doubt directed in the other hemisphere to these abnormal variations in the light of the comet. It will be remembered that the first remarkable change occurred about September 22, three weeks after the discovery by Mr. Brooks, when the distance from the sun was 2·18, and from the earth 2·14.

PROFESSOR HAECKEL ON THE ORDERS OF THE RADIOLARIA[1]

II.

[THE following translation of a recent paper of mine, by Miss Nellie Maclagan, has been revised by myself.—ERNST HAECKEL.]

Systematic Survey of the 4 *Orders*, 10 *Sub-orders, and* 32 *Families of the Class Radiolaria.* (Compare the former survey of the families in my Monograph, 1862, and in "Prodromus," *l.c.* 1881).

1. Order I. ACANTHARIA, Hkl. (*Acantharia*, Hkl., 1881 = *Acanthometrcæ*, Hertwig, 1879 = *Panacantha*, Hkl., 1878).

Central capsule originally (and usually permanently) spherical; nucleus usually early divided into numerous small nuclei. Capsule membrane spherical, pierced on all sides by innumerable fine pores. Extracapsularium, a voluminous gelatinous sheath, without phæodium, usually without zooanthella. Skeleton always intracapsular, consisting of acanthine spicules, which meet in the centre of the central capsule, and pierce the membrane.

---

[1] "Separat-Abdrück aus den Sitzungsberichten der Jenaischen Gesellschaft für Medicin. und Wissenschaft." Jahrg. 1883. Sitzung. vom 16 Februar. Concluded from p. 276.

1A. Sub-order I. Acanthometræ, J. Müller, 1858. Acantharia, in which the acanthine skeleton is composed merely of radial spicules, but does not form a fenestrated shell.

Family 1. Actinelida, Hkl., 1865. Skeleton composed of a varying number of spicules, not distributed according to J. Müller's law (*Astrolophida*, *Litholophida*).

Family 2. Acanthonida, Hkl., 1881. Skeleton composed of twenty radial spicules, distributed regularly according to J. Müller's law, in five quadriradiate zones (*Acanthometrida*, *Acanthostaurida*, *Acantholonchida*).

1B. Sub-order II. Acanthophractæ, Hertwig. Acantharia, in which the skeleton is composed of twenty radial spicules regularly distributed according to J. Müller's law, and forming a fenestrated or solid shell round the central capsule by means of connected transverse processes.

Family 3. Dorataspida, Hkl., 1862. Fenestrated shell, spherical, spheroidal, or ellipsoidal, simple or double (*Phractaspida*, *Sphærocapsida*, *Phractopelmida*.

Family 4. Diploconida, H., 1862. Shell shaped like an hour-glass or a double cone, having in its axis a pair of strong spicules running in opposite directions (*Diploconus*).

2. Order II. SPUMELLARIA, Ehrenberg (= *Peripylea* + *Thalassicollea* + *Sphærozoca*, Hertwig, 1879 = *Sphærellaria* + *Collodaria* + *Polycyttaria*, Hkl., 1881).

Central capsule originally (and usually permanently) spherical, more rarely discoid or polymorphous. Nucleus usually divided only immediately before the formation of spores into a number of small nuclei. Capsule membrane simple, pierced on all sides by innumerable fine pores. Extracapsularium a voluminous gelatinous sheath, without phæodium, usually with zooxanthella. Skeleton consisting of silicium, or of a silicate, originally usually forming a central reticulate sphere, later extremely polymorphous, more rarely rudimentary or entirely wanting.

2A. Sub-order III., Collodaria, H., 1881 (*sensu ampliori*). Spumellaria without skeleton, or with a rudimentary skeleton composed mainly of detached siliceous spicules scattered outside the central capsule.

Family 5. Thalassicollida, H., 1862. Skeleton entirely wanting. Central capsules living solitary, monozoic (*Actissa*, *Thalassolampe*, *Thalassicolla*, &c.

Family 6. Collozoida, H., 1862. Skeleton entirely wanting. Central capsules social, thickly embedded in a common gelatinous body, polyzoic (*Collozoum*).

Family 7. Thalassosphærida, H., 1862. Skeleton composed of numerous detached spicules, scattered round the solitary central capsule. Monozoic (*Thalassosphæra*, *Thalassoxanthium*, &c.).

Family 8. Sphærozoida. Skeleton composed of numerous detached spicules, scattered round the social central capsules, or embedded in their common gelatinous body (*Sphærozoum*, *Rhapidozoum*).

2B. Sub-order IV. Sphærellaria, Hkl., 1881. Spumellaria having a reticulate or spongiose siliceous skeleton, forming a single connected plexus of siliceous fibre, originally evolved from a simple fenestrated sphere.

Family 9. Sphæroida (vel *Sphæridea*, H., 1879. "Protistenreich," p. 103; "Prodromus," 1881, pp. 448, 449). Skeleton either a simple fenestrated sphere, or composed of several concentric fenestrated spheres, with or without radial spicules. Central capsule solitary, monozoic. The family of Spumellaria richest in specific forms (*Monosphæria*, *Diosphæria*, *Triosphæria*, *Tetrasphæria*, *Polysphæria*, *Spongosphæria*).

Family 10. Collosphærida, H., 1862. Skeleton either simple reticulate spheres, or composed of two concentric reticulate spheres, severally inclosing the spherical, social, central capsules. Polyzoic (*Acrosphærida*, *Clathrosphærida*).

Family 11. Pylonida, Hkl., 1881 ("Prodromus," p. 463). Skeleton subspherical, ellipsoid, or polymorphous, distinguished by large fissures or gaps, which break through the originally spherical or ellipsoidal fenestrated shell, at definite points. Fenestrated shell, simple or composed concentrically, with or without spicules. Geometrical fundamental form with three unequal, equipolar axes, perpendicular one to another (*Pylocaspida*, *Pylophonnida*).

Family 12. Zygastida, Hkl., 1881. Skeleton an ellipsoidal or almost cylindrical fenestrated shell prolonged in the direction of one axis and constricted annularly in the middle, perpendicular to the said axis, often articulated by repeated annular strictures. One or two concentric, small, fenestrated shells, often inclosed in the middle. Both poles of the principal axis equal (*Artiscida*, *Cyphinida*).

Family 13. *Lithelida*, Hkl. ("Monogr. Prodrom." 1881, p. 464). Skeleton spheroidal or irregular, composed of a small, central, fenestrated sphere, and of series or heaps of chambers piled round it, sometimes spirally or axially according to definite, complicated laws, sometimes quite irregularly (*Phorticida*, *Soreumida*, *Spireumida*).

Family 14. Discoida (vel *Discidea*, Hkl., 1879, "Protistenreich," p. 103, "Prodrom." p. 456). Skeleton flattened like a disk, originally circular, lenticular, later often polymorphous by means of peripheric processes; sometimes distinctly composed of rings, sometimes spongiose (*Phæodiscida*, *Coccodiscida*, *Porodiscida*, *Spongodiscida*).

3. Order III. NASSELLARIA, Ehrenberg (= Monopylea, Hertwig, 1879; *Monopylaria*, Hkl., 1881).

Central capsule originally invariably uniaxial, oval, or conical, with two different poles of the axis; at one pole the characteristic porous area through which the whole of the pseudopodia project like a bush. Nucleus usually divided late, immediately before the formation of spores, into numerous small nuclei. Capsule membrane simple. Extracapsularium, a voluminous gelatinous sheath without phæodium, usually without zooxanthellæ. Skeleton consisting of silicium or of a silicate, originally (it is probable universally) a ring or a triradiate framework of spicules, later extremely polymorphous, usually forming a dipleuric fenestrated shell (wanting only in the simplest form, *Cystidium*).

3A. Sub-order V., Plectellaria, Hkl. Nassellaria, in which the skeleton consists of a simple siliceous ring or of a triradiate framework of spicules, usually furnished with processes forming simple or branched spicules. The branches of the latter may be united into a loose plexus, without, however, forming a chambered fenestrated shell. The skeleton is entirely wanting only in the simplest form (*Cystidium*).

Family 15. Cystidina, Hkl., nov. fam. Skeleton entirely wanting (*Cystidium*).

Family 16. Plectoida (vel *Plagonida*), Hkl., 1881. Skeleton originally composed of three spicules or siliceous rods, radiating from one point (near the mouth of the central capsule), the latter often ramifying into loose plexus (*Plagonida*, *Plectanida*).

Family 17. Stephoida (vel *Stephanida*), Hkl., 1881. Skeleton originally (?) forming a simple siliceous ring (with or without spicules), later often several connected siliceous rings or a loose plexus, not, however, developed into a regular fenestrated shell *Monostephida*, *Parastephida*, *Dyostephida*, *Triostephida*).

3*b*. Sub-order VI. Cystellaria (Hkl., 1881). Nassellaria, having a chambered (usually dipleuric) fenestrated shell, the primary foundation of which consists either of a simple ring (like the Stephoida), or of a triradiate framework (like the Plectoida), sometimes of a combination of both. Primary foundation sometimes entirely lost.

Family 18. Spyroida (vel *Sphyridina*, Ehrenberg). Skeleton dipleuric, forming a fenestrated twin-shell, the two halves of which (right and left chamber) are connected by a vertical ring, lying in the median plane. At the upper (aboral) pole of the longitudinal axis, usually an occipital apical thorn, at the lower (oral) pole an oscular network, with four (rarely three, five, or more) openings, and three (rarely more) spicules. (*Triospyrida*, *Diospyrida*, *Tetraspyrida*, *Pentaspyrida*, *Polyspyrida*, *Perispyrida*, *Pleurospyrida*) = Zygocystida.

Family 19. Botryoida (Hkl., 1881 = Polycystida, 1862). Skeleton an irregular fenestrated shell, composed of several unequal chambers, piled usually irregularly (rarely in definite order varying from that of the Cyrtida) round a primary capitulum (derivable from the twin-shell of the Spyroida), with or without spicules (*Pylobotryida*, *Cannobotryida*).

Family 20. Cyrtida, Hkl., 1862. Skeleton, dipleuric (at least originally), consisting either of a primary capitulum (derivable from the twin-shell of the Spyroida?) or (usually) of one or more chambers, joined to the oral pole of the said capitulum in the longitudinal axis. Osculum sometimes open, sometimes reticulate. Usually three radial spicules (one median and two lateral), rarely four or more spicules, or none at all (having undergone retrograde formation?). The family most rich in specific forms of all Nassellaria (*Cystocorida, Cystopilida, Cystophonnida, Cystocapsida, Cystoperida, Cystophatuida,* "Prodrom.," 1881, p. 426).

4. Order IV. PHÆODARIA, Hkl., 1879 (= *Pansolenia,* Hkl., 1878 = *Tripylea,* Hertwig, 1879).

Central capsule always uniaxial, sometimes almost spherical, sometimes lenticular or oval, always with two different poles of the axis. At one pole invariably the characteristic principal opening with radiated operculum, from which the bush of pseudopodia project through a tube; at the other pole, frequently (though not invariably) two or more accessory openings. Nucleus usually only late divided into numerous small nuclei. Capsule membrane double. Extracapsularium usually (or always ?) with zooxanthellæ distinguished by the *phæodium,* a voluminous body of pigment lying excentrically in the gelatinous sheath round the principal opening. Skeleton always extracapsular, consisting of silicium or of a silicate, usually composed of hollow tubes, polymorphous (wanting only in the most simple forms, *Phæodina,* &c.).

4A. Sub-order VII. Phæocystia, Hkl., 1879. Phæodaria, without skeleton, or with a rudimentary skeleton formed merely of detached siliceous tubes (or of reticulated pieces of silex) scattered outside the central capsule.

Family 21. Phæodinida, Hkl., 1879. Skeleton entirely wanting (*Phæodina, Phæodella*).

Family 22. Cannoraphida, Hkl., 1879. Skeleton consisting of detached hollow tubes or reticulated pieces of silex, deposited tangentially round the central capsule (*Cannoraphis, Thalassoplaneta, Dictyocha*).

Family 23. Aulacanthida, Hkl., 1862. Skeleton consisting of a superficial pallium of fine tangential tubes and a number of strong radial spicules (simple or branched) which pierce the mantle (*Aulocantha, Aulospathis, Auloraphis, Aulodendrum,* &c).

4B. Sub-order VIII. Phæogromia, Hkl., 1879. Phæodaria with a dipleuric single-chambered shell having a large opening, usually armed with one or more teeth at the basal pole; besides the primary, often several secondary openings.

Family 24. Lithogonida, Hkl., nov. fam., single-chambered dipleuric shell, with solid wall of peculiar crystalline structure, like porcelain (*Lithogromia,* Tuscarora).

Family 25. Challengerida, John Murray, 1876. Single chambered shells, varying greatly in form, with porous glass-like wall, and very fine, perfectly regular, hexagonal pores (resembling the structure of diatoms) (*Challengeria, Gazelletta, Porcupinia,* &c.).

4C. Sub-order IX. Phæosphæria, Hkl., 1879. Phæodaria having a spherical, or subspherical, fenestrated shell, usually consisting of one single, rarely of two concentric spheres; sometimes with a large principal opening, sometimes without; partly with, partly without, radial spicules. Beams of the reticulum sometimes solid, sometimes hollow.

Family 26. Castanellida, Hkl., 1879. Fenestrated shell, spherical, simple, composed of solid rods, having at one point a large principal opening (often armed with a corona of spicules), with or without radial spicules (*Castanella, Castanidium,* &c.).

Family 27. Circoporida, Hkl., 1879. Fenestrated shell, spherical, subspherical, or polyhedric, composed sometimes of reticulate plates, usually with hollow, radial spicules, always with one large, principal opening, and with several detached porous areæ (*Circoporus, Porostephanus, Porospathis,* &c.).

Family 28. Sagenida, Hkl., nov. fam. Fenestrated shell, sometimes spherical, sometimes subspherical or polymorphous, forming a spongiose plexus of solid beams, without principal opening (*Sagena, Sagenidium,* &c.).

Family 29. Aulosphærida, Hkl., 1862. Fenestrated shell, spherical, more rarely subspherical or polymorphous, composed in a peculiar fashion of hollow tubes, usually with hollow, radial spicules, without principal opening (*Aulosphæra, Auloplegma,* &c.).

Family 30. Cannosphærida, Hkl., 1879. Fenestrated shell, spherical or subspherical, double. The inner (medullar layer) composed simply of solid beams, the outer (cortical layer) of hollow tubes with radial spicules at the nodes of junction; both layers connected by hollow, radial rods (*Cannosphæra, Cælocantha,* &c.).

4D. Sub-order 10. Phæoconchia, Hkl., 1879. Phæodaria, having a bivalve fenestrated shell, composed like that of a mussel, of two convex, separate, perforated valves, with or without hollow, radial tubes.

Family 31. Concharida, Hkl., 1879. Fenestrated shell, without radial spicules, composed of two smooth, hemispherical or lenticular valves, the edges of which usually catch one another by rows of teeth (*Concharium, Conchidium, Conchopsis,* &c.).

Family 32. Cœlendrida, Hkl., 1862. Fenestrated shell composed of two hemispherical or lenticular valves, having processes in the form of large, hollow, radial spicules, usually dendritically branched at their apical, centre points or at the two poles of the transverse axis of the shell (*Cœlodendrum, Cœlothamna,* &c.).

Differential Characters of the Four Orders of Radiolaria

Holotrypasta

Radiolaria having the capsule membrane pierced on all sides.

I. ACANTHARIA.	II. SPUMELLARIA.
Central capsule originally spherical. Homaxonous.	Central capsule originally spherical. Homaxonous.
Capsule membrane pierced equally everywhere by innumerable fine pores. (*Peripylea*).	Capsule membrane pierced equally everywhere by innumerable fine pores. (*Peripylea*).
Skeleton acanthine. Zooxanthellæ usually (or invariatly ?) wanting. Without phæodium.	Skeleton siliceous. Zooxanthellæ usually present. Without phæodium.

Merotrypasta

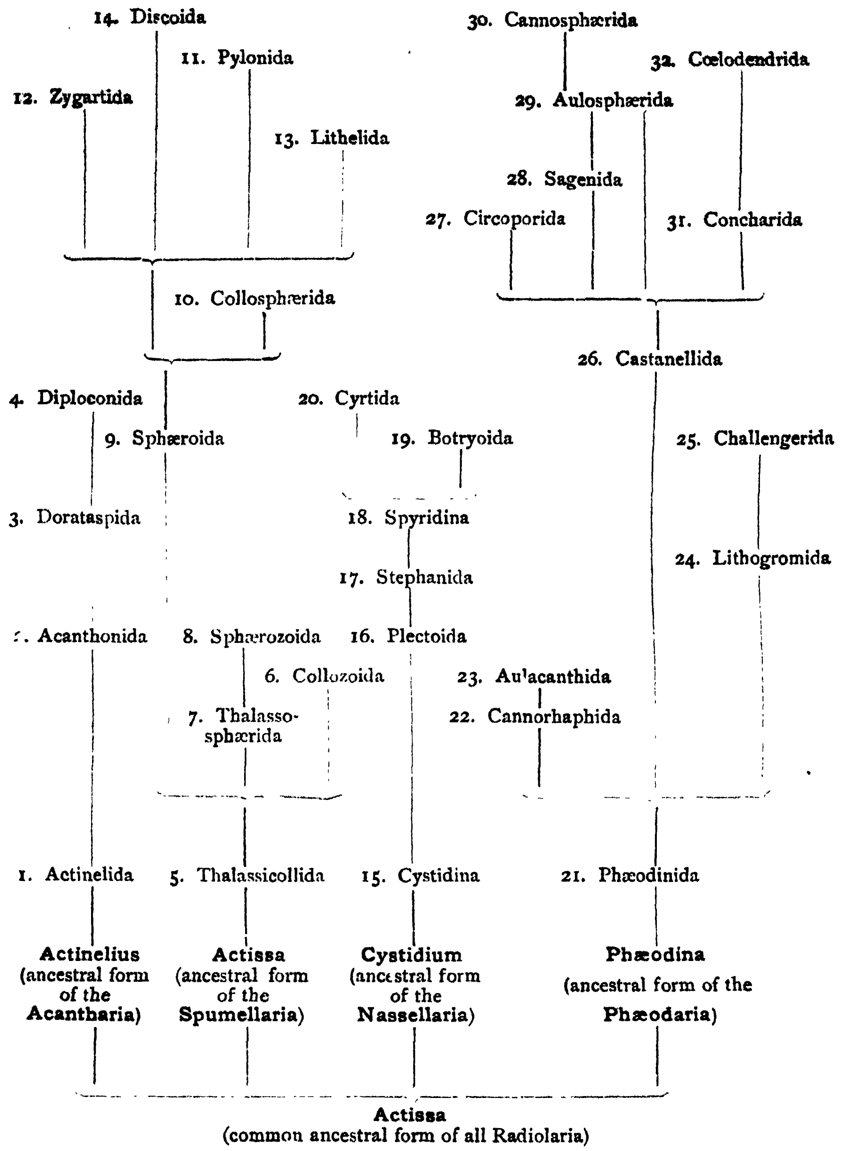
Radiolaria having the capsule membrane partially pierced.

III. NASSELLARIA.	IV. PHÆODARIA.
Central capsule oval or conical. Monaxonous.	Central capsule oval or subspherical. Monaxonous.
Capsule membrane with a single area of pores at the oral pole of the principal axis. (*Monopylea*).	Capsule membrane with a single simple principal opening and often several accessory openings. (*Tripylea*).
Skeleton siliceous. Zooxanthellæ usually present. Without phæodium.	Skeleton siliceous. Zooxanthellæ usually (or invariably ?) wanting. Always with phæodium.

Conspectus Ordinum et Familiarum Radiolarium classis

Ordines	Subordines	Familiæ	Genus typicum
I. Ordo: Acantharia Holotrypasta skeleto acanthinico	I. Acanthometra (sine testa)	1. Actinelida	Actinelius
		2. Acanthonida	Acanthonia
	II. Acanthophracta (testa completa)	3. Dorataspida	Dorataspis
		4. Diploconida	Diploconus
II. Ordo: Spumellaria Holotrypasta skeleto deficiente aut siliceo polymorpho	III. Collodaria (sine testa)	5. Thalassicollida	Actissa
		6. Collozoida	Collozoum
		7. Thalassosphærida	Physematium
		8. Sphærozoida	Sphærozoum
	IV. Sphærellaria (testa completa)	9. Sphærida	Phormosphæra
		10. Collosphærida	Collosphæra
		11. Pylonida	Tetrapyla
		12. Zygartida	Didymocyrtis
		13. Lithelida	Porodiscus
		14. Discoida	Lithelius
III. Ordo: Nassellaria Merotrypasta membrana capsulæ simplici, sine phæodio	V. Plectellaria (sine testa completa)	15. Cystidina	Cystidium
		16. Plectoida	Plagiacantha
		17. Stephanida	Lithocircus
	VI. Cyrtellaria (testa completa)	18. Spyroida	Dictyospyris
		19. Botryoida	Botryocyrtis
		20. Cyrtida	Dictyophimus
IV. Ordo: Phæodaria Merotrypasta membrana capsulæ dupplici, cum phæodio	VII. Phæocystia (sine testa)	21. Phæodinida	Phæodina
		22. Cannorhaphida	Thalassoplaneta
		23. Aulacanthida	Aulacantha
	VIII. Phæogromia (testa dipleura)	24. Lithogromida	Lithogromia
		25. Challengerida	Challengeria
	IX. Phæosphæria (testa globosa aut subglobosa)	26. Castanellida	Castanella
		27. Circoporida	Circoporus
		28. Sagenida	Sagena
		29. Aulosphærida	Aulosphæra
		30. Cannosphærida	Cannosphæra
	X. Phæoconchia (testa bivalva)	31. Concharida	Concharium
		32. Cœlodendrida	Cœlodendrum

HYPOTHETICAL ANCESTRAL TREE OF THE RADIOLARIA (1882)



UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The following courses of lectures and instruction in Natural Science will be held during the present term. In the Department of Physics Prof. Clifton lectures on "The Distribution of Potential in a Circuit," and on the Galvanometer. Mr. Heaton lectures on Elementary Mechanics. Practical instruction in Physics is given daily by Prof. Clifton and Messrs. Heaton and Walker in the Clarendon Laboratory. At Christ Church Mr. Baynes lectures on the Kinetic Theory of Gases, and gives practical instruction in magnetic and electric measurements. At Balliol Mr. Dixon lectures on Elementary Heat and Light.

In the Chemical Department Prof. Odling continues his course on the Naphthalene Compounds. The Courses on Organic and Inorganic Chemistry are continued by Dr. Watts and Mr. Fisher. At Christ Church Mr. Vernon Harcourt has a class for Quantitative Analysis.

Prof. Story-Maskelyne continues his course on Crystallography, and Prof. Prestwich concludes his course on Dynamical Geology, and lectures on Stratigraphical Geology.

In the Department of Morphology practical instruction is given by Prof. Moseley and Messrs. Robertson and Hickson on Human and Comparative Anatomy. Prof. Moseley lectures on the Comparative Anatomy of the Vertebrata, Mr. Hickson on the Elements of Animal Morphology, Mr. Jackson on Mimicry and Parasitism, Mr. Poulton on Descriptive Histology, Mr. Morgan on Odontography, and Mr. Barclay-Thompson on the Anatomy of Amphibia and Reptilia.

In the Department of Physiology (which is much cramped for room pending the erection of new buildings) Prof. Burdon Sanderson lectures on the Nervous System, while practical instruction is given by the Professor and Mr. Gotch on the Elementary Physiology of the Nervous System and of the Sense Organs, and by Mr. Dixey on Histology. At Magdalen Mr. Yule has a class for instruction in Practical Physiology.

The new Reader in Anthropology will give a course of six lectures on the Development of Civilisation and the Arts of Life.

Candidates for the Professorship of Botany are requested to send in their applications to the Registrar of the University on or before January 26. The stipend is 700*l.* a year, and a house rent free in the Botanic Garden.

New College offers an Exhibition in Natural Science (Chemistry or Biology). The examination commences May 6.

CAMBRIDGE.—The following are the principal courses in Natural Science during the present term :—

Mathematics.—Prof. Adams, Lunar Theory, commencing January 31; Mr. Turner (Under Plumian Professor), Instruction in the Use of Astronomical Instruments, January 30; Mr. Mollison, Vibrations and Sound, January 24; Mr. Stearn, Hydrodynamics, January 25; Mr. Hobson, Fourier's Series and Conduction of Heat, January 28; Mr. Thompson, Electromagnetism, January 25; Mr. Glazebrook, Wave Theory of Light, January 24; Mr. Ball, Algebra and Determinants, January 25; Dr. Besant, Analysis, January 23; Mr. Pendlebury, Analytical Optics, January 23.

Chemistry.—Prof. Liveing, General Course, January 24; Prof. Dewar, Organic Chemistry, January 28; Mr. Main, General Course, January 28; Mr. Pattison-Muir, Carbon Compounds, January 25; Non-Metals, January 26; Mr. Scott, Elementary ,Organic Chemistry, January 25; Mr. Lewis, Catechetical Lectures, January 25; Mr. Heycock, Chemical Philosophy.

Practical Chemistry.—Mr. Sell and Mr. Fenton, Demonstrations in Quantitative Analysis, January 25.

Physics.—Lord Rayleigh, Acoustics, January 26; Mr. Trotter, Electricity and Magnetism, January 24; Physical Optics, January 24; Mr. Atkinson, Heat, January 25; Mr. Glazebrook, Elementary Physics, January 25; Mr. Shaw, Elementary and Advanced Physics, Hydrostatics and Heat, January 25.

Mechanism.—Prof. Stuart, Theory of Structures, January 29; Mr. Lyon, Statics and Hydrostatics, January 29; Rigid Dynamics, January 30; Mr. Ames, Elementary Mathematics for Students of Mechanism, January 30.

Geology.—Principles of Geology and Stratigraphy (advanced), Prof. Hughes, January 24; Dynamical Geology, Mr. Roberts, January 24; Palæontology and Petrology, by Demonstrators, January 26.

Botany.—General Elementary Course, Mr. Vines, January 24; Anatomy of Plants, Mr. Gardiner, January 25; General Biology of Plants (advanced), Mr. F. Darwin, January 26; Morphological Botany, Mr. Hicks, January 26.

Zoology and Comparative Anatomy.—Geographical Distribution of the Vertebrata, by Prof. Newton, January 30; Elementary Biology, Mr. Vines and Mr. Sedgwick, January 25; Practical Morphology, Mr. Sedgwick, January 24; Morphology of Sauropsida, Mr. Gadow, January 23.

Biology.—Elementary, Mr. Vines and Mr. Sedgwick, January 25.

Anatomy and Physiology.—Osteology, Prof. Macalister, January 25; Physiology, Prof. Foster, January 24; Anatomy of the Digestive and Circulatory Organs, Prof. Macalister, January 24; Chemical Physiology, Mr. Lea, January 25; Physiology of the Circulation, Dr. Gaskell, January 24; Practical Work, Dissection, under the supervision of the Professor and Demonstrator, in the Dissecting Room.

SCIENTIFIC SERIALS

Bulletin de la Société des Naturalistes de Moscou, année 1883, No. 2.—Researches into the compounds of the acetylenes, by A P. Sabanéeff. The author has studied these imperfectly known compounds, namely, di-brom-acetylene, and the double compounds of acetylene with bromine and chlorine, and with chlorine and iodine. He has discovered a new method of preparing larger quantities of the former by acting with zinc on an alcoholic solution of the four-brom-acetylene, and describes its various reactions.—On the periodical changes of level of the ocean, by H. Trautschold (in German). The author, who already in 1869 supported the idea that the geological changes are due, not to the rise of the continents, but to the falling of the level of the ocean, finds in the disposition of the series of deposits of all ages up from the Silurian, on the plains of Russia, new and very interesting arguments for his idea. He maintains that the level of the ocean was falling from the Silurian epoch to the end of the Trias, when the seas had, around the now Russian plains, nearly the same shape as now. The level of the ocean rose, however, during the Jurassic period, retiring again about the end of the Chalk period.—On the bastard of the *Anas crecca* with *Anas boschas*, by Dr. N. Sewertsoff, with a coloured plate (in German). The most interesting bastard of the nearly two extremes of the ducks (relatively to their size) has been shot in the province of Ryazan. The Russian ornithologist describes its features at length, and adds some remarks on the bastards of the ducks generally.—Monopetal plants of Radde, by Ferd. von Herden (continued).—Description (in German) of the Veronicas, Castillejas, *Siphonostegia*, *Phtheirospermum*, and Omphalotrix.—A Mastodon tooth, note by H. Trautschold.—On the photographic photometry of fixed stars, by Ed. Lindemann (in German).—Materials for the fauna of Hemiptera of Russia, by W. Yakovleff, being a description, in Russian, of several new species.

Rivista Scientifico-Industriale, October 31.—A detailed account of the electric exhibition held in September at Lodi, by Prof. Alessandro Volta.—Programme of the anthropological section of the Italian exhibition to be held next year in Turin. Amongst other attractions there will be a large collection of typical Italian skulls of all dates and from every part of the peninsula. Materials will also be brought together for studying the history, ethnography, language, and present condition of all the foreign communities (Albanian, Greek, Catalonian, Slav, German, Rumansch, French) settled in various parts of the country.

Rendiconti del R. Istituto Lombardo di Scienze e Lettere, November 29, 1883.—On Lagrange's general expression of the force necessary to produce a tautocronous motion regarded as a function of space and velocity, by Prof. C. Formenti.—Geological notes on the Alps of the provinces of Reggio and Modena, by D. Pantanelli.—On the first traces of a national debt in the Byzantine Empire, by Z. von Lingenthal.—Unimetalism and bimetalism, by Dr. A. Villa Pernice.—Meteorological observations in the Brera Observatory, Milan, during the month of September, 1883.

Nachrichten of the Royal Society of Sciences and of the University of Göttingen, August 22, 1883.—Contributions to the study of spermatozoa and their evolution (preliminary paper), by Dr. A. von Brunn.—Researches on the action of glycol on orthophenylendiamin, orthodinitrobenzine, and sulphuric acid.

November 7.—On the meteorological relations of Göttingen, by Hugo Meyer.—Optical researches on the substance (calcareous spath) into which crystals of aragonite become decomposed under the action of heat, by C. Klein.—On the age of the iron ores at Hohenkirchen, by A. von Koenen.—On the theory of modular equations, by A. Hurwitz.—On the relations between solar and atmospheric electricity, showing how the latter is referable to the former and allied causes.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, November 22, 1883.—"Some Relations of Heat to Voltaic and Thermo-Electric Action of Metals in Electrolytes," by G. Gore, F.R.S., LL.D.

The experiments described in this paper throw considerable light upon the real cause of the voltaic current. The results of them are contained in twenty tables; and by comparing them with each other, and also by means of additional experiments, the following general conclusions and chief facts were obtained.

When metals in liquids are heated, they are more frequently rendered positive than negative in the proportion of about 2·8 to 1·0; and whilst the proportion in weak solutions was about 2·29 to 1·0, in strong ones it was about 3·27 to 1·0, and this accords with their thermo-electric behaviour as metals alone. The thermo-electric order of metals in liquids was, with nearly every solution, whether strong or weak, widely different from the thermo-electric order of the same metals alone. A conclusion previously arrived at was also confirmed, viz. that the liquids in which the hot metal was thermo-electro-positive in the largest proportion of cases were those containing highly electro-positive bases, such as the alkali metals. The thermo-electric effect of *gradually* heating a metal in a liquid was sometimes different from that of *suddenly* heating it, and was occasionally attended by a reversal of the current.

Degree of strength of liquid greatly affected the thermo-electric order of metals. Increase of strength usually and considerably increased the potential of metals thermo-electro-negative in liquids, and somewhat increased that of those positive in liquids.

The electric potential of metals, thermo-electro-positive in weak liquids, was usually about 3·87 times, and in strong ones 1·87 times, as great as of those which were negative. The potential of the strongest thermo-electric couple, viz. that of aluminium in weak solution of sodic phosphate, was ·66 volt for 100° F. difference of temperature, or about 100 times that of a bismuth and antimony couple.

Heating one of the metals, either the positive or negative, of a voltaic couple, usually increased their electric difference, making most metal more positive, and some more negative; whilst heating the second one also, usually neutralised to a large extent the effect of heating the first one. The electrical effect of heating a voltaic couple is nearly wholly composed of the united effects of heating each of the two metals separately, but is not however exactly the same, because whilst in the former case the metals are dissimilar, and are heated to the same temperature, in the latter they are similar, but heated to different temperatures. Also, when heating a voltaic pair, the heat applied to two metals, both of which are previously electro-polar by contact with each other as well as by contact with the liquid; but when heating one junction of a metal and liquid couple, the metal has not been previously rendered electro-polar by contact with a different one, and is therefore in a somewhat different state. When a voltaic combination, in which the positive metal is thermo-negative, and the negative one is thermo-positive, is heated, the electric potential of the couple diminishes, notwithstanding that the internal resistance is decreased.

Magnesium in particular, also zinc and cadmium, were greatly depressed in electromotive force in electrolytes by elevation of temperature. Reversals of position of two metals of a voltaic couple in the tension series by rise of temperature were chiefly due to one of the two metals increasing in electromotive force faster than the other, and in many cases to one metal increasing and the other decreasing in electromotive force, but only in a few cases was it a result of simultaneous but unequal diminution of potential of the two metals. With eighteen different voltaic couples, by rise of temperature from 60° to 160° F., the electromotive force in twelve cases was increased, and in six decreased, and the average proportions of increase for the eighteen instances was ·10 volt for the 100° F. of elevation.

A great difference in chemical composition of the liquid was attended by a considerable change in the order of the volta-tension series, and the differences of such order in two similar liquids, such as solutions of hydric chloride and potassic chloride, were much greater than those produced in either of those liquids by a difference of 100° F. of temperature. Difference of strength of solution, like difference of composition or of temperature, altered the order of such series with nearly every liquid; and the amount of such alteration by an increase of four or five times in the strength of the liquid was rather less than that caused by a difference of 100° F. of temperature. Whilst also a variation of strength of liquid caused only a moderate amount of change of order in the volta tension series, it produced more than three times that amount of change in the thermo-electric tension series. The usual effect of increasing the strength of the liquid upon the volta-electromotive force was to considerably increase it, but its effect upon the thermo-electromotive force was to largely decrease it. The degree of potential of a metal and liquid thermo-couple was not always exactly the same at the same temperature during a rise as during a fall of temperature; this is analogous to the variations of melting and solidifying points of bodies under such conditions, and also to that of supersaturation of a liquid by a salt, and is probably due to some hindrance to change of molecular movement.

The rate of ordinary chemical corrosion of each metal varied in every different liquid; in each solution also it differed with every different metal. The most chemically positive metals were usually the most quickly corroded, and the corrosion of each metal was usually the fastest with the most acid solutions. The rate of corrosion at any given temperature was dependent both upon the nature of the metal and upon that of the liquid, and was limited by the most feebly active of the two, usually the electrolyte. The order of rate of corrosion of metals also differed in every different liquid. The more dissimilar the chemical characters of two liquids the more diverse usually was the order of rapidity of corrosion of a series of metals in them. The order of rate of simple corrosion in any of the liquids examined differed from that of chemico-electric and still more from that of thermo-electric tension. Corrosion is not the cause of thermo-electric action of metals in liquids.

Out of fifty-eight cases of rise of temperature the rate of ordinary corrosion was increased in every instance except one, and that was only a feeble exception—the increase of corrosion from 60° to 160° F. with different metals was extremely variable, and was from 1·5 to 321·6 times. Whether a metal increased or decreased in thermo-electromotive force by being heated, it increased in rapidity of corrosion. The proportions in which the most corroded metal was also the most thermo-electro-positive one was 65·57 per cent. in liquids at 60° F. and 69·12 in the same liquids at 160° F.; and the proportion in which it was the most chemico-electro-positive at 60° F. was 84·44 per cent., and at 160° F. 80·77 per cent. The proportion of cases therefore in which the most chemico-electro-negative metal was the most corroded one increased from 15·56 to 19·23 per cent. by a rise of temperature of 100° F. Comparison of these proportions shows that corrosion usually influenced in a greater degree chemico-electric rather than thermo-electric actions of metals in liquids. Not only was the relative number of cases in which the volta-negative metal was the most corroded increased by rise of temperature, but also the average relative loss by corrosion of the negative to that of the positive one was increased from 3·11 to 6·32.

The explanation most consistent with all the various results and conclusions is a kinetic one:—That metals and electrolytes are throughout their masses in a state of molecular vibration. That the molecules of those substances, being frictionless bodies in a frictionless medium, and their motion not being dissipated by conduction or radiation, continue incessantly in motion until some cause arises to prevent them. That each metal (or electrolyte), when unequally heated, has to a certain extent an unlike class of motions in its differently heated parts, and behaves in those parts somewhat like two metals (or electrolytes), and those unlike motions are enabled, through the intermediate conducting portion of the substance, to render those parts electro-polar. That every different metal and electrolyte has a different class of motions, and in consequence of this they also, by contact alone with each other at the same temperature, become electro-polar. The molecular motion of each different substance also increases at a different rate by rise of temperature.

This theory is equally in agreement with the chemico-electric results. In accordance with it, when in the case of a metal and an electrolyte, the two classes of motions are sufficiently unlike, chemical corrosion of the metal by the liquid takes place, and the voltaic current, originated by inherent molecular motion under the condition of contact, is maintained by the portions of motion lost by the metal and liquid during the act of uniting together. Corrosion therefore is an effect of molecular motion, and is one of the modes by which that motion is converted into and produces electric current.

In accordance with this theory, if we take a thermo-electric pair consisting of a non-corrodible metal and an electrolyte (the two being already electro-polar by mutual contact), and heat one of their points of contact, the molecular motions of the heated end of each substance at the junction are altered; and as thermo-electric energy in such combinations usually increases by rise of temperature, the metal and liquid, each singly, usually becomes more electro-polar. In such a case the unequally heated metal behaves to some extent like two metals, and the unequally heated liquid like two liquids, and so the thermo-electric pair is like a feeble chemico-electric one of two metals in two liquids, but without corrosion of either metal. If the metal and liquid are each, when alone, thermo-electro-positive, and if, when in contact, the metal increases in positive condition faster than the liquid by being heated, the latter appears thermo-electro-negative, but if less rapidly than the liquid, the metal appears thermo-electro-negative.

As also the proportion of cases is small in which metals that are positive in the ordinary thermo-electric series of metals only become negative in the metal and liquid ones (viz. only 73 out of 286 in weak solutions, and 48 out of the same number in strong ones), we may conclude that the metals, more frequently than the liquids, have the greatest thermo-electric influence, and also that the relative largeness of the number of instances of thermo-electro-positive metals in the series of metals and liquids, as in the series of metals only, is partly a consequence of the circumstance that rise of temperature usually makes substance—metals in particular—electro-positive. These statements are also consistent with the view that the elementary substances lose a portion of their molecular activity when they unite to form acids or salts, and that electrolytes therefore have usually a less degree of molecular motion than the metals of which they are partly composed.

The current from a thermo-couple of metal and liquid, therefore, may be viewed as the united result of difference of molecular motion, first, of the two junctions, and second, of the two heated (or cooled) substances; and in all cases, both of thermo- and chemico-electric action, the immediate true cause of the current is the original molecular vibrations of the substances, whilst contact is only a static permitting condition. Also that whilst in the case of thermo-electric action the sustaining cause is molecular motion, supplied by an external source of heat, in the case of chemico-electric action it is the motion lost by the metal and liquid when chemically uniting together. The direction of the current in thermo-electric cases appears to depend upon which of the two substances composing a junction increases in molecular activity the fastest by rise of temperature, or decreases the most rapidly by cooling.

Zoological Society, January 15.—E. W. H. Holdsworth, F.Z.S., in the chair.—The Secretary exhibited, on the part of Mr. H. Whitely, an immature specimen of the Night-Heron (*Nycticorax griseus*), which had been shot in Plumstead Marshes, Kent, in December last.—A communication was read from Mr. J. C. O'Halloran, Chief Commissioner and Police Magistrate for Rodriguez, accompanying a specimen of a large lizard found only in that island, and very rare there. The specimen had been identified by Mr. Boulenger as *Phelsuma newtoni*, belonging to the family Geckotidæ.—Sir Joseph Fayrer exhibited some additional specimens of the horns of deer gnawed by other deer, in confirmation of previous remarks on the subject.—Canon Tristram, F.R.S., exhibited and made remarks upon some specimens of species of the genus *Pachycephala*, which appeared to have been ignored or wrongly united to other species in a recently published volume of the Catalogue of Birds of the British Museum.—Mr. W. F. R. Weldon read a paper in which he gave a description of the placenta in *Tetraceros quadricornis*. The author showed that this placenta is intermediate between that of *Moschus* and that of the typical Bovidæ, having few cotyledons with diffuse vascular ridges between them. Associated with this primitive character is a uniserial psalterium.—A second paper by Mr. Weldon contained some notes on the anatomy of a rare American monkey, *Callithrix gigot*, which had recently died in the Society's Gardens. The author gave a description of the external characters, and the principal viscera were compared with those of *C. moloch* and of *Mycetes*.—A communication was read from Mr. E. J. Miers, F.Z.S., giving an account of a collection of Crustacea from the Mauritius, which had been forwarded to the British Museum by M. V. de Robillard. In the collection was an example of a new species of *Callianassa*, proposed to be called *C. martensi*.—Mr. Francis Day read a paper on races and hybrids among the Salmonidæ, and exhibited a series of specimens of young salmon and hybrid Salmonidæ reared at Sir J. Gibson Maitland's Howie-town Fish Establishment.—Prof. F. Jeffrey Bell read a paper on the generic position and relations of *Echinanthus tumidus* of Tenison-Woods, from the Australian seas, which he showed to belong to a different genus, proposed to be called *Anomalanthus*.

Chemical Society, January 17.—Dr. W. H. Perkin, president, in the chair.—The following gentlemen were elected Fellows :—B. H. Brough, G. Daubeney, C. C. Hutchinson, W. S. Kilpatrick, E. Matthey, H. Peile, J. Pallister, R. Romanis, S. G. Rawson, F. M. Rogers, W. Robinson, T. Stenhouse, W. O. Senier, J. A Voelcker.—The following papers were read:—On camphoric peroxide and barium camphorate, by C. T. Kingzett. In 1863 Brodie described the formation of camphoric peroxide by triturating camphoric anhydride with barium peroxide in the presence of ice-cold water. The author has repeated the above experiments, and concludes that no camphoric peroxide is formed, but that the anhydride is first converted into camphoric acid, which decomposes the barium peroxide, yielding camphorate of barium and peroxide of hydrogen.—On the decomposition of silver fulminate by hydrochloric acid, by E. Divers and Michitada Kawakita. Formic acid and hydroxyammonium chloride are formed, as is the case with mercury fulminate, but the authors have only been able to obtain two-thirds of the calculated quantity of these bodies. Some ammonia and hydrocyanic acid are also formed.—Supplementary note on Liebig's production of fulminating silver without the use of nitric acid, by E. Divers and Michitada Kawakita. The authors have succeeded in preparing the fulminate, but only when the reaction was allowed to proceed for some time. The solution was then warm, and always contained nitric acid.—On hyponitrites, by E. Divers and Tamemasa Haga. The authors criticise the recent paper of Berthelot and Ogier, and give an account of fresh investigations, which confirm the formula originally proposed by Divers, AgNO. They have not been able to obtain hyponitrite, either by the method proposed by Mencke, *i.e.* heating potassium nitrate with iron filings, or the method proposed by Zorn, in which ferrous hydrate is used as the reducing agent.

Royal Meteorological Society, January 16.—Mr. J. K. Laughton, F.R.A.S., president, in the chair.—The Secretary read the Report of the Council, which showed that the past few months mark a very important epoch in the history of the Society. In October the Council received the intimation that Her Majesty had been graciously pleased to grant the Society permission to assume the prefix "Royal." In consequence the Society has become, and will henceforth be called, the Royal Meteorological Society. In December the Fellows made certain alterations in the by-laws by which the annual subscription has been increased. The Report also showed that the Society is doing a great deal of practical work, not only by holding meetings and publishing the papers read at the same, but also by the establishment of a large number of observing-stations, which are regularly inspected, so that the results obtained from them may be strictly uniform and comparable. The number of Fellows is 549 and of honorary members 19, thus making a total of 568.—The President then delivered his address, in which he referred to the experiments made by Mr. Saxon Snell, Mr. Bertram, and Mr. Hele Shaw, with the object of determining the coefficients of Biram's anemometers; as yet these can scarcely be considered quite satisfactory, for, though made with the utmost care, they give results differing from each other by nearly 25 per cent. and from the known truth in opposite directions. The reduction of barometric readings to sea-level is another problem of great interest and importance, the solution of which is far from perfect, and, as applied to the converse determination of altitudes, has been pronounced by Mr. Gilbert, of the U.S. Geological Survey, to be beset with difficulties "so numerous and so baffling that there is no reason to hope that they will ever be fully overcome." In many cases, too, the reduction, even if correct, implies an accumulation of air in places where no air exists; and isobars so drawn, traversing mighty mountain ranges such as the Rocky Mountains or the Himalayas, or elevated plateaus such as those of Central or Eastern Asia, convey an impression which may easily lead to serious mistakes. The great achievement of the year is unquestionably the gathering in of the observations taken, by international agreement, at nine Arctic stations, in which, amidst circumstances of more or less discomfort, parties continued through a full period of twelve months. With one station established by the United States on the shores of Lady Franklin Bay, it has been found impossible to communicate; this was established in the summer of 1881, and no trustworthy news has since been received. Preliminary reports have been published from the English station at Fort Rae on the northern shores of the Great Slave Lake; from the German station in Cumberland Sound; from the Austrian at Jan Mayen, and from some of the others; but the principal interest attaches not to the observations taken separately but to the collation and comparison of the whole, which may be expected to lead the way towards problems of the greatest importance to meteorology. In the present day one science is so mixed up with a number of others, and so involved in them, that it is impossible to separate them, or to define the exact limits of each. Many of the problems of meteorology belong as much to geography, or at times even to experimental physics, and an address which speaks of the progress of meteorology is perhaps apt to appear in some degree discursive. It is that the true student of nature, whilst limiting his detailed work to one particular direction, must consider her kingdom as a grand and comprehensive whole, one and indivisible.—The following gentlemen were elected the officers and Council for the ensuing year:—President: Robert Henry Scott, F.R.S.; Vice-Presidents: Hon. Ralph Abercromby, Edmund Douglas Archibald, M.A., John Knox Laughton, F.R.A.S., William Marcet, M.D., F.R.S.; Treasurer: Henry Perigral, F.R.A.S.; Trustees: Hon. Francis Albert Rollo Russell, M.A., Stephen William Silver, F.R.G.S.;

Secretaries: George James Symons, F.R.S., John William Tripe, M.D.; Foreign Secretary: George Mathews Whipple, F.R.A.S.; Council: William Morris Beaufort, F.R.A.S.; George Chatterton, John Sanford Dyason, F.R.G.S., William Ellis, F.R.A.S., Charles Harding, Richard Inwards, F.R.A.S., Baldwin Latham, F.G.S., Robert John Lecky, F.R.A.S., Edward Mawley, F.R.H.S., Cuthbert E. Peek, F.R.G.S., Capt. Henry Toynbee, F.R.A.S., Charles Theodore Williams, M.D.

Anthropological Institute, January 8.—Prof. Flower, F.R.S., president, in the chair.—The election of the following new members was announced:—Rev. E. S. Dewick, M.A., F.G.S., Prof. A. Macalister, M.D., F.R.S., and Mr. Oldfield Thomas as ordinary members, Dr. E. T. Hamy and Dr. Hermann Welcker as honorary members, and Mr. Lucien Carr and Dr. A. B. Meyer as corresponding members.—The President stated that Mr. Francis Galton had offered 500*l*. in prizes to those who should before May 1, 1884, furnish him with the best extracts from their family records according to the form prescribed in his "Record of Family Faculties," published by Macmillan and Co., and he urged all members of the Anthropological Institute to give Mr. Galton every assistance in their power.—Mr. H. H. Johnston read a paper on the races of the Congo and the Portuguese colonies in Western Africa. The author stated that Western Tropical Africa, between Senegambia to the north and the River Cunéné, offered a vast studying ground to the anthropologist, wherein types of nearly every well-marked African race might be observed. After detailing many of the various races, he proceeded to describe the Bushmen north of Cunéné, which he characterised as about the lowest type of men, but, of the five or six specimens which came more particularly under his notice, he remarked that their mental ability was strangely at variance with their low physical characteristics. The Hottentots were much finer men than the Bushmen as regarded height and build, but they exceeded the latter in baboon-like licentiousness. The western slopes of the Shella Mountains were peopled by a tribe called the A-ndombe, a sturdy race of carriers, which extended as far north as Benguela. Referring to the races of the lower Congo, Mr. Johnston observed that they depended almost entirely upon vegetable diet, whilst they were remarkable for their initiation ceremonies. Traces of phallic worship were noticed, especially in the interior, and more particularly in the neighbourhood of Stanley Pool. A Congo market was exceedingly interesting, and was held for about four or eight days. The natives would often go 100 miles to attend one of these markets, the women generally being the keenest traders. Between Stanley Pool and the coast there is only one great leading tongue spoken, though this has several dialects. This is the Congo language, one known to and studied by Europeans probably before any other Bantu tongue. It bears many signs of Portuguese influence.

Geological Society, January 9.—J. W. Hulke, F.R.S., president, in the chair.—Patrick Doyle, Alfred Harker, Rev. Frederick Hastings, Rev. John Milne-Curran, and William Ford Stanley, were elected Fellows; Prof. G. Capellini, of Bologna, a Foreign Member, and M. Alphonse Briart, of Mons, a Foreign Correspondent of the Society.—The following communications were read:—On the volcanic group of St. David's, by the Rev. Prof. J. F. Blake, F.G.S. The result of the author's examination of the rocks in the district of St. David's which have been designated *Dimetian*, *Arvonian*, and *Pebidian*, is that they belong to one volcanic series, whose members are those usually recognised in eruptive areas, and whose age is anterior to and independent of the true Cambrian epoch. The independence of this series and the Cambrian is shown by the nature of the junction at all points of the circuit that have been seen. The supposed isocline west of the granitic mass cannot be verified on an examination of the coast-section, there being great irregularity and gentle synclinals not far from where the apex of the isocline should be. With regard to the nature of the rocks which thus antedate the Cambrian, the author was unable to recognise any true alternations in the materials of the granitic axis, though the rock is a peculiar one in the arrangement of its constituents. The felsitic rocks are not independent of the granite, as they surround it on all sides, the line along the north and south being specially traced. They are also often intrusive into the ashes, and hence can have no definite strike. Attention was drawn to the highly acid character of the whole series, and to the small size of the centres of eruption, and it was suggested that such centres have continually decreased in number and increased in magnitude during geological time.—On further discoveries of vertebrate remains in the Triassic strata of the south coast of Devonshire, between Budleigh Salterton and Sidmouth, by A. T. Metcalfe, F.G.S. The author gave a brief stratigraphical account of the Triassic rocks of the coast. He then described some vertebrate remains, consisting chiefly of portions of jaw-bones with teeth in line, probably of Labyrinthodonts, found in the upper sandstones (Ussher's classification) at High Peake Hill, near Sidmouth, by H. J. Carter, F.R.S. At numerous places between Budleigh Salterton and Sidmouth, Mr. Carter and the author had found a large number of isolated bone fragments. Such fragments had been submitted to a microscopical examination by Mr. Carter. In some specimens the bone structure was visible throughout; in some the bony portion had been partially removed and replaced by an infiltration of mineral matter; in others the removal of the bony portion was complete. From these facts the author drew the conclusion that a comparative abundance of vertebrate life was maintained during the Triassic period; and that the rareness of Triassic fossils was due not so much to the paucity of animal life during that period as to the fact that Triassic strata afforded no suitable conditions for the *preservation* of organic remains.

EDINBURGH

Royal Physical Society, January 16.—J. A. Harvie-Brown, F.R.S.E., president, in the chair.—The following communications were read:—On intra-epithelial capillaries in Oligochæta, by F. E. Beddard, F.R.S.E.—On the geognosy of the Harz Mountains, part 1, by H. M. Cadell, B.Sc., of the Scottish Geological Survey. The writer stated that there was still some room for original investigation in that quarter, notwithstanding the great attention the German geologists had bestowed on the region. The Germans had not yet learned the art of detailed structural geological mapping and section-drawing as carried out in the British geological surveys, and many of their so-called geological maps were nothing more than mere petrographical pictures. The writer then went over the various formations of the Harz, and noticed the fact that graptolites were found at the top only of the lowest or Hercynian rocks, which he suggested might be cited as an example of one of Banaudes' "colonies." The older or "core rocks" of the Harz terminating in the Kulm were overlaid in violent unconformability by the border rocks, beginning at the coal measures and extending upwards to the Trias and Cretaceous systems. He agreed with those who consider the loess an "æolian" deposit swept as dust into sheltered valleys and nooks by the wind, and thought that water had had nothing directly to do with its origin. The paper was illustrated by the exhibition of rocks and metallic minerals from the region described.—Prof. Cossar Ewart, F.R.S.E., exhibited, with remarks, a large torpedo recently caught in a trawl off Wick, and believed to be the only specimen of the kind ever found north of the English Channel. The specimen exhibited was 28 inches in length and 19½ inches across the pectoral fins, and belonged to the species *hebetans*.

SYDNEY

Linnean Society of New South Wales, November 28, 1883.—C. S. Wilkinson, F.G.S., F.L.S., president, in the chair.—The following papers were read:—Some fishes of New Britain and the adjoining islands, by Charles W. De Vis, B.A. The names of the new specimens described are—*Serranus perguttatus* and *cruentus*, *Mesoprion flavirosea*, *Tetraroge vestita*, *Acanthurus zebra*, *Rynchichthys novæ-britanniæ*, *Harpage rosea* (a new genus of the Berycidæ), *Salarias æquipinnis*, *Amphiprion arion*, *Pomacentrus onyx* and *notatus*, *Nesiotes purpurascens* (a new genus of the Labridæ), *Exocœtus longibarba*, *Arius armiger*, *Herpetichthys cobra*, (a new genus of the Murænidæ), *Tetrodon insularium* and *lævis*.—Some results of trawl fishing outside Port Jackson, by William Macleay, F.L.S. In this paper are given—(1) An account of two trials of a large beam trawl in forty to fifty fathoms water, by the order of the Commissioner of Fisheries; (2) a list of the fishes captured; and (3) descriptions of two new species—a skate, *Raia australis*, and a gurnard, *Lepidotrigla mulhalli*. Mr. Macleay considers the result promising on the whole.—Baron Maclay read a note on the "Barometro Araucano" from the Chiloe Islands. He stated that this remarkable instrument had been shown to him among a number of other curiosities by Capt. C. de Amezaga, of the

Italian corvette *Caraciolo*, who informed him that it was used by the natives of the Chiloe Islands as a kind of barometer to foretell the approach of either dry or wet weather. This "Barometro Araucano," which consisted merely of the shell of a crab, pronounced by Mr. Haswell to be one of the *Anomura*, probably of the genus *Lithodes*, is most peculiarly sensitive to atmospheric changes. In dry weather it remains nearly white, but, with the approach of moisture, small red spots appear on the shell, increasing in number and size with the increase of humidity, until during the wet season it becomes completely red.

PARIS

Academy of Sciences, January 14.—M. Rolland in the chair.—On the researches of M. Guntz in the thermo-chemistry of the fluorides, in reply to the strictures of M. Tommasi, by M. Berthelot.—On a process of anæsthesis by the method of titrate mixtures of vapours and air; its application to the human subject in the form of vapours of chloroform, by M. Paul Bert. The chief advantages of this process are stated to be: delirium always slight, sometimes altogether absent, even in adults; absolute and regular insensibility obtained in six to eight minutes; quiet sleep; normal breathing, circulation, and temperature; no symptoms of nausea; normal and perfectly reassuring appearance of the patient while asleep; constant and always very protracted consecutive anæsthesis; great economy in the outlay for chloroform.—Generalisation and strictly mechanical demonstration of Joule's electrical formula, $w = i e T$, by M. A. Ledieu.—On the preparation in large quantities of artificial virus attenuated by rapid heating, by M. A. Chauveau. By this process sufficient virus for the prophylactic inoculation of from 4000 to 8000 sheep may be rapidly prepared in the same reservoir.—Observations of the Pons-Brooks comet made at the bent equatorial of the Paris Observatory, by M. Périgaud.—On the genus of some entire functions in mathematical analysis, by M. Laguerre.—On the geometrical curve known as Pascal's "limaçon," by M. A. Genocchi.—On linear differential equations with doubly periodical coefficients, by M. G. Floquet.—On the adiabatic expansion of the vapour of water, by M. P. Charpentier.—On the agreement of experience with the general theoretic law regulating capillary surfaces, especially in its application to water confined between two moistened plaques, vertical and parallel, by M. Quet.—On a new method of determining the magnetic inclination by means of the induction compass, by M. Wild.—On the observation of earth currents whose intensity is shown to be subject to secondary fluctuations depending on the degree of moisture and temperature of the zone comprised within the circuit, by M. Larroque.—Determination of the intensity of combustion in some acetones and in the two ethers of carbonic acid, by M. W. Louguinine.—On the phenomena of chemical dissociation, by M. Isambert. Here the author endeavours to resume the results of his experimental researches on dissociation in a simple theory based on the thermic data, by means of which alone it is possible to appreciate chemical phenomena.—On the preparation of the sulphate of the sesquioxide of pure chromium, by M. H. Baubigny.—Explanation of a method for determining the density of liquid oxygen, by M. Menges. The author obtains the equation $d = \frac{V_1 d_1}{v - v_1}$, where d = the density of the liquid gas, v = its volume, V = the volume of the gaseous portion, all known quantities.—On colloidal ferric ethylate and ferric hydrate, by M. Ed. Grimaux.—On a chloruretted silicate of manganese, by M. Al. Gorgeu.—On the influence of plastering on the composition and the chemical properties of wine, by M. L. Magnier de la Source. The plastering process with chemically pure sulphate of lime has the effect of decomposing not only the cream of tartar, but also the neutral organic combinations of potassium which are present in a very considerable proportion in the perfectly ripe grape.—On the presence of the diamond in some graphic stone occurring near Bellary, Madras Presidency, by M. Chaper.—On the fossil Echinidæ of the Eocene formations at Saint-Palais (Charente Inférieure), by M. G. Cotteau.

BERLIN

Physical Society, January 4.—Prof. Neesen briefly communicated the contents of a paper sent in by Herr Friedrich C. S. Müller, describing three apparatus used in connection with the delivery of lectures: a tangent compass, a galvanometer, and a rheostat. These instruments were intended to take rapid measurements, and to render them visible to a large audience. Following up this subject, Prof. Neesen gave a short account of the contrivance by which in his lectures he measured the mutual attraction of two magnets by means of scales. In conclusion, he reported experiments instituted by him with a view to determining the influence of magnetisation on electrical conducting power. In these experiments he had made use of a magnetic substance of high specific resistance, a solution of chloride of iron. Two equal tubes were filled with the same solution, and inserted as the two branches of a Wheatstone bridge into the circuit of a galvanic battery; the two other branches being so arranged that the galvanometer stood at zero. The electrodes in the two tubes consisted of iron plates, and were exactly alike. The tubes, that is, the fluid conductors, had in the different experiments different shapes and different diameters. The contents of the one tube were then magnetised either by a magnetising spiral or by a powerful electromagnet, and the galvanometer was observed during this process of magnetisation. The result of the experiments was in every case a negative one. Very slight deflexions were indeed observed in the galvanometer needle in the case of the experiments with the magnetising spiral, but these proceeded from the slight heating of the fluid, an effect which, notwithstanding the solution of chloride of iron was surrounded by a casing of circulating water, had not been wholly avoided. In those experiments, on the other hand, in which the magnetisation was made by means of the electromagnet, the needle remained invariably at rest.—Prof. Rœber discussed and explained the principle of experiments made on the Rhone and reported in the *Comptes Rendus*. These experiments had for their object the towing of ships by means of ropes wound round the whole vessel.—Dr. Kœnig gave a short preliminary communication on the experiments, which, in cooperation with Dr. Dietrici, he had made, with a view to determining the precise position of different spectral colours and the sensitiveness of the eye for distinguishing colours. At the next meeting of the Society he would speak at greater length on the subject, illustrating it by numerical data.

THE INDIANS OF GUIANA

Among the Indians of Guiana: being Sketches chiefly Anthropologic from the Interior of British Guiana. By Everard F. Im Thurn, M.A. Oxon. (London: Kegan Paul, Trench, and Co., 1883.)

GENERALLY speaking, the books of travel on which anthropologists have to depend for information as to the less cultured tribes of mankind are descriptions of a country and its exploration, with a chapter or two on the natives. Here the plan is reversed, the main book being a treatise on Caribs and Arawaks, to which is prefaced a short but lively description of the forests and savannahs of Guiana, with their plants and animals, forming as it were a frame in which to set the human picture. When Mr. Im Thurn first went to Guiana in 1877, he spent much of his two years' stay in wanderings among the Indians, and before the end of 1881 went back to the colony, where he is now Resident Magistrate of the Pomeroon District. Such appointments are much to be commended, on the one hand as putting the indigenous tribes under the control and protection of an official thoroughly conversant with native character and custom, on the other hand as placing a scientific man in intimate relations with the fast disappearing culture of the lower races.

The question to what races these native tribes of Guiana belong has occupied Mr. Im Thurn, with results which are not only interesting in themselves but have a bearing on larger problems of anthropology. We too readily take it for granted that the lower barbarians have no history beyond two or three generations of old men's memory. In the present district, however, something far beyond this seems to be made out. The native tribes of Guiana fall into two divisions. One group is made up of the Arawaks, Warraus, and Wapianas; and these, though unintelligible and hostile to one another, are united by a common feeling of aversion to the Caribs, who, native tradition says, came from the West India Islands. These Caribs, who form the other group of tribes of Guiana, are in appearance, language, and customs similar to those of the West Indies, so that we have here a case of native tradition asserting that certain tribes of a country were invaders from another region, though the Carib immigration thus remembered took place perhaps three to five hundred years ago. The present author is so convinced of the reality of this event that he calls the Caribs in Guiana "stranger" tribes to distinguish them from the "native" tribes. Long ago as the invasion happened, Mr. Im Thurn points out that the industrial arts of the two races have not yet become blended. The Arawaks and other native tribes continue to make their hammocks of palm fibre, not taking to the use of cotton thread for hammock-weaving, although the Caribs brought this art so long ago with them from their islands, and have practised it in Guiana ever since. What is still more curious is that the rude method of making thread by rolling palm or grass fibre into a twist with the palm of the hand on the thigh, may be commonly seen in Guiana, although the use of the spindle for spinning cotton is also usual. The explanation of this coexistence of a savage and a more civilised art is no doubt that the old native tribes were "thigh-twisters," but the new stranger tribes were spinners, and the descendants of both have more or less kept up their hereditary methods (pp. 171, 287).

Among matters bearing on the history of civilisation which struck Mr. Im Thurn was the custom of building houses on piles. This may be seen in its primary form among the Warraus (p. 202); although quiet times and security from enemies make it no longer worth their while to build actually out in the waters, they still build many pile-huts in the swamps. These miserable huts have been described as standing on a platform of interlaced stems of the manicole palm, supported on tree trunks five or six feet high, with a notched trunk serving as a ladder, to which, when the waters were high, the canoe was made fast. The motive of building in such a situation is intelligible enough as a means of safety from enemies, but next we come to an extension of the practice requiring explanation:—

> "A most remarkable fact is that houses on piles are not unfrequently built, for no apparent reason, on the savannah; and this is done not by any special tribe, but occasionally by Arecunas, Macusis, and by other Carib tribes. They stand not in swamps but on dry ground, sometimes on top of a hill. Except that they are much larger, they are exactly like the Warrau houses already described; and it is a noteworthy fact that the platform on which the house stands is, as in the case of the Warrau houses, made of the stems of manicole palms (*Euterpe oleracea*), though this moisture-loving palm is very locally distributed in the savannah region, and the Indians fetch it from long distances, although other apparently equally suitable material is at hand. It is probable that these savannah pile-builders revert to a form of house which they saw—and perhaps used—on the coast land, when they first reached the mainland from the islands."

This explanation of pile-houses on land as due to survival of the once purposeful habit of building them in the water is the more interesting from its correspondence with a theory based on similar facts on the other side of the globe. Prof. Moseley, describing New Guinea ("Notes by a Naturalist on the *Challenger*," p. 396) points out that the pile-dwellings must have been first built in the water for protection and afterwards were continued on land. Pushing the argument further, he suggests that the pile-house on dry ground was converted into a two-story dwelling by filling in the spaces between the poles with leaves or mats, so that the lower part might serve as a storehouse or cowhouse. In this way Prof. Moseley accounts for the Swiss peasant's châlet as derived from the watery home of the ancient lake-dweller, the present balcony representing the old platform to which the lakemen climbed up from their canoes. When the present remarks find their way into Mr. Im Thurn's hands, it is to be hoped that he will test this ingenious view by the evidence within his reach.

Mr. Im Thurn's researches into the religious ideas of the Guiana tribes disclose a remarkable theological condition. To so acute a student of the theory of religion it must have been an exciting occupation to live in daily mental contact with Animistic conceptions at once so primitive and so vivid. In any future discussion of

Animism, the results obtained by him must take a prominent place.[1] Few, if any, Europeans have had such perfect opportunity of seeing the idea of soul originate in the evidence of the senses in dreams, as interpreted by childlike, savage philosophy. Dreams are, to these rude people, events of real life, in which the spirits or phantoms of other men come to them in sleep, or are seen when the sleeper, in like manner, leaves his own body lying and goes forth into the dream-world. Both these conceptions are illustrated in the following stories of what occurred to our traveller :—

> "It becomes important, therefore fully to recognise the complete belief of the Indian in the reality of his dream-life, and in the unbroken continuity of this with his working life. It is easy to show this belief by many incidents which came under my notice. For instance, one morning when it was important to me to get away from a camp on the Essequibo River, at which I had been detained for some days by the illness of some of my Indian companions, I found that one of the invalids, a young Macusi, though better in health, was so enraged against me that he refused to stir, for he declared that, with great want of consideration for his weak health, I had taken him out during the night and had made him haul the canoe up a series of difficult cataracts. Nothing could persuade him that this was but a dream, and it was some time before he was so far pacified as to throw himself sulkily into the bottom of the canoe. At that time we were all suffering from a great scarcity of food, and hunger having its usual effect in producing vivid dreams, similar effects frequently occurred. More than once the men declared in the morning that some absent men, whom they named, had come during the night and had beaten or otherwise maltreated them; and they insisted upon much rubbing of the bruised parts of their bodies. Another instance was amusing. In the middle of one night I was awakened by an Arawak named Sam, the captain or head man of the Indians who were with me, only to be told the bewildering words, 'George speak me very bad, boss; you cut his bits!' It was some time before I could collect my senses sufficiently to remember that 'bits' or fourpenny-pieces are the units in which, among Creoles and semi-civilised Indians, calculation of money, and consequently of wages, is made; that to cut bits means to reduce the number of bits or wages given; and to understand that Captain Sam, having dreamed that his subordinate George had spoken insolently to him, the former, with a fine sense of the dignity of his office, now insisted that the culprit should be punished in real life" (p. 344).

Not less clear is the train of native argument by which the notion of soul extends itself from man to the other animals, which in the view of the rude Indian are beings differing indeed from man in bodily form and strength, but comparable with him in ways and cunning, creatures talking among themselves in their own languages, not more unintelligible to him than are the languages of surrounding tribes of men. Indeed the peai-man or magician of his own tribe, carrying into fraudulent effect this real belief, holds converse in his hearing with birds and beasts. What rude men think of the intelligence of animals is well illustrated by a custom which came under Mr. Im Thurn's own notice. "Before leaving a temporary camp in the forest, where they have killed a tapir and dried the meat on a babracot (stage of green sticks for smoking meat over a fire), Indians invariably destroy this babracot, saying that should a tapir passing that way find traces of the slaughter of one of his kind, he would come by night on the next occasion when Indians slept at that place, and taking a man, would babracot him in revenge."

Not to discuss here the spirits of rocks, waterfalls, and objects generally, which animate the Indian's world, mention may be made of those particular phases of Animism which underlie the proceedings of the native magicians, as to which Mr. Im Thurn has brought some picturesque and instructive facts into view. To understand these ideas, it has to be borne in mind that by the native law of vengeance, when an injury has been done (or believed to have been done) to a man, his nearest relative, as his avenger (*kenaima*), sets himself to follow and slay the wrongdoer, or, if he cannot be found, one of his relatives. Thus every Indian lives in constant dread that a kenaima may be following him like a shadow through the forest till he can catch him sleeping or helpless, strike him down, and rub deadly poison into his flesh, or dislocate his limbs. All this really happens, but the Indian extends the idea into his spirit-world, and, with a rude but sufficient philosophy, finds a cause of all sickness and death in attacks by the spirits sent by the imaginary kenaimas, which enter into the bodies of beasts of prey to attack their victims, or poison them, or, embodied in worms or insects, or any other small objects, pass into their bodies, and cause aches and pains. Against these spirit-foes the Indian has a protector, the magician or *peai*-man. This personage's craft is based on the same Animistic theory as that of his dupes, as is plain from the training for the profession which he undergoes, fasting, wandering in the forest, and drinking large draughts of tobacco-water, till he can work himself up into morbid passions of excitement, in which his intercourse with the spirits is carried on, partly no doubt in knavish imposture, but partly also in genuine belief. The methods by which this practitioner drives out disease-spirits from his patients were actually experienced by Mr. Im Thurn, who had the luck of getting a peai-man to operate on him for a slight headache and fever. A company of some thirty people, mostly attracted by the prospect of so novel a performance as peai-ing a white man, were assembled in the house of the doctor, the entrance was closed, the fires put out, and all lay in their hammocks, our traveller being especially warned not to set foot on the ground, for the kenaimas would be on the floor, and would do dreadful things to him if they caught him. Much like his analogue the professional medium at a modern *séance*, the peai-man made the patient promise not to stir out of his hammock, nor look, nor lay hands on anything that might touch him. For a while all was still, till suddenly the silence was broken by a burst of indescribable and really terrible yells and shouts, which filled the house, shaking walls and roof, sometimes rising rhythmically to a roar, which never ceased for six hours. Questions seemed to be thundered out and answers shouted back, with no pause in the sound. A little Macusi boy, who had slung his hammock close to Mr. Im Thurn's, whispered to him that it was the peai-man roaring his questions and commands to the kenaimas, who were yelling and growling and shouting their answers. Every now and then, through the mad din, there was a sound, at first low and indistinct, and then gathering in volume, as if some big winged thing came from far toward the house, passed through the roof and then settled heavily on the floor: and again, after an interval, as if the same winged thing rose and passed away as it had come. As each of these mysterious beings came and went, the air, as if displaced by wings, was driven over the patient's face. They were the kenaimas coming and going. As each came, his yells were first indistinctly heard from far off, but grew louder and louder until, as he alighted on the floor of the house, they reached their height. The first thing each did was to lap up some of the tobacco-water, with an ostentatious noise, from the calabash on the floor. But while he lapped the peai-man kept up the shouts, until the kenaima was ready to answer. When each kenaima had given an account of itself, and had promised not to trouble the sick man, it flew rustling away. They came in the form of tigers, deer, monkeys, birds, turtles, snakes, and of Ackawoi and Arecuna Indians. Their voices were slightly different in tone, and they all shouted in voices which were supposed to be appropriate to their forms, but, oddly enough, all hoarsely. It was a clever piece of ventriloquism and acting. The whole long terrific noise came from the throat of the peai-man, or perhaps a little of it from his wife. The only marvel was that the man could sustain so tremendous a strain upon his voice and throat for six long hours. The rustling of the wings of the kenaimas, and the thud which was heard as each alighted on the floor, were produced by the magician skilfully shaking the leafy boughs brought in for the purpose, and then dashing them suddenly against the ground. This Mr. Im Thurn discovered by the boughs accidentally touching his face, when he seized some of the leaves with his teeth. At the crisis he seemed to feel a hand laid on his face. The effect of all this upon him was very strange. Before long he passed into a kind of fitful sleep or stupor, probably akin to mesmeric trance. Incapable of voluntary motion, he seemed to be suspended somewhere in a ceaselessly surging din. Now and then when the noise all but died away, and the peai-man was supposed to have passed out through the roof and to be heard from a great distance, he awoke to half-consciousness, but as the magician came back and the noise grew again he fell back into stupor. At last towards morning, when the noise ended, he awoke thoroughly, and finding the entrance unbarred, rushed out to find relief in the rain and storm. His head was indeed anything but cured of its ache, but the peai-man insisted that he must be cured, and asked for payment, producing a caterpillar, which he declared was the kenaima which had caused the pain, and which he had extracted when he touched the patient's face. Accordingly he received a fourpenny looking-glass as his fee, and was satisfied.

---

[1] A paper by Mr. Im Thurn, embodying much of this research, will be found in the *Journal of the Anthropological Institute*, vol. xi., and remarks of mine on it in a lecture on anthropology printed in NATURE, May 3 and [illegible] 188[illegible].—E. B. T.

These extracts will give an idea of the goodness of the material contributed by Mr. Im Thurn to the study of the lower phases of human thought. In conclusion, a few words may be said as to his suggestions on the interesting problem how an explorer may reach the plateau-top of the precipice-walled Roraima, and settle the question what ancient and modern animals and plants have survived and developed there, and whether there may be any truth in fancies of strange human tribes dwelling there, cut off for ages from their fellow-men. In the far west of Guiana or over the Brazilian boundary, where the savannah itself rises 5000 feet above the sea, Roraima springs from it in perpendicular sandstone cliffs 2000 feet high, topped by a flat tableland apparently forest-covered, and whence waterfalls pour down. Round the whole circumference the cliff-wall is said to be perpendicular, but this is mere conjecture, for no traveller has ever been round it. The summit may prove accessible from the other side, and at any rate enough is known of the fauna and flora of the district to make it certain that a naturalist who should accomplish the circuit would be well rewarded by discoveries, even if he failed to reach the top. There is a way as yet untried, which Mr. Im Thurn is convinced will prove more practicable than those by which Roraima has been hitherto approached. He recommends going up the Potaro as far as possible by boats, and thence striking across the savannah on foot. The journey is one of difficulty and privation, which Mr. Im Thurn warns any explorer against undertaking without fully weighing the difficulty and cost. Perhaps we may hear some day of himself, as the leader of a well-equipped expedition, making the attempt.

E. B. Tylor

THE COLLECTION OF DEERS' HORNS AT THE ROYAL CASTLE OF MORITZBURG

Die Hirschgeweih-sammlung im Königlichen Schlosse zu Moritzburg bei Dresden, mit allerhöchster Genehmigung und Unterstützung Seiner Magestät des Königs Albert von Sachsen. Herausgegeben von Dr. Adolf Bernhard Meyer, K.S. Hofrath und Director des K. Zoologischen Museums zu Dresden. (Dresden: Wilhelm Hoffmann, 1883.)

THE King of Saxony's Hunting Lodge of Moritzburg lies some three hours' journey north from Dresden; it is built on an island in a little lake embowered amid the Friedewald. It was built between the years 1542 and 1589, under the Electors Moritz (1541-1553), August (1553-1586), and Christian I. (1586-1591), after the plans of the first of these Electors, apparently by the architect Hans von Dehn-Rothfelser, and it has been enlarged and renovated from time to time chiefly under the Electors John George I. (1611-1656), and John George IV. (1691-1694), and August II. King of Poland (1694-1763). It contains some two hundred rooms and seven halls, in which latter are arranged the series of pictures relating to hunting, and a collection of horns of all sorts. For this latter the Castle may thank the celebrity which it has among all sporting characters and zoologists. The walls of the large Banqueting Hall, which is 20·25 m. long, 10·50 m. wide, and 11·60 m. in height, are adorned with a collection of seventy-one noble horns of deer, of which none are under four-and-twenty points; while in the Audience Hall is preserved a collection of forty-two more or less extraordinary or monstrous horns, amongst which is the celebrated pair with sixty-six points.

It was a happy thought of Dr. A. B. Meyer, the indefatigable Director of the Royal Zoological Museum at Dresden, to publish an illustrated catalogue of this collection, which, with the gracious approval and assistance of the present King Albert of Saxony, has assumed the form of a splendid folio volume, with 30 plates, in which from 1 to 26 contain figures of all the remarkable horns from the Banqueting Hall, and from 27 to 29 represent some of the more interesting of the monstrous horns, while on Plate 30 we have a most extraordinary instance of a pair of horns—one of ten, the other of twelve, points—which had during life got inextricably interlocked with one another. The finest and most characteristic pairs of horns were selected for these photographs, which are by a new process most excellently reproduced on the plates. As a frontispiece to the text we have a photograph of a quaint sketch of the Castle.

About 1861, Dr. Meyer informs us, acting under the direction of Grand Marshall H. von Freisen, a catalogue of the seventy-one horns in the Banqueting Hall, with measurements in inches, was compiled, but unfortunately some of the identifications cannot be regarded as certain. It is strange that, in spite of the great care with which this collection of horns has been kept, there seems to be no record of when and whence the very ancient ones came to Moritzburg. Even the *Archives* of the place are nearly silent about them. Dr. Meyer has in this quite luxurious catalogue done what he could to rescue all that is known about the collection from oblivion, and he promises at some future time to give the history of the remaining two-thirds as a continuation of this work.

OUR BOOK SHELF

Guide to Methods of Insect Life, and Prevention and Remedy of Insect Ravage. By Eleanor A. Ormerod. Pp. 1–167, 8vo. (London: Simpkin, Marshall, and Co., 1884.)

THE text contains the substance of ten lectures delivered for the Institute of Agriculture. At p. 7 there is an italicised remark to the effect that "*insects always begin life by being produced by a female.*" This may be regarded as an indication of the presumably ultra-ignorant class for whose benefit the lectures were prepared. But we prefer to think that far too low an estimate of the knowledge possessed by our agriculturists has been made, and doubt not that, by a majority of them, the remark will be taken as the reverse of complimentary. The book is exceedingly well got up, and in a very attractive style, and will no doubt become popular (on account of the multitude of illustrations. For the agriculturist purely, it seems to us that it goes either not far enough or too far; it is too "showy" for practical purposes, and often, unwittingly, too abstruse. The copious illustrations are mostly excellent, and many of them are original (among the very few very indifferent figures, that of the "Bee-parasite" may be cited). But the necessity for many of the figures in a book apparently intended for the agricultural class may be doubted, and some have evidently been introduced for effect. That American bogey (or "fraud") the "Colorado Beetle," is honoured by the reproduction of his portrait, and the *Phylloxera* is dismissed with only dishonourable mention. The general information is sound, but occasionally vague, as in the definitions of the terms "larva" and "pupa," and in the apparent assumption that respiration is exclusively effected by the external air being conveyed to the tracheæ by means of *spiracles*. The "Glossary" will no doubt be found very useful to the majority of the readers of the book, but some terms (e.g. "*Telum*") appear wonderfully abstruse, as used in a work in which it was necessary to explain that "*insects always begin life by being produced by a female.*"

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

The Remarkable Sunsets

ON Friday, the 11th inst., the weather was very remarkable; it recalled to our minds, though on a smaller scale, the storm of December 12, 1883. In the afternoon, about three o'clock, the wind arose with violence, and great squalls alternated with relative calms. The movements of the clouds were also very curious. Layers of air of different elevation floated in various directions, and the lower very low-hanging clouds which moved at the same level had, at different points of the sky, an unequal and changing rapidity. The wind beneath was, at 6 p.m., west-south-west; the lower clouds came from the west, the more elevated, on the contrary, from the north-north-west, so there is no doubt that whirlwinds blew that day in the upper air. The sun had set with a very fine after-glow, and in the ensuing night and morning there fell, now and then, showers of rain occasionally accompanied by snow and hail. Besides, the night before a magnificent halo had been observed around the moon, so that the presence of ice-crystals on January 11, in the higher regions of the atmosphere, is certain. In consequence of the low temperature, the air in those regions must have had a great density, and so, apparently, there must have been a great chance that the whirlwinds on Friday had moved the heavy, cold air from above downwards.

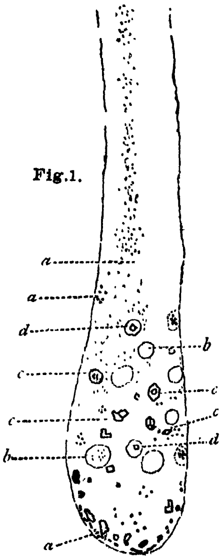

Fig. 1.

FIG. 1.—Sediment and residue of an evaporated drop of rain, fallen January 12, 1884, on a window-pane. *a a a*, particles of the ash; *b b*, drops of hygroscopic matter; *c c c*, crystals of common salt and andesitous mineral; *d d*, drops with salt crystals.

That this was really the case seems to proceed from the fact that during the night of January 11 and 12 the rain had brought down on my windows the same sediment as that of December 12, though in smaller quantity. The identity of this sediment with the ashes of Krakatoa will now be beyond doubt to any one who has read the numerous communications in NATURE on the remarkable sunsets. Why I wish to refer to this affair once more is that at the microscopic examination of the dust of January 12 I found in it a relatively great quantity of complete individual crystals, partly soluble, partly insoluble, in water, which had remained unobserved by me in December.

After having scraped the dust off the window-panes and put it on the slide in a drop of oil, I made a drawing of the crystals by means of the camera lucida, magnifying them 400 times, as represented in Fig. 2.

The crystals, as seen in Fig. 2 *a*, evidently exist in common salt; this follows from their solubility in water, their crystalline form, and their reaction in the flame. They are found in so great a number in the residuum of every drop of rain that we come to the conclusion that these little crystals must be found as such in those regions of the atmosphere where the dust is floating, the air containing there hardly anything else but ice, and surely little liquid water.

In Fig. 2 *b* we see the crystals insoluble in water. They are uncoloured and perfectly transparent, and may be considered to be the crystalline form of the andesitous mineral of which the ashes consist for the greater part.

The residuum of the evaporated rain-drop of January 12 showed itself about in the manner seen in Fig. 1. If the window-pane is used as a slide and the dust examined directly with the microscope, one will find there a great number of little drops (*b b*, Fig. 1), in most of which a very fine sediment is seen of the constituents of the ashes; in a few drops, however, there are to be found crystals of common salt (*d d*); further, many loose crystals spread over the whole space (*c c*). Probably the little drops are due to the presence of some hygroscopic matter such as $MgCl_2$ or $CaCl_2$ around some salt crystals. Especially at the lower end of the whole drop assemble the larger, glassy, black and brown particles of the ashes.

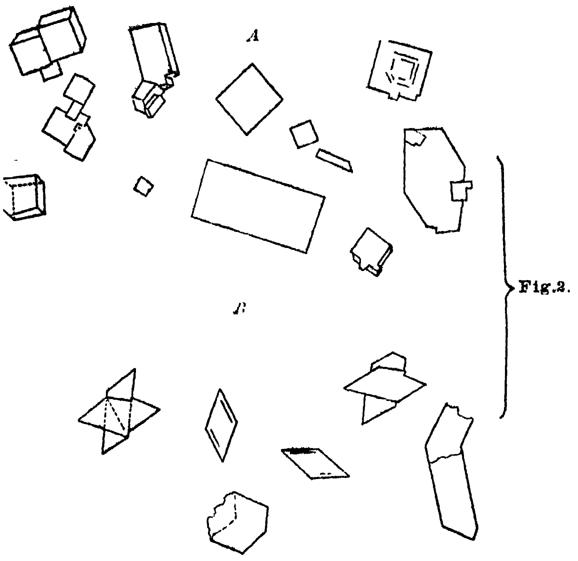

FIG. 2 (× 400).—Crystalline matter in the residue of Fig. 1. *A*, crystals of common salt; *B*, crystals of the andesitous mineral, insoluble in water.

The above proves that during the last few weeks crystals of a particular nature were floating in the air, and will perhaps explain the appearance of mock suns described by some of the observers of the after-glow.

In a sample of original ashes from Krakatoa, when examined in oil, I only found very few salt crystals, and the completely outgrown andesitous crystals not at all. I am, however, convinced that with longer research I should have found the latter, and others seem to have discovered them indeed, but they are without doubt very rare. So it seems to me that it may be taken for granted that in the atmospheric dust the proportionate number of completely formed crystals is larger than in the natural ashes, and the presence of so much common salt in the upper air during these days is surely a remarkable fact.

Wageningen, January 14 M. W. BEYERINCK

THE atmospheric appearances frequently seen during the last few months, principally at sunrise and sunset, from the similarity of some of the manifestations to auroral appearance, have led some persons to suspect connection of the phenomena with magnetism.

Hitherto auroral exhibitions have, at Greenwich, been invariably accompanied by considerable magnetic disturbance, and the absence of such disturbance on days on which the recent remarkable atmospheric phenomena have been seen at Greenwich seems conclusive as to the question of direct connection with magnetism. The Astronomer-Royal has therefore thought that a brief statement of the circumstances in this respect might be of interest to your readers. It appears that, either at sunrise or sunset, unusual atmospheric appearances were seen at Greenwich on November 8, 9, 13, 25, 26, 27, 28, 29, December 1, 2, 4, 5, 6, 7, 11, 17, and January 12 last. Of these days, on November 13 and January 12 the magnets were quiet, and on November 8, 9, 25, 26, 29, December 4, 5, 6, 7, and 17 very quiet; on November 27, 28, December 1, 2, and 11, there was a little motion. The whole period was quiet generally as regards magnetic activity; only at one time during the period from November 8 to January 12 was there any noteworthy disturbance, which occurred on the days from November 19 to 22, and in no case was it in any degree remarkable. WILLIAM ELLIS

Royal Observatory, Greenwich, January 26

ON p. 157 of your current volume you ask your "readers in all parts of the world" to communicate facts relative to the singular sunsets which have been seen.

Until seeing your request I had made no note of dates, but as far as I can trust my memory the "after-glow" was noticed here early in September, 1883. On one night it lasted about two hours after sunset. The phenomenon of "Contrast-Farben" mentioned by von Helmholtz in NATURE, December 6, 1883, p. 130, I have noticed most markedly on two occasions—once in October, and again on December 28 or 29, 1883. During this year the sunsets on January 5, 9, 12, and 13, have been accompanied by the "after-glow."

About 12 o'clock on the 13th I saw a peculiar colour in the neighbourhood of the sun, which on closer inspection was seen to be in the form of an ellipse, the major axis being in the plane of the meridian. The length of this axis was about 50°. The sun was situated nearer the upper extremity of this axis, in breadth about 20°. The colour of this ellipse was a pale reddish-violet ashen (if you can imagine such a combination). The sky at the time was a deep blue, except in the ellipse. I suppose the violet tinge was due to a combination of the red of what at evening forms the "after-glow" and the blue sky. There were a few clouds slowly moving from the west, and as one of these approached the sun, when within about 6 diameters of the sun, the edge nearer the sun became coloured a faint yellow; then followed pale pink, dark pink, green, then again dark pink in bands; as the cloud floated over the sun's disk one saw the bands of colour continuous, forming a halo. The clouds were of a fleecy texture; I believe they were "cirro-stratus," not, however, as open as what we call a "mackerel sky," and so tenuous that they did not appreciably diminish the sun's brilliancy. The sunset on this day (January 13) was followed by a most intense "after-glow," but of only short duration. The pink colour was at first in three broad rays, extending about 50° from the point at which the sun disappeared, the central ray almost vertical, one of the others on each side between the central ray and the horizon. After a short time the intermediate spaces became coloured red and then the colour ceased.

The colour itself when most marked I can best describe as that of burning cyanogen gas, a deep peach blossom. I have noticed that the brilliant after-glows here have been preceded by a dazzling glow, elliptical in shape, in the immediate neighbourhood of the sun, the outer edge of this ellipse being comparatively dull and marked, and not having the same colour as the sky a little further removed. The eastern horizon I have also seen tinged pinkish before the colours make their appearance in the west, and so marked has this been that I have regarded it as a sign of the coming after-glow.

I may add that for the last ten days the ground has been covered with snow, and the temperature during the early part of last week quite low, from 15°-20° F. during the day. During the end of the week the temperature was about 32° F.

I have written thus at length, hoping that there may be something of interest to you. Should you find anything it will give me pleasure; should you not, this will at least show you that some of your distant readers would like to aid you in paths which are not their own. W. G. BROWN

University of Virginia, U.S.A., January 15

The brilliant morning and evening glows have not yet left us. In connection with a letter of one of your correspondents of December 20, 1883, it may be interesting to add that the year 1783, which was characterised by a fearful eruption of Skaptar Jokul in Iceland, and by remarkable sky-colour phenomena similar to those we have lately had, was also the year in which the last *great* eruption of Asama Yama in Japan took place (see *Transactions of the Asiatic Society of Japan*, vol. vi. part ii. p. 327). Asama Yama is the greatest *active* volcano in Japan. In connection also with the unusual quantity of aqueous vapour with which the atmosphere has been charged, as proved by the spectroscopic observations of Prof. Michie Smith and others, and the facility that dust particles give for the formation of clouds, and therefore also of snow, it may be interesting to note that the beginning of the present year has been characterised by the greatest fall of snow that the oldest inhabitants here have known for thirty years. The minimum temperature reached this winter (– 28° C. on the morning of December 23 in the neighbourhood of the college) is also the lowest for Kingston during the same period. Prof. Goodwin is now engaged in analysing the snow in order to find out whether similar impurities to those found in Europe and in Java are present.

Circular Rainbow seen from a Hill-top

IN the *Philosophical Magazine* for January, 1884, p. 61, is an interesting article by Prof. Tyndall describing experiments made to produce circular rainbows by artificial light and artificial mist, his attention having been attracted to the subject by an observation made in the Alps on one occasion when the shadow of his body was projected at night time on to mist by a lamp behind him, and was seen to be surrounded by a luminous circle, or halo of light. I was so fortunate as to see lately identically the same effect produced with remarkable beauty and completeness in broad daylight from the summit of a Welsh hill. Staying last week for a couple of days at Pen-y-Gwryd, near Snowdon, in company with a friend, we walked one morning up the Glydr-Vach. The rain was steadily descending as we left the little inn, and the thick mist swathed the hill-sides in obliterating folds. Just as we reached the summit at noon a slight breeze thinned away the mist in front of the sun, and a burst of sunshine illuminated the hill-tops. Clambering on to the natural cairn which crowns the summit, we looked down into the valley, in which lies the small lake Llyn Idwal. Along the valley the wind drove masses of thin mist and scud, and on this we saw to our surprise the shadow of the summit with our own sharply-marked shadows projected on it. We waved our arms, and the mystic figures replied by waving theirs. Surrounding these immense shadowy figures we could see two concentric rainbows completely circular, the centre being the shadow of our heads. The colours of the inner rainbow were in the order of the primary bow, and the outer was a secondary and more faintly-tinted rainbow. During all this time the sun was shining brightly on our backs; when the wind cleared away the mist completely in the valley, the shadows and the rainbows vanished, but reappeared when fresh masses of vapour were blown into the line of our shadows. A very rough attempt at determining the angle subtended by the diameter of the primary bow seemed to show that it was much less than 90°, in fact not probably above 20°. This interesting appearance lasted only for a few minutes, as the wind drove up fresh mist in front of the sun, and the rainbow-circled phantoms disappeared. It would be interesting to know if any of your readers have ever observed a similar phenomenon. It has, I believe, been seen by balloonists when the altitude of the sun is great and a layer of mist and cloud lies beneath. Shadows thrown on mist are common; but this rainbow addition was new, not only to me, but to my friend, and his mountaineering experience has been very considerable.

J. A. FLEMING

Unconscious Bias in Walking

MR. LARDEN's letter in your issue of the 17th inst. (p. 262) regarding "circling to the left in a mist," and the replies of Messrs. G. H. Darwin and Hawksley, have opened an interesting question, and one which seems to be but imperfectly understood. The true explanation of this vexed question has for some years appeared to me to be that to which it is attributed by Mr. Hawksley, namely, inequality in the length of the legs. A few years ago I made some investigations on the length of the lower limbs in man, the results of which were published in the *Journal of Anatomy and Physiology*, vol. xiii. p. 502 (1879). I found that of seventy well-authenticated skeletons which I examined, the lower limbs were equal in length in only seven instances, or in 10 per cent.; in twenty-five instances, or 35·8 per cent., the *right* limb was longer than the left, while in thirty-eight instances, or 54·3 per cent., the *left* limb was longer than the right. The left leg I found not only to be more frequently longer than the right, but the difference in length between the two limbs is greater on an average when the left is the longer. Inequality in length is not confined to any particular age, sex, or race, but seems to be universal in all respects. My observations corroborated those of several American surgeons made on the living subject. The result of one limb being longer than the other will naturally be that a person will unconsciously take a longer step with the longer limb, and consequently will circle to the right or to the left according as the left or right leg is the longer, unless the tendency to deviation is corrected by the eye. The left leg being more frequently the longer, circling should, if this theory of its being due to inequality of the limbs be correct, take place more frequently to the right than to the left. This is precisely what we find to obtain, and in this respect Messrs. Larden, Darwin, and Hawksley's observations agree with some I made myself on this question. The diameter of the circle formed by those circling to the right should, if my observations on the skeletons be correct, be less than that made by those circling to the left, since the difference in length between the two limbs is greater when the left is the longer.

To determine the comparative lengths of the right and left arms I made observations on fifty skeletons (the first fifty of those measured to estimate the length of the lower limbs), the results of which I hope to publish soon. In thirty-six of these skeletons, or in 72 per cent., the right arm is longer than the left; in twelve, or in 24 per cent., the left arm is the longer; and in two, or 4 per cent., the arms are of equal length.

On comparing these measurements of arm and leg in the fifty skeletons the *right arm and left leg* are longer than the left arm and right leg in twenty-three instances, or in 46 per cent.; the *left arm and right leg* are the longer in six instances, or 12 per cent.; the *right arm and right leg* are longer than those of the left side of the body in thirteen instances, or 26 per cent.; the latter are the longer in four instances, or 8 per cent.; while in the remaining four skeletons the legs are of equal length but the right arm is longer than the left in two instances, and the arms are equal in two cases, but the left leg is the longer in one of those and the right in the other.

Asymmetry of both upper and lower limbs, then, is the rule, and not the exception, as might naturally be supposed. Not knowing the histories of the persons whose skeletons I measured, I am unable to throw any light as to the connection between the proportions of the limbs and right- and left-handedness.

The particular causes of inequality in the length of the bones of the right and left sides of the body will probably always be more or less a matter of theory. The general cause is, as Mr. Hawksley states, owing to more rapid growth of the one limb than the other. I do not think in the majority of instances it can be attributed to "illnesses to which we are subject in early life," as he surmises. Asymmetry is almost invariably found throughout the whole skeleton, for example it is extremely rare to find a skull the two sides of which are absolutely symmetrical. In the limbs it is perhaps more easily attributable to the blood-supply being greater to one bone than to another. The nervous system may also have to be taken into account as a cause.

J. G. GARSON

Royal College of Surgeons, London, January 26

I AM left-handed and left-footed; that is, if there is anything to do that requires strength or skill, the left hand is always used; in football-playing, or anything requiring the use of the foot, the left foot gets the work to do.

I remember being once lost in the woods in America whilst trying to make a short cut home, and, after walking a good many miles, came upon my own snow-shoe track on its left side; thus my bias had been from right to left.

In a bitter cold day with thick snowdrift and a gale of wind on our "left front," as a soldier would say, some men were on a sledge journey on the Arctic coast in 1847. It was important to reach a certain point, and each of the party in turn (including an Esquimaux) took the lead, but all failed to keep the correct course beyond a minute or two, so that the constant stoppages necessary to consult the compass were trying to the hands; in fact one of the native dogs, protected by a thick fur, fairly succumbed to the cold, and the poor thing had to be abandoned to its fate.

We at last thought of placing an Esquimaux boy of about fourteen as leader, and he managed to keep a straight course with wonderful accuracy, although he walked crab-fashion, sideways, so as to protect his face from the bitter blast.

Is Mr. Larden's theory correct, namely, "that those in whom the left leg is strongest would circle to the right?" I think not, because according to my idea it is the leg *from* which one steps, and not the leg that *takes the step* or that is placed in advance that imparts the impetus; so that a strong left leg would cause the step with the right foot to be longest, and the person would circle to the left. JOHN RAE

4, Addison Gardens, January 26

WITH reference to the letters by Messrs. Darwin and Hawksley in the current number of NATURE (p. 286), I may say that I am very strongly "left-legged" (also strongly right-handed), but so far as I am aware there is not the slightest difference in the *lengths* of the two limbs. I became aware of the peculiarity when a child, by noticing that on a slide the other boys used to go right foot first, and I left foot. Subsequent attempts to break myself of the habit only resulted in my coming ignominiously to grief, and if I tried now to leap a ditch right foot first I would tumble headlong into it instead of clearing it. The next time I find occasion to *kick* I will *try* to remember which foot was used. It is right to state, however, that in my case I think there has probably existed from infancy a very slight natural weakness of the right ankle. Attempts with me to walk a straight line with the eyes shut seem invariably to result in my swerving to the *left*, which appears to be contrary to Mr. Darwin's experience.

Lewisham, January 25 R. McLACHLAN

MIGHT not the longer step taken by one leg be explained as follows:—

Most people when standing at ease habitually throw their weight on one leg; but, whichever it be, its movement is more likely to disturb the balance of the body. It would therefore be more quickly replaced on the ground, and a shorter step would result.

The unequal steps would not necessarily effect a circular course, as may be easily shown by experiment. A divergence, say, to the right would be caused by the left leg swinging in its step towards the right, and such would be its natural movement if the body inclined to the right. Now a person who constantly stands more on the right leg than the left would have that inclination in his walk, in spite of the alternate removal of the burden from each leg. This tendency to lean towards the right would be still further encouraged by the ancestral or individual use of the walking-stick in the right hand.

The suggestion of Mr. G. H. Darwin (January 24, p. 286) that the mounting a horse on the left side may be accounted for by the sword is strengthened by the freedom of the sword-arm requiring that the left hand be used to grasp the reins, which is the first act in mounting. There would be a momentary want of control over the horse if, under these circumstances, it were mounted from the right side. F. M. CAMPBELL

Rose Hill, Hoddesdon, January 28

IN a letter to you about another subject Mr. G. H. Darwin suggested last week that the British rule of the road for riding was justified by the advantage of having your sword hand towards a stranger, but why then should the rule of the road in walking be, what I understand it to be, the reverse of the rule in riding?

I would suggest that perhaps the rule in riding is adopted from the rule in driving, and that the latter results from the fact that a driver may be assumed to carry his whip in his right hand and therefore to sit to the right if there be two on the driving seat, and that when he is so seated he can see better how he is passing another vehicle if our rule is adopted.

This, like Mr. Darwin's suggestion, would leave us without xplanation why most nations have adopted a rule the reverse f ours.

It would perhaps be hardly scientific to say it is because Englishmen are always right and foreigners always wrong, nor would it be much more so to say that it is because English drivers like to make a close shave and foreigners as a rule give an obstacle a wide berth, for the latter fact, if it be an observed fact, may be the effect, not the cause, of the rule of the road. Can it be that the foreign rule was adopted where it was customary for the driver to sit alone on his seat and could therefore see equally well on both sides, and at the same time wished to have freedom to use his whip. STEPHEN A. MARSHALL

Diffusion of Scientific Memoirs

WHEN, in reviewing Prof. Stokes' *Reprint*, I spoke of "the almost inaccessible volumes of the *Cambridge Philosophical Transactions*," I was referring *expressly* to the *Transactions* only, and to the period 1845-54. That there are *now* 120 "centres" in which "*Transactions* or *Proceedings*, or both" are accessible, is an interesting and important fact, but wholly beside the question raised by my remark. [I leave out of account copies sent to Honorary Fellows; for these are not more accessible than those obtained by Ordinary Fellows.]

The question at issue between the Secretary of the Society and myself is:—What was the state of matters in 1854? Mr. Glazebrook gives me data for the present time, and for 1869, only. From these it is not possible to obtain more than an approximate answer to the question. But, in default of further data, I assume that (in accordance with the published statistics of similar Societies) the number of Hon. Fellows of the C.P.S. has not changed since 1854; and that the increase of "centres" from 1854 to 1869 was nearly the same as from 1869 to the present time. It follows from Mr. Glazebrook's data that the number of "centres" in 1854 must have been about 40 only.

But I referred to *Transactions* alone, not to "*Transactions* or *Proceedings*, or both." To obtain a rough idea of the correction to be made on this account, I take the numbers for the *Royal Society of Edinburgh* (with which I am best acquainted, and which are at least as large as those for the *Royal Society*). In Mr. Glazebrook's form of statement, these numbers are at present

Hon. Fellows	56
Total number distributed	343

Deduct the first number, and there remains 287. But of these "centres" 96 (one-third, say) receive *Proceedings* only.

Hence it would appear that, in 1854 and previous years, to which alone I referred, the *Cambridge Philosophical Transactions* were to be found at some 27 "centres" only; say 10 at home and 17 abroad. Surely this would much more than justify the term "almost inaccessible"!

I cannot recollect having made any application for the C.P.S.'s publications, though I have often asked Cambridge friends why I did not get them regularly. But, according to Mr. Glazebrook's view, I should either have received all, *or none*.

The state of matters, in the three Edinburgh "centres" to which Mr. Glazebrook alludes, is at present as follows:—

All three "centres" have the *Transactions* complete; except the University Library, which wants vol. xiii. parts 1 and 2.

The Advocates' Library has *not* the *Proceedings*; the Royal Society wants vols. i. and ii., all but a few pages; and the University Library wants vol. iv. parts 1, 2, 3, 4, 5. Thus one "centre" has no *Proceedings*, another has almost half, and the third three-fourths.

I must, in concluding, repeat my hope that NATURE may do a new and great service to science by collecting full statistics as to the "centres" at which the publications of the various scientific Societies are accessible. P. G. TAIT

College, Edinburgh, January 26

Water in Australia

REFERRING to my letters in NATURE of May 12, 1881, and March 30, 1882, on the underground water supply of Australia, it is interesting to observe that the search for it is being actively carried on by some energetic colonists, and that their efforts are successful. The following extract from *The Queenslander* of May 26, 1883, shows what can be done:—

"The subterranean waterflow now proved to exist beneath the vast arid plains of the west has been tapped at yet another point, and the discovery of another invaluable spring of fresh water is the result. Recently we have had many discoveries to record, all tending to encourage the search for underground water, on the supply of which the pastoral industry of this district so much depends; but none has been of more value to the discoverers or has tended more to encourage others to persevere in spite of difficulties. This latest discovery was made last week in the country known as the Pack-Saddle, forming the western portion of Messrs. Donelly and Co.'s Gnalta run. The well was started in the summer of 1881, but had to be abandoned some time after for want of water for the use of the men, and Mr. Donelly was urged to choose another site. He persisted, however, in continuing the original work as soon as surface water was available, and he has now come upon a practically inexhaustible spring. The flow was cut at 272 feet in a properly slabbed 6 feet × 3 feet shaft, and during the night following the water rose 172 feet, or within 100 feet of the surface. The discovery is worth every penny of 10,000*l.*, as it renders immediately available a large tract of good country hitherto dry and therefore comparatively useless. There is another fine well on Gnalta, from which 30,000 sheep have been watered in the dry season, and that discovered last week promises to be as good, if not better."

In my first letter I pointed out as one evidence of the underground water the growth of huge gum trees where there was no visible supply. In a recent number of the *Scientific American* it is stated that, on clearing out a well, the owner was surprised to find the bottom covered with a dense mass of fine, fibrous roots, which were traced to a Eucalyptus growing at a distance of fifty yards. The large Eucalypti are trees of remarkably rapid growth, which implies the absorption of large quantities of water. By what subtle sense did that root find out where water could be had, and travel so far to get it? Darwin has shown that there is some kind of irritability in the growing points of plants, and that it is sometimes communicable to distant parts. We shall probably come in time to admit that there is a nervous current in plants, though without visible nerves; and that this rudimentary system of sensation is accompanied by rudimentary desires, and even by rudimentary ideas, which guide the growing points in their search for the desired objects.

F. T. Mott

Birstal Hill, Leicester, January 20

Deafness in White Cats

This subject has been of much interest to me, and otologists as well as evolutionists must feel indebted to your contributor in Nature of December 13, Mr. Lawson Tait, for his efforts to determine the cause. May I be permitted, however, from an otologist's point of view, to draw attention to a possible source of error in conducting researches of this kind when deductions are made, as they were in this instance, from acoustic experiments mainly? I allude to Mr. Tait's method of determining the hearing power of the animal experimented on, namely, his cat, "Old Pudge," and the conclusions that he has drawn from the results obtained; thus he infers that purely "tympanic" deafness, consisting in an entire failure of the transmitting mechanism of the middle ear to respond to aërial undulations of sound, existed in the case of "Old Pudge," *because* the concussion produced by stamping on the floor could be heard by that animal, whilst the voice was not heard. Abnormal hearing of this kind, I am convinced, by no means establishes the fact that inner ear trouble does not exist, since such deaf-mutes as are believed to be defective in this regard are very sensitive to grave or deep tones—thunder, for example, being painful even to them. Pudge's cochlear (inner ear) functions were believed to be serviceable, inasmuch as he could use his voice; but such evidence cannot be accepted as conclusive, for absolutely deaf persons, who have been deprived of both "tympanic" and "cochlear" functions, are yet capable of making noises, and often of learning to speak after a fashion. Another point is also of interest in this connection: the ears of Pudge, it is said, were found to be normal in every respect, both as to their transmitting and perceptive functions, with the exception of the absence of a triangular gap from either tympanic membrane. In reference to this it may be said, in the first place, that it is difficult to understand how the delicate mucous membrane lining the tympanum retained its "normal" condition under such exposure; and, in the second place, these defects could scarcely be the cause of absolute deafness, since it is a well-known fact that quite good hearing often remains in the human subject where, from disease, much greater loss in the tympanic membrane has been sustained than was found to exist in the hearing organs of Pudge. Altogether it seems probable that in certain white cats great congenital deafness may exist, and that the animal, on finding aërial transmission of sound to be imperfect, comes finally, like man under similar circumstances, to disregard its use entirely, and place its reliance solely on sound that can be *felt*, as it were. Moreover, is it not probable also that the trouble, in some degree at least, may lie in the perceptive centre of the brain? It is a significant fact that in Pudge at least some disease of the nervous centres existed, since he was the subject of epileptic convulsions.

Samuel Sexton

12, West Thirty-fifth Street, New York, January 3

FURTHER DISCOVERIES IN THE FLORA OF ANCIENT EGYPT[1]

Since my last communication on the Flora of Ancient Egypt (Nature, vol. xxviii. p. 109) I have made some interesting new botanical discoveries in connection with the mummies of the twenty-first dynasty, found at Deir-el-Bahari in July, 1881, which I will now describe in some detail; the objects having been forwarded to the Museum of the Royal Gardens, Kew.

In the coffin of the Princess Nzi-Khonsu of the twenty-first dynasty there was a large number of well-preserved wreaths, in which I found three species of plants of the ancient flora not previously authenticated by specimens. Besides wreaths of the leaves of *Mimusops Schimperi* and the petals of *Nymphæa cœrulea*, already described from examples found on the mummy of Ramses II., there were on the mummy of the Princess Nzi-Khonsu, daughter of Tontonthuti, numerous floral wreaths composed as follows: (1) folded leaves of a willow (*Salix safsaf*) strung on threads of the leaves of the date palm, and serving as clasps; (2) perfect flowers of the corn poppy (*Papaver rhœas*); (3) complete flower-heads of a corn flower (*Centaurea depressa*); and (4) complete flower-heads of a composite (*Picris coronopifolia*).

The flowers of *Papaver rhœas* equal in size those of the small form one has an opportunity of seeing in such abundance in the Mediterranean region in the spring months as a weed in cornfields, by roadsides, and on walls. In order to prevent the petals from falling, the flowers were picked in an unopened condition; and in drying in the vault the petals had shrivelled and shrunk up into a ball, to which circumstance is due the fact that in examining the moistened flowers all the inner parts appear before the eyes in a wonderful state of perfection. Not a stamen, not an anther is wanting; nay, one might almost say that not even a pollen-grain is missing. Rarely are such perfect and well-preserved specimens of this fragile flower met with in herbaria. The colour, too, of the petals is maintained in a high degree, as in dried specimens of the present day. It is a dark brown-red, that leaves a deep stain on the paper where the flowers have been soaked. The very caducous sepals were wanting in the flowers examined; but all the peduncles were thickly beset with the characteristic, horizontally-spreading, bristly hairs. The petals are destitute of the dark spot on the claw which is common to many varieties of the species. The naked ovary is shortly obovate in shape, or, in some of the very young flowers, cylindrical, though never so much elongated that one could doubt its belonging to the genuine variety described by Boissier in his "Flora Orientalis." The stigmatic disk is obtusely and broadly conical; and the rays vary in number from eight to ten. The edge of the stigmatic disk is bordered with orbiculate, auriculate, white appendages incumbent upon it. The anthers are oblong, twice as long as broad, and the filaments subulate. The smallness of the flowers (2½ cm. in diameter), the broad petals, the red colour, the bristly peduncles, the 8–10 stigmatic rays, the oblong oval anthers, the subulate filaments, &c., point conclusively to the determination of the plant as *Papaver rhœas*, var. *genuina*.

---

[1] This article was sent by the author, Dr. G. Schweinfurth, to Sir Joseph Hooker, together with the botanical objects described therein. The original is in German, and the translation here given is as nearly literal as possible.—W. Botting Hemsley.

At the present time this species is found nowhere in Upper Egypt, and also appears to be absent from the whole Nile Valley, while it is met with in abundance near Alexandria and on the Mediterranean coast as a weed in cornfields.

The flower-heads of *Centaurea depressa*, the involucral part of which is 15 to 17 cm. in diameter, belong to a form that is now met with in Persia and Afghanistan; whereas in many countries—Greece, for instance—only small-headed varieties seem to occur. The peduncle served, as in the poppy flowers, to fix the heads in the garlands, which was not always the case in the ancient floral wreaths.[1] Two or three of the leaves are still left on many of the specimens. They are narrow-linear, almost sessile, and exhibit, besides the arachnoid-canescent pubescence characteristic of the species, the peculiar prickle-like tip, which is several millimetres long, and serves to distinguish *C. depressa* from its only allies *C. cyanus* and *C. cyanoides*. From most of the leaves, however, this brittle appendage has fallen, in consequence of repeated handling of the wreaths. Close under the base of the flower-heads appear some linear bracts, shaped like the upper leaves of the stem. In the ancient specimens these bracts were present in unequal numbers, from two to seven, and often wanting altogether. They do not overtop the whole involucre. This character was rather against the correctness of the identification, for such bracts are not usually present below the heads of *C. depressa*, though they are in *C. cyanoides*, which differs very much in having pappusless achenes. But I have seen a recent specimen (Afghanistan, Griffith, 3294) having one or two leafy bracts at the base of each head. In the recent forms of *Centaurea depressa*, the lanceolate teeth of the membranous margin of the involucral bracts are sometimes colourless, sometimes brown at the base. In the flower-heads of the twenty-first dynasty these teeth are deep brown in the middle, with a white margin and a white tip, and they are here, as the specific character requires, a little shorter than the breadth of the bract. The three or five teeth at the tips of the bracts are grown together about half their length. On the lowermost bracts of the involucre the teeth are quite decurrent and colourless; on the upper they are more limited in number—from eleven to fifteen—and only towards the tip. In consequence of the incautious handling of the wreaths when the coffin was opened, the beautiful ray-flowers, which in this species are exceptionally large, are mostly fallen away. In many heads, however, they are still attached, and exhibit a dark violet colour, similar to recently-dried specimens. The lobes of the limb of the corolla are broad, almost ovate and acuminate. Very well-developed achenes occur in the ancient flower-heads, affording indubitable evidence of the correctness of the determination of the species. The achene is light in colour, shining, slightly laterally compressed, and oblong-ovoid in shape. The areole incloses half the length of the achene, and at the base there are a few small hairs, as in recent specimens from Schiraz (Kotschy, 302), Afghanistan (Griffith, 3294), and from Sber (C. Koch), while others from Asia Minor are quite naked.[2] The intermediate bristles of the pappus are one-fourth longer than the achene, the inner ones half as long. The long prickly tips of the upper leaves, the large, broadly-lobed ray-flowers, and the achene bearing a pappus exceeding it in length, prove that the flower-heads of the mummy-wreaths belong to *Centaurea depressa*. This species is wanting in the present flora of Egypt as well as in that of the contiguous countries. It now occurs as a cornfield weed in all parts of Asia Minor, Armenia, Persia, Afghanistan, Beluchistan, and West Thibet; and Prof. Heldreich found it around Tripolitsa, in Arcadia, and in the Attic Plain, near Hergellon. In the last-named country the species flowers in April. There are no localities for this plant in Syria and Palestine to my knowledge. Specimens of this Centaurea from ancient Egyptian wreaths are preserved in the museum at Leyden.[1] It is not stated, however, from what epoch they date.

Many of the wreaths of the mummy of Nzi-Khonsu consist entirely of willow leaves and the flower-heads of *Picris coronopifolia*, Asch.[2] The numerous features in the parts of the flower-heads which characterise this species are easily seen in the ancient specimens, and not a single peculiarity is apparent by which it might be distinguished from the recent small form with low-spreading branches, now so common on the outskirts of the desert.

The indumentum of the involucral bracts is particularly well preserved. The bracts themselves are long lanceolate with an undulated membranous naked edge, and taper off into a long point; while on the outside along the midrib they are furnished with one to three rows of spreading bristles, glochidiate at the tip, and between these a white arachnoid felt—the same kind of tomentum clothing the peduncles. The achenes of the ray are smooth and cylindrical, more or less curved, as thick at the tip as in the middle, and crowned with a pappus of short persistent bristles cohering about half their length. The achenes of the disk are broadly club-shaped, somewhat constricted at the tip, and provided between the ten angles with two rows of small round tubercles. The pappus consists of bristles plumose at the tips and is deciduous, and exceeds the achene in length five times.

The dissimilarity of the inner and outer achenes of the ancient Egyptian *Picris* at once shows that it belongs to the section *Spitzelia*, Schultz Bip. The smallness of the flower-heads and the nature of the indumentum prove that it belonged to the small desert form, still common about Thebes, and not to the large-headed, otherwise hairy, varieties (*Picris lyrata* and *P. pilosa*), only found in the neighbourhood of Alexandria, and on the coast of the Mediterranean Sea. The ultimate inflexion of the involucral bracts over the ripening achenes ("phyllis demum carinatis, incurvis") is perceptible in many of the flower-heads from the ancient wreaths.

Picris coronopifolia belongs to that set of desert plants which are usually only found on the border of the desert as far as the waters of the Nile reach by infiltration. It is not met with in the valleys and channels of the lower desert strips any more than among the weeds which follow cultivation in the black earth of the Nile alluvium. It generally grows associated with *Crepis senecioides*, *Leontodon hispidulum*, *Picris sulphurea*, *Lotus pusillus*, &c., which likewise belong to the flora characteristic of the borders of the desert. The flowering time of these plants in Middle Egypt is March and April. In February they only begin to develop, and it may be assumed that the flora of Thebes is from two to four weeks in advance of that of the neighbourhood of Cairo. From the occurrence of the flowers of *Picris coronopifolia* in the wreaths of the mummy of Nzi-Chonsu we may conjecture that the solemn rites of placing this princess in the vault took place in March or April. The assumption that it took place in February or May would be doubtful, and it is very unlikely to have happened in any other months of the year. At Thebes the floral carpet is quite dried up and destroyed as early as April, and in the district of Cairo in May, so that there would have been great difficulties attending the collection in one day towards the end of April of the large number of flower-heads requisite for the preparation of the wreaths of Nzi-Chonsu. And as far as the other flowers of these wreaths are concerned February to March are the only admissible months. This applies especially to the flowers of the poppy, which even in Alexandria disappear towards the end of April.

---

[1] Thus, for example, only flowers of *Sesbania ægyptiaca* with half of the calyx cut off were used.

[2] Hooker, "Fl. Brit. Ind.," iii. p. 385, in his diagnosis of the species has "basal areole bearded."

[1] According to Prof. P. Ascherson in *Zeitschrift für Ethnologie*, ix. Jahrg., 1877, and Dr. W. Pleyte in 2 Bylage tot de 35ste Jaarver-gadering der Ned.-Bat. Vereeniging, 29 Juli, 1882.

[2] Boissier, in his "Flora Orientalis," iii. p. 740, reduces this species to *Crepis radiata* (= *C. senecioides*, Del.), and this is done by many other authors. *Picris lyrata*, Del., and *P. pilosa*, Del., can only be regarded as varieties of *P. coronopifolia*, Asch. (*Leontodon coronopifolium*, Desf.).

If we are able, from our knowledge of the seasons of the present Egyptian vegetation, to limit the interment of a mummy to a short series of months, it follows therefrom the fact, that in the case of the date of the funeral rites attending the placing of a mummy in the final tomb being originally indicated in the inscription on the coffin or elsewhere, light might be thrown on the theoretical determination of the relative Sothis (Sirius) periods. In chronological determinations, which, as far as concerns ancient Egypt, anterior to the time of the twenty-sixth dynasty, are still open to grave suspicion, the aid thus possibly attainable is not to be despised. We know from the hieroglyphical writings, the temple inscriptions and ornamental pictures of the temple, that the ancient Egyptians had a great predilection for their gardens; and we learn from the narratives of their crusades in distant countries that they gave a prominent place to foreign vegetable productions, even in their triumphal processions. Amongst objects met with in the funeral repasts and in the offerings in the tombs there are, moreover, so many products of evident foreign origin, that we cannot be surprised at finding that many of the flowers and leaves employed in the composition of the funeral wreaths and garlands could not have belonged to the native flora of the country, but must have been cultivated expressly for the purpose. This may, then, have been the case with *Centaurea depressa*, which, like *Alcea ficifolia* and *Delphinium orientale*, suggests Western Asia, and especially the countries of the Upper Euphrates. As far as *Papaver rhœas* is concerned, it may also be assumed that it was cultivated by the ancient Egyptians on account of its brilliantly coloured flowers, although this does not exclude the possibility, independently of any necessity for a change in the climate to have taken place in the interval, that the common poppy was not such an extraordinary rarity in the cornfields of that period as it is at the present time.

Among the mummies of the twenty-first dynasty discovered at Deir-el-Bahari, there may lie hidden a number of plant remains still unknown to me; as a careful search through the coffins, especially as far as those mummies are concerned which are still preserved with their wrappers intact, was for many reasons necessarily postponed. The garlands, particularly, in those coffins, composed as they are of various leaves and flowers, may be expected to furnish many novelties to the ancient flora of Egypt. Among a few fragments of the wreaths of Mimusops leaves and Nymphæa petals that have reached the Natural History Museum of Milan there accidentally appeared a detached corolla of a Jasmine, which may belong to *Jasminum sambac*, a species still commonly cultivated in Egyptian gardens. The Egyptian Museum in the Cairo suburb of Boulak contains in addition a number of plant remains of authenticated species taken from earlier explorations of tombs that would go to enrich the flora of ancient Egypt.

In the spring of last year Dr. Maspero discovered in the well-known burying-place of Nofert Sekeru, near Sheykh Abdel Gurna, Thebes, an unopened vault of later date, in which was a well-preserved female mummy of the Greco-Roman period. This mummy is swathed from head to foot in wreaths of the leaves of Mimusops, without any flowers. These leaves are larger (eight centimetres without the petiole), because fully grown, than those in the older garlands. The petioles are broken off short, and the whole construction of the wreaths is of a much ruder and more careless description. Specially interesting in this mummy is a wreath around the forehead composed entirely of the leaves of *Olea europæa*. These leaves are also folded and threaded edge to edge with the tips directed upwards; but the mode in which they are sewn together is different from the other wreaths, being done by a coarse string of a fibrous material as yet unknown. The Leyden Museum possesses similar funeral wreaths of olive leaves,[1] and in the Berlin Museum there are some bundles composed of branchlets of the olive tree. Whether the "wreath of justification" mentioned in the obituary of Osiris was such a wreath of olive leaves, or whether under this designation the garlands of Mimusops and willow leaves which encircled the neck and breast of the mummies were intended has not yet been ascertained.

Moreover, Theophrastus, Pliny, and Strabo authenticate the presence of the olive in Upper Egypt. According to Theophrastus (iv. 2, 9) the olive tree grew in the Theban province. According to Strabo (xvii. § 293) olive trees were only found in Fajum and in the vicinity of Alexandria. Now the olive tree flourishes in Lower and Middle Egypt, and very old trees exist in Fajum and in the Oases.

In a special glass case in the Egyptian museum at Boulak is a variety of objects which formed the funeral repasts and offerings in a vault at Dra Abu Negga (Thebes) of the twelfth dynasty (2200 to 2400 B.C.) Among them are the following vegetable products: grains of barley[2] and wheat; tubers of *Cyperus esculentus*; kernels of *Mimusops Schimperi*; fruits of *Punica gravatum*, *Ficus Carica*, *Balanites ægyptiaca*, *Hyphæne thebaica*, *Medenia argun*; a water-flask of *Lagenaria vulgaris*; two cones of *Pinus Pinea*; a mess of *Lens esculenta*; two seeds of *Faba vulgaris*, and one seed of *Cajanus indicus*; a broom made of *Ceruana pratensis*; a bowl full of capsules of *Linum humile* intermixed with pods of *Sinapis arvensis*, var. *Allionii*. Among the plants here cited the Linum deserves special consideration, for, notwithstanding our ample knowledge of its cultivation, thanks to the records of the early authors, botanists who have busied themselves with the investigation of the vegetable remains of ancient Egypt have hitherto not been able to determine with certainty the species of Linum cultivated.

Linum capsules of the twelfth dynasty exist in a very good state, together with the calyx and pedicel, the latter two centimetres long. They are all closed, although the seeds appear to have attained perfect maturity. The length of the capsules reaches 8 millimetres, and the breadth 6·75 millimetres; and the seeds are 5 mm. long. The dimensions given are very little inferior to those of the capsule of the Linum, cultivated in Egypt at the present day. In external characters it is so like the capsule of the flax now cultivated, that one detects no difference at first sight; and it is only after cutting the seed through that one becomes aware of the change wrought in the course of 4000 years. The proportionate size of the seed, which is much narrowed upwards, but above all the numerous long weak hairs which occur on the inside of the partitions of the capsule, leave no doubt as to the ancient flax belonging to the kind exclusively cultivated still in Egypt and Abyssinia, the *Linum humile*, Mill. (syn. *Linum usitatissimum*, Linn., var. *crepitans*, Schübl. and Martens).

Another coincidence in the ancient and modern Linum cultivation is the presence among the ancient capsules of numerous seed-vessels of a species of mustard which is still the commonest and most flourishing weed in every flax field in Egypt. The pods of mustard are almost spherical in shape with a long point, and are seated on pedicels a little less than half the length of the whole pod. Judging from the shape described, the pods must belong to one of the two varieties, common in Egypt, of *Sinapis arvensis*, Linn., namely, *S. Allionii*, Jacq., and *S. turgida*, Del., for the common form of this species is distinguished by elongated pods. As the two varieties named can only be distinguished from each other with certainty by the degree of cutting of the leaves, it would be difficult to decide to which of the two the pods of the twelfth dynasty belong were it not for the circumstance that as *S. Allionii*, Jacq. (characterised by the long-pointed much-divided leaves), is the prevailing form at the present time in Middle Egypt, a probability offers itself that the ancient pods belong to this form. On the other hand *Sinapis arvensis*, Linn., var. *turgida*, Linn., affects the winter cornfields.

---

[1] They belong, according to Dr. Pleyte, to a mummy of the time of Osorkon (twenty-second dynasty). See also De Candolle, "Physiologie," p. 696.

[2] In this museum is also preserved a bowl containing broken ears of barley of the time of the fifth dynasty (3300 to 3500 years B.C.) which was found near Sakhara.

It may be assumed that this species of wild or colonised mustard answers to the Sinapis to which Pliny refers (lib. xix. 54 [8]), as a plant commonly met with under such conditions, and of which he asserts that the Egyptian was the best for yielding oil, and that the Athenians called it Napy, others Thapsi, and others again Saurion.

Lentils, as far as I know, have not hitherto been authenticated from the ancient graves. Pliny (lib. xviii. 31) mentions them as a product of Egypt, where two kinds of them were cultivated. The lentils of the twelfth dynasty appear in consequence of boiling and subsequent shrivelling to have lost a considerable part of their bulk. They are 3½ mm. in diameter, while the recent ones average 4½.

From *Ceruana pratensis*, a characteristic composita of the banks of the Nile, which has hitherto only been found in Nubia and Egypt, the ancients made those hard hand brooms, still met with in every part of Egypt, and used for sweeping out the houses and especially the privies; for which purposes they are offered for sale in all the markets. The Egyptian department of the British Museum contains a similar specimen.

Furthermore, the two pine cones (*Pinus Pinea*) noted belong to a species not previously known from the ancient Egyptian relics. Like *Parmelia furfuracea* and the juniper berries (*Juniperus phœniceus*), they point to the commercial relations that existed between Egypt and Greece, Asia Minor and Syria. The pine cones which were found in a large basket filled with numerous kinds of fine linen thread, fruits of the Doum palm and a small calabash of Lagenaria, are small and unripe, the scales clinging close together. It is evident that only such of these rare northern exotic fruits as were unsuitable for the table were put in the offerings.

Among objects not previously authenticated from ancient Egypt are the legumes *Faba vulgaris* and *Cajanus indicus*. Unger[1] suggests that the broad bean (*Faba*) was probably not found in the tombs because it was regarded as unclean.[2] The two seeds in question were found amongst dried grape-skins and matters of that kind. In shape and relative size they fully correspond to the variety cultivated on a large scale in Egypt at the present day. They are smaller, rounder, and thicker than the European broad bean.[3] The dimensions of the ancient beans are 10, 8, and 6½ mm.

Pliny (lib. xviii. 12 [30]) says of the broad bean that it was used in funeral solemnities; hence the priests ate none, &c. Perhaps the presence of the broad bean in the offerings of the twelfth dynasty had a meaning similar to that which it had for the Romans.

Among the funeral offerings of the ancient Egyptians often occur messes of a pap of roughly cut or coarsely ground grain of barley. They are in small earthen bowls, placed on the floor of the vault like the other offerings. In Prof. Maspero's opinion these messes of barley, which are in no way suitable for human nourishment, answer to the Mola (*Mola salsa*) offerings of the Romans of earlier epochs; and I would hazard an explanation of the presence of the broad beans in the offerings of the twelfth dynasty as an example of a possible analogy between ancient Rome and ancient Egypt. For, supposing the correctness of Herodotus's account that the ancient Egyptians regarded the broad bean as unclean, that they ate it in no shape or form, and that their priests could not bear the sight of it, some explanation for its presence must be found. The single seed of *Cajanus indicus* found with the broad beans in no way differs from the Upper Egyptian variety with yellow flowers. The plant, which is cultivated and wild all over India, as well as in all parts of tropical Africa, is nowhere cultivated in Egypt, though it occurs here and there in a wild state in Upper Egypt. It is certainly one of the oldest cultivated plants in the world, a fact further attested by its discovery in the ancient tombs. G. SCHWEINFURTH

[2] Compare "Herodotus," ii. p. 37.

[3] The author most likely alludes to the variety called "field" or "horse-bean" in this country.—W. B. H.

METAMORPHISM AMONG DEVONIAN ROCKS

THE tract of Devonian rocks which stretches through the north of France and Belgium, and across Rhenish Prussia into Westphalia and Nassau, has furnished ample materials for geological disquisition. Among the problems which it presents to the observer, not the least important is the remarkable metamorphism of certain bands or areas of its component strata. Dumont first called attention to this feature in the Belgian Ardennes. It was subsequently shown by Lossen to be extensively developed in the Taunus. More recently the question has been attacked anew with all the appliances of modern petrography. M. Renard has subjected some of Dumont's original localities to a critical revision, which has resulted in a confirmation of the accuracy of that remarkable geologist's observations. The latest contribution to the literature of the subject is a paper (*Annales Soc. Géol. du Nord*, vol. x. p. 194) by Prof. Gosselet, who at first refused to admit the metamorphism contended for by Dumont and corroborated by M. Renard, but who now comes forward with independent evidence in its support, from another locality. He describes the arkose of Haybes and of Franc-Bois de Villerzies on the frontier of Belgium as having undergone such a metamorphism as to be no longer recognisable. M. Barrois reports that on examining microscopically some sections of the altered rocks, he found among them bi-pyramidal crystals of quartz with liquid inclusions and movable bubbles, as in the quartz of pegmatite. These crystals have been broken *in situ*, with conchoidal fractures, and the surrounding paste appears as if injected into them. This paste is composed of small irregular quartz-grains like those of schists, and is coloured by fibrous chlorite, so arranged as to impart a more or less schist-like structure. The chlorite, arising from alteration of biotite, is predominant in some specimens, while the quartz-grains preponderate in others. M. Barrois compares this altered arkose with some porphyroids and some granitic veins in Brittany recently studied by him. Prof. Gosselet shows that these crystalline intercalations are portions of the true Devonian strata, and he accounts for their highly altered condition by what he terms a metamorphism by friction. A portion of the Devonian rocks has slipped down between two faults and has undergone great lateral pressure, and has in consequence been heated sufficiently that metamorphism has been determined in it. The extent of change has been proportionate to the degree of pressure. The metamorphosed arkose is provisionally referred to the Gedinnian division of the system.

M. Renard is understood to be at work upon a detailed memoir on the metamorphosed rocks of the Ardennes, in which their chemical constitution and microscopic characters will be fully described.

THE RECENT STORM

THE great and destructive storm of Saturday and Sunday last may almost take rank as a historical event, seeing that on the Saturday evening atmospheric pressure fell considerably lower in Scotland than is known ever to have occurred in these islands since the barometer became an instrument of observation. This remarkable barometric fluctuation, as observed at Edinburgh, is shown by the following observations made on those two days, the observations being reduced to 32° and sea level :—

	Barometer Inches		Barometer Inches		Barometer Inches
Saturday.		Saturday.		Saturday.	
9.0 a.m.	28·934	5.30 p.m.	27·853	9.30 p.m.	27·467
2.0 p.m.	28·376	6.0 ,,	·819	10.0 ,,	·451
2.30 ,,	·266	6.30 ,,	·779	10.30 ,,	·464
3.0 ,,	·167	7.0 ,,	·721	11.0 ,,	·505
3.30 ,,	·064	7.30 ,,	·6·1	11.30 ,,	·565
4.0 ,,	27·984	8.0 ,,	·580	Sunday.	
4.30 ,,	·934	8.30 ,,	·516	3.0 a.m.	27·835
5.0 ,,	·921	9.0 ,,	·494	4.30 ,,	·968
				9.0 ,,	28·311

As the barometer was closely watched for some time before and after 10 p.m., and no change was observed, the reading 27·451 inches may be regarded as absolutely the lowest that occurred. Since the wind veered during the storm from S.E. by S.W. to N.W., the centre of the storm passed to the northward, and along its path still lower readings were doubtless recorded.

The following observations have been already received, showing in inches the lowest observed readings and the hour when they occurred :—Moffat, 27·662 at 10·15 p.m.; Marchmont, near Duns, 27·581 at 11 p.m. ; Inverness, 27·516 at 11·10 p.m. ; Fort William, 27·467 at 8 p.m. ; Joppa, near Edinburgh, 27 464, Leith, 27·453, and Edinburgh, 27·451, at 10 p.m. ; Glasgow, 27·427 at 9 p.m. ; Dundee, 27·382 at 10·30 p.m. ; Ochtertyre, near Crieff, 27·332 at 9·45 p.m. ; and 27·400 is stated to have occurred at Aberdeen. With the observations made at the 160 stations of the Scottish Meteorological Society, it will, in a few days, be easy to trace the history of this extraordinary atmospheric depression in its passage across the island.

At Ben Nevis Observatory, the lowest reading of the barometer on Saturday, 23·173 inches, occurred at 8.30 p.m.; at noon, temperature was 15°, and at 10 p.m. 22°; at 7 p.m. the wind was S.E. force 8, and at 10 p.m., N.E. force 4.

In the sixty years preceding 1827, during which Mr. James Hoy made barometric observations, the lowest reading was 28·007 inches; during the last 43 years observations have been made at Culloden, and the lowest reading, observed by the late Mr. Arthur Forbes, was 27·984 inches at 11 a.m. on December 27, 1852. During the interval between these two long continued series of observations, Mr. George Innes, optician, made observations at Aberdeen ; and on the occasion of the memorable storm of January 7, 1839, recorded an observation on that morning of 27·695 inches. On the same morning, at 9 o'clock, the lighthouses on the east of Scotland, which were near the centre of the storm at the time showed readings varying from 27·806 inches in the Firth of Forth, to 27·716 inches near Peterhead.

As these three series of observations extend over the last 120 years, it is evident that over at least the east of Scotland, from Inverness to the Tweed, atmospheric pressure fell on the evening of Saturday the 26th from a third to half an inch lower than has occurred during that extended period.

NOTES

WE are glad to be able to announce that Prof. Flower has been definitely appointed by the Trustees to the position of Superintendent of the Natural History Department of the British Museum, vacated by the recent resignation of Sir Richard Owen.

THE German Emperor, at the instance of the Berlin Academy of Sciences, has been pleased to make Prof. Sir William Thomson a Knight of the Order *Pour le Mérite* for Science and Art.

ACCORDING to an announcement made by Prof. E. Stefan at the last meeting of the Vienna Physical Society, Prof. S. von Wroblewski, of Krakow, has succeeded in solidifying hydrogen.

IT is reported that Prof. Wilhelm Klinkerfues, the well-known astronomer, shot himself on Monday in the Observatory at Göttingen.

WE are glad to see that the fishermen of Scotland have at last realised the necessity of a thorough scientific investigation into the habits of fish. At a meeting at Peterhead the other day the Solicitor-General for Scotland was requested to help the fishermen to obtain Government aid for the prosecution of such research; the country, it was admitted, is behind all others "in scientific information on fish." The Solicitor-General, Mr. Asher, admitted the lamentable deficiency of our knowledge of the habits of food fishes, and promised to do all he could to obtain a grant for the Committee of the Fisheries Board, who are now endeavouring, with the slender means at their command, to investigate the subject. "Prof. Ewart and his colleagues," Mr. Asher stated, "had entered upon an investigation which, if duly prosecuted, could not fail to be productive of immense results and advantages in connection with all kinds of fisheries."

AT the end of March the Austrian botanist, Mr. Joseph Knapp, Conservator des Herbariums des Allgemeinen Oesterreichischen Apothekervereines of Vienna, will go to Northern Persia (Azerbijan), with a scientific expedition for exploring the flora and fauna of that little-known province.

DURING February Prof. W. K. Parker will give a series of lectures at the Royal College of Surgeons on Mammalian Descent, as follows :—February 4th, Introductory ; 6th, On Monotremes ; 8th, On Marsupials ; 11th, On Edentata ; 13th, On Insectivora ; 15th, Insectivora (continued) ; 18th, Insectivora (concluded) ; 20th, On the remaining Orders of Mammalia ; 22nd, On Man (conclusion).

IN connection with the opening of the Turin Exhibition, the Italian Government offers a prize of 400*l.* to the inventor of the most practicable method for the transmission of electricity to a distance. The competition will be international.

WITHIN a few days the exhibition of the *Talisman* collection will be opened at the Jardin des Plantes of Paris, with diagrams exhibiting the circumstances of the operations, and the instruments which were used.

THE Asiatic Society of Bengal celebrated its centenary on Tuesday last week. The proceedings began with a special meeting, the Hon. H. Reynolds, the President of the Society, being in the chair. Six gentlemen, namely, Dr. Joule, Prof. Haeckel, Mr. Charles Meldrum, Prof. Sayce, M. E. Senart, and Prof. Monier Williams, were elected honorary members.

The Cambridge University Press announces for publication "A Treatise on the General Principles of Chemistry," by M. M. Pattison Muir, M.A. This book is intended to give a fairly complete account of the present state of knowledge regarding the principles and general laws of chemistry; it is addressed to those students who have already a considerable acquaintance with descriptive chemistry, and it is hoped that by such students the book will be found complete in itself. An attempt is made to treat the chief theories of modern chemistry to some extent from an historical point of view, and to trace the connection between the older theories and those which now prevail in the science. Full references are given to all memoirs of importance. The first part treats of the atomic and molecular theory, and the application thereof to such objects as allotropy, isomerism, and the classification of elements and compounds; fairly complete accounts are also given of the methods and more important applications of thermal, optical, and other parts of physical chemistry. The second part is devoted to the subjects of chemical affinity, relations between chemical action and losses or gains of energy, and the various questions suggested by the expression "chemical equilibrium."

At the weekly meeting of the Society of Arts on Wednesday last week, under the presidency of Sir John Lubbock, a paper was read by Mr. W. L. Carpenter, on "Science Teaching in Elementary Schools." The chairman said the subject under consideration was one of very great importance. The Duke of Devonshire's Commission had reported that the neglect of science and modern languages in our schools was a national misfortune; and though, no doubt, there was some improvement since that time, almost the same might be said now. Considering how much science had done, and was doing for us, the general, though happily now not universal, neglect of it in our schools was astonishing. If we did not avail ourselves to the utmost of the resources of nature, our great and growing population would become more and more miserable, and they would be distanced in the race by foreign nations. Mr. Carpenter said his object was not merely to draw attention to the crying need for elementary scientific instruction in our primary schools, but also to point out how such instruction could best be given, and to show that that could be done, and had been done on a large scale, with extraordinarily beneficial results to the children thus taught, without any more expenditure of time than at present. The one great mistake which vitiated the whole organisation of English education was the conception of intellectual training as the acquisition of information rather than as the development of the faculties. He pointed out the enormous value of science teaching in quickening the intelligence, as well as the very great practical value of the knowledge imparted. The special feature of the Liverpool School Board system was that the science demonstrations and experiments were given not by the ordinary staff of the school, but by a specially-appointed expert, whose sole duty it was to go round from school to school, giving practically the same lesson in each one until all had been visited, and abandoning altogether the use of text-books by the scholars. The results of that system were (1) the general quickening of the intellectual life of the school; (2) the sending of a large number of lads to science classes after leaving school; (3) the finding out of lads of exceptional scientific ability, and setting them on their road; (4) the attracting the attention of the ordinary teachers to science and to the results of teaching it. He concluded by urging that instruction in some branch of elementary science, preferably mechanics or physics for boys, and domestic economy for girls, should form a necssary part of the education of every child who remained in a public elementary school above Standard IV., that such instruction should be oral, that such teaching should be given during the ordinary school hours, and that such alterations should be made in the scale of grants under the new Code as should encourage the teaching of elementary science.

Our readers may remember that some years ago Lieut. Julius von Payer, one of the discoverers of Franz Josef Land, gave up the sea for the brush; but he has carried his Arctic enthusiasm into art. He has for years been engaged on a series of four pictures illustrating the last expedition of Sir John Franklin, and according to the *Times* Paris Correspondent, the last of them, entitled "Starvation Cove," is just completed. Lieut. Payer has taken the greatest pains to acquaint himself with the minutest details of the expeditions of the *Erebus* and *Terror*, their formation and equipment, and the pictures will at least be interesting. We hope they may be exhibited in this country.

The catalogue of the scientific books in the Reference Department of the Nottingham Free Library spins a list of about 750 titles out into a catalogue of nearly 40 pages, with between 50 and 60 entries upon each, and among them are a good collection of the most important *Journals* and *Transactions*. To a library the wide circle of whose frequenters forbids its shelves being thrown open to them all, it is doubtful whether a small collection of works with a full subject-catalogue is not of greater advantage than a large accumulation of books of which the librarian only is aware. But instead of giving any reference at all to the *subjects* treated in these books and papers, there is only given here the name of each *writer* and the heading under which his production may be found. This can be of little use to any student and none at all to the majority of those using a free library. A supplement of something less than 200 titles is added now, but the collection is so small at present that it is beneath criticism as to its deficiencies.

A telegram from Constantinople, Jan. 23, states that during the previous fortnight shocks of earthquake, varying in severity, have been felt throughout the district of Kalah-Jik, in the province of Castambul. Some of the minarets of the mosques have fallen in. Shocks also continue to be felt in Central Asia. One occurred at Tashkend a few days ago. A correspondent, writing from Vierno to the *Turkestan Gazette*, states that they have been lately very frequent, and somewhat severe at Oosh. Several shocks have also been recently experienced at Tiflis.

The Naples Correspondent of the *Standard* writes:—"Prof. Silvestri, Director of the Observatory on Mount Etna, reported on the 15th inst. that frequent movements of the soil had taken place at Nicolosi and all the other villages near the site of the eruption of last March. Besides this, within a zone of about 60 km. in extent, the villages of Biancaritta, Aderno, Bronte, Maletto, Randazzo, Linguaglossa, and Piedimonte have experienced during the last few days subsultory and undulatory shocks; the most remarkable occurring on the evenings of the 10th and 14th inst. The oscillations moved in a north-easterly direction, along the mountain chain of Pilori, and were distinctly but slightly felt at Castiglione, Rovara, Castroreale, and as far as Messina. No damage was done, but at Randazzo and Linguaglossa, where the shocks were stronger, the people were much alarmed. At Catania, only the instruments of the Observatory registered the perturbation coincident with the above-mentioned shocks."

The additions to the Zoological Society's Gardens during the past week include three Bonnet Monkeys (*Macacus sinicus* ♂ ♀ ♀) from India, a Toque Monkey (*Macacus pileatus*) from Ceylon, an Arabian Baboon (*Cynocephalus hamadryas* ♂) from Arabia, an Indian Gazelle (*Gazella bennetti* ♂) from India, presented by Capt. Spencer Stanhope; two Bonnet Monkeys (*Macacus sinicus* ♂ ♀) from India, presented by Mrs. St. John Mitchell; a Huanaco (*Lama huanacos* ♀) from Peru, presented by Mr. J. W. Firth; four Harvest Mice (*Mus minutus*), British, presented by Mr. G. T. Rope; a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, presented by Mr. George Wood; a Great Grey Shrike (*Lanius excubitor*), British, presented by Master Arthur Blyth; two American Flying Squirrels (*Sciuropterus volucella*) from North America, presented by Mr. F. S. Mosely, F.Z.S.; a Cape Adder (*Vipera atropus*) from South Africa, presented by Mr. C. B. Pillans; a Black Tanager (*Tachyphonus melaleucus*), a White-throated Finch (*Spermophila albigularis*), a Tropical Seed Finch (*Orysoborus torridus*), a Common Boa (*Boa constrictor*), a South African Rat Snake (*Spilotes variabilis*) from South America, a Cheela Eagle (*Spilornis cheela*) from Ceylon, two Illiger's Macaws (*Ara maracana*) from Brazil, a Common Guillemot (*Lomvia troile*), British, purchased; two Brown-tailed Gerbilles (*Gerbillus erythrurus*), born in the Gardens.

GEOGRAPHICAL NOTES

THE first report of Prof. Hull, dated from Gaza, January 1, has been received. It is necessarily brief, the details being reserved for the full report to follow, but it announces the success of the expedition so far. The professor has made a complete geological survey of the Wady Arabah and the Dead Sea, with a traverse across Southern Palestine. Capt. Kitchener, R.E., who accompanied him, has made a trigonometrical survey. Akabah he found to be laid down too far south; the south part of the Dead Sea as shown on the maps, is quite out of its true shape and position, and the Lisan has to be shifted three miles. From Gaza, when the rest of the party were in quarantine, Capt. Kitchener rode back to Egypt, accompanied by four Arabs only. He took a previously unknown route, particulars as to which will follow, and arrived at Ismaïlia after a ride of 200 miles. He was everywhere well received by the Arabs, who took him for a cousin of Sheikh Abdullah (the late Prof. Palmer), whose memory is still revered among them, and whose murder they still deplore. They are also reported to be deeply impressed with the energy and pertinacity of Sir Charles Warren's pursuit of the murderers. As regards the other members of Prof. Hull's party, Mr. Hart is reported to have made large additions to the flora; Mr. Lawrence has kept a continuous series of meteorological observations, and Mr. Gordon Hull has obtained a hundred photographs, large and small. Prof. Hull had still to execute two traverses of the country, in which he is no doubt at present engaged. The complete reports, both of himself and Capt. Kitchener, will be extremely important. They will probably be published in the journal of the Society.

WE have received the ninth issue of the *Geographisches Jahrbuch.* In the present volume, the reports which appeared in the first six publications on the additions successively made to our knowledge of extra-European parts of the earth are resumed; the new African annexations to geography being disposed of by Prof. K. Zöppritz, the Asiatic by Dr. Hans Lullies, and the Polar by Herr W. Wichmann. Two important departments in geography find for the first time distinct places assigned them in the present number; geographical onomatology and theoretic cartography. The former has indeed but very recently been recognised as the independent and important province of geography it really is. The first and as yet only comprehensive scientific work on the subject is that by its reviewer in the present *Jahrbuch*, Prof. J. J. Egli, "Versuch einer Allgemeinen Geographischen Onomatologie" (Leipzig, 1870–72), essay towards a general geographical onomatology. The name of a place is either immediately descriptive of its physical features ("nature-names," as Prof. Egli calls this class) or descriptive of some historical or other connection between the place and its earlier or later inhabitants or discoverers ("culture-names"), in either and every case is significant and interesting and an organic part of its geography.—Prof. Sigismund Günther, in his masterly review of theoretic cartography, first gives a brief yet clear and comprehensive "history of the development of geometrical cartography," taking notice more particularly of modern works on the subject, and then estimates recent works on projection.—Prof. von Oppolzer, reporting the progress made in European measurement of degrees, summarises the transactions of the sixth General Conference held on the subject at Munich, September 13–16, 1880. He calls special attention to the results deduced by von Bauernfeind from taking the measurement of the zenith simultaneously at Dobra and Kappellenburg, in which the same anomalies came to light as those pointed out years before by von Bayer. These anomalies are entirely parallel with those which appear in taking barometrical measurements of heights, and von Bauernfeind attributes them to the circumstance that the registered temperatures at given places form no correct criterion of the temperatures of the intermediate air-strata, the temperatures at the given places being to a certain extent determined by purely local influences. These conclusions are confirmed by Oppolzer's studies in astronomical refraction, in which analogous anomalies are to be explained by the fact that the universal law of diminution of temperature with ascent is modified in the lowest air-strata by local causes. In clear nights, *e.g.*, the temperature in the lowest atmospheric strata invariably rises with ascent up to a certain moderate height. During the day, on the other hand, in corresponding conditions, temperature diminishes with ascent at a rate considerably above the average. These facts afford Oppolzer a very simple explanation of hitherto puzzling phenomena.—In the review of geographical meteorology by Prof. J. Hann is presented a great treasure of data as to rainfall, nebulosity, atmospheric pressures, winds, &c.—In a map by Remon of the nebulosities of different parts of Europe and North Africa, the extremes are given at 20° in the Algerian Sahara, and 68° in the north-west of Europe. Cloudiness in general diminishes southwards and eastwards, as compared with the centre of Europe.—Space allows only of the bare mention of the review of the geography of plants by Prof. Drude; of animals, by Prof. Schmarda; of ethnology, by Prof. Gerland; of deep-sea exploration, by Prof. von Boguslawski; of the structure of the earth's surface, by Prof. von Fritsch; and of the method of geography, by Prof. Wagner.

WE understand that the expedition with which Mr. Wilfred Powell has undertaken to explore New Guinea will leave this country about the beginning of March. It will consist of Mr. Powell, with four or five Europeans, including a naturalist and a geologist, and the work of traversing the thousand or twelve hundred miles which have been mapped out for the route is likely to occupy over a year. Mr. Powell has chartered a small screw steamer, in which the party will proceed up the Ambernoli river, a large stream in Dutch territory, on the north coast. The explorers will proceed up this river in a steam launch as far as they can get. The launch will then return to the steamer, and the party will strike in a south-westerly direction across the high central range of mountains which runs from east to west, called the Snow Mountains, or the Finisterre Mountains. When this difficult task has been accomplished, Mr. Powell will march to the east coast, where he will hope to find his screw steamer in Astrolabe Bay. After refitting, he will again strike westwards, across the south-east corner of the island, to Port Moresby. Mr. Powell will thus explore the country from north to south, avoiding the Fly River, or any other portion which has been visited by Europeans.

THE *St. Petersburger Zeitung* has received news from Khartoum about Dr. Junker. Herr Bohndorf, Dr. Junker's companion, has arrived at Khartoum, and reports that Junker is still in the Niam Niam country, and that his researches are favourably progressing.

THE last issue of the *Bulletin* of the St. Petersburg Academy of Sciences contains a letter of M. Bunge, the medical officer of the Lena polar meteorological station. The country around the station is but little fitted for collecting. It is a flat region periodically covered by the tide, and there may be no question about sea-flora or sea-fauna to be found in the creeks that intersect the ground. The ice bear sometimes makes his appearance, as also the wolf, the fox, especially *Canis lagopus*, of which the neighbouring Yakuts catch about 300 every year; the *Mustela herminea* is not very rare. The Yakuts do not know lemmings, but one species at least, the *Myodes torquatus*, inhabits the delta. The reindeer come in large flocks in the summer, returning to the forest region in the autumn. They are killed when passing the streams, shooting being prohibited by the Yakut community. One *Ægocerus montanus* has been perceived, from a great distance, within the delta. Walruses, sometimes seals, and dolphins also enter the mouth of the Lena. As to the birds, M. Bunge gives a list of 101 species he has observed or shot during his journey. The water invertebrata are very poorly represented in the Lena. As M. Bunge gives great attention to the collecting of skulls of animals, his collection promises to be of great value, as also his collection of human skulls taken from the coffins that dot the *tundra*—the Yakuts merely putting them on the surface between a few rough planks. It is worthy of notice that, whilst having many opportunities for visiting the sick Yakuts in the neighbourhood, M. Bunge has not yet noticed a single case of scurvy; it is quite unknown among them.

WE have received a separate copy from the forthcoming number of the *Izvestia* of the Russian Geographical Society of a notice of the remarkable Russian expeditions to the Pamir, carried on during last summer. It is sufficient to cast a glance at the map that accompanies this note to ascertain that "the Roof of the World" has now been quite deprived of the veil of mystery that covered it for centuries past. Many years since Russian travellers penetrated into it, and studied detached portions as they followed the course of the rivers which led to these gigantic plateaux, inclosed between still higher mountains. Pursuing his researches for several consecutive years, Dr. Regel and his companions have explored the valleys of the Panj and of its numerous tributaries, penetrating as far south as Sist (37° N. lat.) and as far east as the sources of Shakh-dere, 72° 50′ E. long. An immense bend to the west of the Panj River beneath Kala-vamar, due to the presence of a high chain of mountains running north-east, and a wide lake, Shiva, 11,000 feet high, situated to the west of this bend, discovered by Dr. Regel, considerably modify our former maps of the western part of the Pamir region. But the expedition of last summer, which consisted of MM. Putiata, of the general staff, Ivanoff, geologist, and Bendersky, topographer, throws quite a new light on the still less known eastern Pamir. The expedition has literally covered with a network of surveys the whole of this region from 39° 30′ N. lat. to the sources of the Vakhan-daria, in 37° 10′, and from 72° 10′ to 75° 20′ E. long., penetrating thus twice to the foot of the Mustag-aga, or Tagarma Peak. The great Pamir chain, between the Shakh-dere and the Upper Panj has been crossed at four places, 100 miles distant, and the Russian surveys have been brought into connection with those of the pundit M. S. The expedition seems to have established that the pundit M. S. was misled, and that the Ak-su is really the upper part of the Murghab. The other results of this expedition are also very important: not only a map on the scale of five versts to an inch of the whole of this wide region has been drawn, but also the heights of a very great number of points have been determined by barometrical and trigonometrical measurements; large geological and botanical collections have been brought in, as well as many drawings, and a dictionary of the Shugnan language. Detailed reports will follow, the foregoing information being due to a preliminary letter of M. Ivanoff.

A TELEGRAM from Nerchinsk, in Siberia, states that M. Joseph Martin, the French traveller, passed through that place recently on his way to Irkutsk. M. Martin has (says a Reuter's telegram) explored the country from the Lena to the Amur, and has crossed the intervening Starovi Mountain range He has collected a large amount of geographical and geological information concerning the region which he has traversed.

MR. SCHUVER, the Dutch African explorer, has been murdered at Bahr Gazal, in South Kordofan.

ACCORDING to the latest number of the *Annalen der Hydrographie und maritimen Meteorologie* the greatest depth of the Atlantic is 8341 metres; this was found in 19° 39′ 10″ N. lat., and 60° 26′ 5″ W. long. The next greatest depression of the sea bottom is in 19° 23′ 30″ N. lat., and 66° 11′ 45″ W. long., where 7723 metres were found.

THE AIMS AND PROSPECTS OF THE STUDY OF ANTHROPOLOGY[1]

THOSE who are present at this meeting need scarcely be reminded of the importance of the subject which is our common bond of union, that which is defined in the prospectus of the Institute as "the promotion of the science of mankind by the accumulation of observations bearing on man's past history and present state in all parts of the globe."

But those present are a very small fraction indeed of the persons in this country to whom this great subject is, or should be in some one or other of its various divisions, a matter of deep interest, and as it is possible that the words which it is my privilege and duty as your president to address to you on this occasion may be read by some who are not yet so much conversant with the aims of anthropology and the means for its cultivation which this Institute affords as those who have taken the trouble to come here this evening, I hope that you will pardon me if I bring before you some general considerations, perhaps familiar to all of you, regarding the scope and value of the science the advancement of which we have at heart.

One of the great difficulties with regard to making anthropology a special subject of study, and devoting a special organisation to its promotion, is the multifarious nature of the branches of knowledge comprehended under the title. This very ambition, which endeavours to include such an extensive range of knowledge, ramifying in all directions, illustrating and receiving light from so many other sciences, appears often to overleap itself and give a looseness and indefiniteness to the aims of the individual or the institution proposing to cultivate it.

The old term ethnology has a far more limited and definite meaning. It is the study of the different peoples or races who compose the varied population of the world, including their physical characters, their intellectual and moral development, their languages, social customs, opinions, and beliefs, their origin, history, migrations, and present geographical distribution, and their relations to each other. These subjects may be treated of under two aspects—first, by a consideration of the general laws by which the modifications in all these characters are determined and regulated; this is called general ethnology: secondly, by the study and description of the races themselves, as distinguished from each other by the special manifestations of these characters in them. To this the term special ethnology, or, more often, ethnography, is applied.

Ethnology thus treats of the resemblances and differences of the modifications of the human species in their relations to each other, but anthropology, as now understood, has a far wider scope. It treats of mankind as a whole. It investigates his origin and his relations to the rest of the universe. It invokes the aid of the sciences of zoology, comparative anatomy, and physiology; and the wider the range of knowledge met with in other regions of natural structure, and the more abundant the terms of comparison known, the less risk there will be of error in attempting to estimate the distinctions and resemblances between man and his nearest allies, and fixing his place in the zoological scale. Here we are drawn into contact with an immense domain of knowledge, including a study of all the laws which modify the conditions under which organic bodies are manifested, which at first sight seem to have little bearing upon the particular study of man.

Furthermore, it is not only into man's bodily structure and its relations to that of the lower animals that we have to deal; the moral and intellectual side of his nature finds its rudiments in them also, and the difficult study of comparative psychology, now attracting much attention, is an important factor in any complete system of anthropology.

In endeavouring to investigate the origin of mankind as a whole, geology must lend its assistance to determine the comparative ages of the strata in which the evidences of his existence are found; but researches into his early history soon trench upon totally different branches of knowledge. In tracing the progress of the race from its most primitive condition, the characteristics of its physical structure and relations with the lower animals are soon left behind, and it is upon evidence of a kind peculiar to the human species, and by which man is so pre-eminently distinguished from all other living beings, that our conclusions mainly rest. The study of the works of our earliest known forefathers, "prehistoric archæology," as it is commonly called, although one of the most recently developed branches of knowledge, is now almost a science by itself, and one which is receiving a great amount of attention in all parts of the civilised world. It investigates the origin of all human culture, endeavours to trace to their common beginning the sources of all our arts, customs, and history. The difficulty is what to include and where to stop; as, though the term "prehistoric" may roughly indicate an artificial line between the province of the anthropologist and that which more legitimately belongs to the archæologist, the antiquary, and the historian, that the studies of the one pass insensibly into those of the other is an evident and necessary proposition. Knowledge of the origin and development of particular existing customs throws immense light upon their real nature and importance, and conversely, it is often only from a profound acquaintance with the present or comparatively modern manifestations of culture that we are able to interpret the slight indications afforded us by the scanty remains of primitive civilisation.

---

[1] Address delivered at the anniversary meeting of the Anthropological Institute of Great Britain and Ireland, January 22, 1884, by Prof. Flower, LL.D., F.R.S., P.Z.S., &c., President.

Even the more limited subject of ethnology must be approached from many sides, and requires for its cultivation knowledge derived from sciences so diverse, and requiring such different mental attributes and systems of training, as scarcely ever to be found combined in one individual. This will become perfectly evident when we consider the various factors or elements which constitute the differential characters of the groups or races into which mankind is divided. The most important of these are—

1. Structural or anatomical characters, derived from diversities of stature, proportions of different parts of the body, complexion, features, colour and character of the hair, form of the skull and other bones, and the hitherto little-studied anatomy of the nervous, muscular, vascular, and other systems. The modifications in these structures in the different varieties of man are so slight and subtile, and so variously combined, that their due appreciation, and the discrimination of what in them is essential or important, and what incidental or merely superficial, requires a long and careful training, superadded to a preliminary knowledge of the general anatomy of man and the higher animals. The study of physical or zoological ethnology, though it lies at the basis of that of race, is thus necessarily limited to a comparatively few original investigators.

2. The mental and moral characters by which different races are distinguished are still more difficult to fathom and to describe and define, and although the subject of much vague statement, as there are few people who do not consider themselves competent to give an opinion about them, they have hitherto been rarely approached by any strictly scientific method of inquiry.

3. Language.—The same difficulties are met with in the study of language as in that of physical peculiarities, in the discrimination between the fundamental and essential, and the mere accidental and superficial resemblances, and in proportion as these difficulties are successfully overcome will be the results of the study become valuable instead of misleading. Though the science of language is an essential part of ethnology, and one which generally absorbs almost the entire energies of any one who cultivates it, its place in discriminating racial affinities is unquestionably below that of physical characters. Used, however, with due caution, it is a powerful aid to our investigations, and in the difficulties with which the subject is surrounded, one which we can by no means afford to do without.

4. The same may be said of social customs, including habitations, dress, arms, food, as well as ceremonies, beliefs, and laws, in themselves fascinating subjects of study, placed here in the fourth rank, not as possessing any want of interest, but as contributing comparatively little to our knowledge of the natural classification and affinities of the racial divisions of man. When we see identical and most strange customs, such as particular modes of mutilation of the body, showing themselves among races the most diverse in character and remote geographically, we cannot help coming to the conclusion that these customs have either been communicated in some hitherto unexplained manner, or are the outcome of some common element of humanity, in either of which cases they tell nothing of the special relations or affinities of the races which practise them.

This subject of ethnography, or the discrimination and description of race characteristics, is perhaps the most practically important of the various branches of anthropology. Its importance to those who have to rule, and there are few of us now who are not called upon to bear our share of the responsibility of government, can scarcely be overestimated in an empire like this, the population of which is composed of examples of almost every diversity under which the human body and mind can manifest itself. The physical characterestics of race, so strongly marked in many cases, are probably always associated with equally or more diverse characteristics of temper and intellect. In fact, even when the physical divergences are weakly shown, as in the case of the different races which contribute to make up the home portion of the empire, the mental and moral characteristics are still most strongly marked. As it behoves the wise physician not only to study the particular kind of disease under which his patient is suffering, and then to administer the approved remedies for such disease, but also to take into careful account the peculiar idiosyncracy and inherited tendencies of the individual, which so greatly modify both the course of the disease and the action of remedies, so it is absolutely necessary for the statesman who would govern successfully, not to look upon human nature in the abstract and endeavour to apply universal rules, but to consider the special moral, intellectual, and social capabilities, wants, and aspirations of each particular race with which he has to deal. A form of government under which one race would live happily and prosperously would to another be the cause of unendurable misery. No greater mistake could be made, for instance, than to apply to the case of the Egyptian fellah the remedies which may be desirable to remove the difficulties and disadvantages under which the Birmingham artisan may labour in his struggle through life. It is not only that their education, training, and circumstances are dissimilar, but that their very mental constitution is totally distinct. And when we have to do with people still more widely removed from ourselves, African Negroes, American Indians, Australian or Pacific Islanders, it seems almost impossible to find any common ground of union or *modus vivendi*; the mere contact of the races generally ends in the extermination of one of them. If such disastrous consequences cannot be altogether averted, we have it still in our power to do much to mitigate their evils.

All these questions, then, should be carefully studied by those who have any share in the government of people of races alien to themselves. A knowledge of their special characters and relations to one another has a more practical object than the mere gratification of scientific curiosity; it is a knowledge upon which the happiness and prosperity, or the reverse, of millions of our fellow-creatures may depend.

It is gratifying to find, then, that there are in our own country—for on this occasion I will not speak of what is being done elsewhere—many signs that the prospects of a thorough and scientific cultivation of anthropology in its several branches are brightening.

I may first mention the publication of the final Report of the Anthropometric Committee of the British Association for the Advancement of Science, of which formerly the late Dr. W. Farr, and recently our vice-president, Mr. Francis Galton, have been chairmen, and in which Mr. Charles Roberts, Dr. Beddoe, Sir Rawson Rawson, and some other of our members have taken so active a part. This Report, and those which have from time to time been issued by the Committee during the progress of the work, contain a large mass of valuable statistical information relating to the physical characters, including stature, weight, chest girth, colour of eyes and hair, strength of arm, &c., of the inhabitants of the British Isles, illustrated by maps and diagrams. Excellent as has been the work of the Committee, there is still much to be done in the same direction, and larger numbers of observations even than those already obtained are in many cases necessary to verify or correct the inferences drawn from them. This is thoroughly acknowledged in the Report, which states in one of the concluding paragraphs that "the Committee believes that it has laid a substantial foundation for a further and more exhaustive study of the physical condition of a people by anthropometric methods, and that its action will prove that it has been useful as an example to other scientific societies and to individuals in stimulating them, as well as directing them in the methods of making statistical inquiries relative to social questions."

It is satisfactory to learn that many portions of the work thus inaugurated will be carried on by bodies specially interested in particular departments, as the Collective Investigation Committee of the British Medical Association, and the Committee of the British Association for collecting photographs and defining the characteristics of the principal races of the United Kingdom, a subject in which Mr. Park Harrison is taking so deep an interest.

It should be mentioned that the original returns upon which the reports of the Committee are based, including much information which has not yet been analysed and tabulated, on account of the time and labour such a process would involve, as well as the instruments of investigation purchased with funds supplied by the British Association, have been, by the consent of the Council of the Association, placed under the charge of the officers of this Institute.

It is very satisfactory, in the next place, to be able to record that our great centres of intellectual culture are gradually waking up from that state of apathy with which they have hitherto regarded the subject of anthropology.

In Oxford the impulse given by the genius and energy of Rolleston has begun to bear fruit. The University has taken charge of the grand collection of ethnological objects most liberally offered to it by our former president, General Pitt-Rivers, and has undertaken not only to provide a suitable building for its reception but also to maintain it in a manner worthy of the scientific discernment and munificence displayed by the donor in collecting and arranging it. Furthermore Oxford has shown her wisdom in affiliating to herself the most learned of English anthropologists in the widest sense of the word, one of the few men in this country who has made the subject the principal occupation of his life. I need scarcely say that I refer to another of our former presidents, Mr. E. B. Tylor. By conferring a Readership in Anthropology upon him Oxford has instituted the first systematic teaching of the subject yet given in any educational establishment in this country, and it is a great credit to the oldest University that it should thus lead the way in one of the most modern of sciences. It is, however, only a beginning; the whole of the great subject is confined to the teaching of one individual with modest stipend, and not admitted to the dignity of the professoriate. In the École des Hautes Études at Paris anthropology is taught theoretically and practically in six different branches, each under the direction of a professor who has specially devoted himself to it, aided, in some cases, by several assistants.

In Cambridge also there are many hopeful signs. The recently-appointed Professor of Anatomy, Dr. Macalister, is known to have paid much attention to anatomical anthropology, and has already intimated that he proposes to give instruction in it during the summer term. An Ethnological and Archæological Museum is also in progress of formation, which, if not destined to rival that of Oxford, already contains many objects of great value, and a guarantee of its good preservation and arrangement may be looked for in the recent appointment of Baron Anatole von Hügel as its first curator.

Perhaps in no place in the world could so varied and complete an anthropological collection be expected as in the national museum of this country, which should be the great repository of the scientific gleanings of the numerous naval, military, exploring, and mercantile expeditions sent out by the Government or by private enterprise for more than a century past, and penetrating into almost every region of the globe. Our insular position, maritime supremacy, numerous dependencies, and ramifying commerce, have given us unusually favourable opportunities for the formation of such collections, opportunities which unfortunately in past times have not been used so fully as might be desired. There is, however, a great change coming over those who have charge of our national collections in regard to this subject. Thanks to the foresight and munificence of the late Mr. Henry Christy, and the well-directed energies of Mr. Franks and his colleagues, the collection illustrating the customs, clothing, arts, and arms of the various existing and extinct races of men, in the British Museum, is rapidly assuming an importance which will be a surprise to those who see it for the first time arranged in the large galleries formerly devoted to mammals and birds. Even the grand proportion of space allotted to this collection in the rearrangement of the Museum is, I am told, scarcely sufficient for its present needs, to say nothing of the accessions which it will doubtless receive now that its importance and good order are manifest.

A national collection of illustrations of the physical characters of the races of men, fully illustrated by skeletons, by anatomical specimens preserved in spirit, by casts, models, drawings, and photographs such as that which exists in the Muséum d'Histoire Naturelle at Paris, is still a desideratum in this country. The British Museum till lately ignored the subject altogether, and in the beginning of the century actually expelled such specimens of the kind as had accidentally found their way within its walls. Recently, however, skulls and skeletons of man have been admitted, and since the removal of the zoological collections to the new building at South Kensington their importance as an integral part of the series has been recognised, and their exhibition in the osteological gallery will doubtless stimulate the growth of what we may trust will be ultimately a collection worthy of the nation, although unfortunately, from causes too well known, the difficulties of procuring pure examples of many races are gradually increasing, and in some cases have become well-nigh insuperable. The museum contains at present 407 specimens illustrating human osteology, of which 10 are skeletons more or less complete.

In the meantime the College of Surgeons of England has done much to supply the deficiency. During the last twenty years it has let few opportunities pass of attracting to itself, and therefore saving from the destruction or lapse into the neglected, valueless condition into which small private collections almost invariably ultimately fall, a large number of specimens, now, it is to be hoped, placed permanently within the reach of scientific observation. The growth of this collection may be illustrated by the fact that, whereas at the time of the publication of the Catalogue in 1853 it consisted of 18 skeletons and 242 crania, it now contains 89 more or less complete skeletons and 1380 crania, nearly all of which have been added during the last twenty years. This is, moreover, irrespective of the great collection of Dr. Barnard Davis, purchased in 1880 by the College, which was thus the means of preserving intact, for the future advantage and instruction of British anthropologists, an invaluable series of specimens otherwise probably destined to have been dispersed or lost to the country for ever. This collection consists of 24 skeletons and 1539 crania, making, with the remainder of the College collection, a total of 3032 specimens illustrating the osteological modifications of the human species. These are all in excellent order, clean, accessible, and catalogued in a manner convenient for reference, although somewhat too crowded in their present locality to be readily available for observation.

Large as is this collection, and rich in rare and interesting types, it is far from exhaustive; many great groups are almost or entirely unrepresented even by crania, and the series of skeletons is (with the exception of one race only, the Andamanese) quite insufficient to give any correct idea of the average proportions of different parts of the framework. In fact, such a collection as would be required for this purpose must be quite beyond the resources of, as well as out of place in, any but a national museum.

The collections illustrating anatomical anthropology in the University museums of Oxford, Cambridge, Edinburgh, and Dublin have all greatly increased of late, but for the reasons just given they can never be expected to attain the dimensions required for the study of the subject in its profoundest details. The small, but very choice collections formed by the officers of the medical department of the army, and kept in the museum of the Royal Victoria Hospital at Netley, and that of the navy at Haslar Hospital, are, I believe, in a stationary condition, but in good preservation. Our own collection, which also contains some valuable specimens (notably the complete skeleton of one of the extinct Tasmanian aborigines, presented by the late Mr. Morton Allport), and which during the past year has been catalogued for the first time by Mr. Bloxam, has not been added to, owing to a feeling which the Council has long entertained, and which induced them to part with the ethnological collection, that a museum, entailing as it does, if worthily kept up, a very considerable annual expense, is not within the means of the Institute, at all events not until the more pressing claims of the library and the publications are fully satisfied.

This leads me to speak, in conclusion, of the work accomplished during the past year by the Institute, and of its present position and future prospects.

I must first refer to that portion of the retrospect of the year which always casts a certain sadness over these occasions—the losses we have sustained by death. Happily these have not been numerous, and do not include, as has been the case in many former years, any from whom great work in our own subject might still have been expected. Though we were all proud to number William Spottiswoode, the President of the Royal Society, among our members, and though we all honoured him for his accomplishments in other branches of science, and loved him for his work as a man who rose high above his fellows in his chivalrous sense of honour and simple dignity of demeanour, we could not claim him as a worker at anthropology.

Lord Talbot de Malahide's antiquarian pursuits frequently verged upon our own subjects in their proper sense, and he was often present at our meetings, and a very recent contributor to our journal. He had, however, reached the ripe old age of eighty-two.

From the list of our honorary members we have lost a still more venerable name, that of Sven Nilsson, Professor in the Academy of Lund. He was born on March 8, 1787, and died on November 30 of last year, and was therefore well on in his ninety-seventh year. His long-continued and laborious researches in the zoology, palæontology, anthropology, and antiquities of his native land gave him a high place among men of science. Among a host of minor contributions he was the author of a standard work on the Scandinavian fauna; but that by which he was best known to us is the book of which the English translation, edited by Sir John Lubbock, bears the title of "The Primitive Inhabitants of Scandinavia; an Essay on Comparative Ethnography, and a Contribution to the History of the Development of Mankind."

The number of our ordinary members has been fairly kept up, the additions by election having slightly exceeded the losses by death and resignation; but a larger increase in the future will be necessary in order to carry on the operations of the Institute in a successful manner, especially under the new conditions to which I shall have to advert presently. Even by the most careful management our treasurer has not succeeded in bringing the expenditure of the year quite within our ordinary income.

The journal, I am glad to report, has been brought out with exemplary punctuality, under the able and energetic supervision of our director, Mr. Rudler. To this part of our operations I think we may look with unmixed satisfaction, the number, character, and variety of the communications contained in it being quite equal to those of former years.

With regard to our future, the next year will probably be one of the most momentous in our annals, as we have determined upon a great step, no less than a change of domicile. It was ascertained in the course of last summer that we could only remain in our present quarters at an increased rent upon that which we had hitherto paid, and we therefore considered whether it would be possible to obtain as good or better accommodation elsewhere. It happened fortunately that the Zoological Society was about to move into new freehold premises at No. 3, Hanover Square, and would have spare rooms available for the occupation of other societies. A committee of the Council was appointed to examine and report upon the desirability of moving, and negotiations were entered into with the Council of the Zoological Society which have ended in our becoming their tenants for the future. We shall have for the purposes of our library, office, and Council meetings, two convenient rooms on the second floor immediately above the library of the Zoological Society, and for the purpose of storing our stock of publications a small room on the basement. We shall also have the use of a far more handsome and commodious meeting room than that which we occupy at the present moment, and in a situation which is in many respects more advantageous. Let us trust that this change may be the inauguration of an era of prosperity to the Institute, and of increased scientific activity among its members.

THE FORMATION OF SMALL CLEAR SPACES IN DUSTY AIR[1]

IN the introduction a few remarks are made on the growing interest in everything connected with dust, whether it be the organic germs floating in the air, or the inorganic particles that pollute our atmosphere. Prof. Tyndall's observations on the dark plane seen over a hot wire[2] are referred to, Lord Rayleigh's recent discovery of the dark plane formed under a cold body[3] is described, and attention called to Dr. Lodge's experiments described in a letter to NATURE, vol. xxviii. p. 297.

The experiments described in this paper were made in a small dust-box, blackened inside, glazed in front, and provided with a window at one side. For illumination two jets of gas inclosed in a dark lantern were used. The light entered the dust-box by the side window and could be condensed on any part of the inside of the box, by means of two lenses fixed in a short tube, and loosely attached to the front of the lantern. Magnifying glasses of different powers were used for observation. The dusts experimented on were made, some of hydrochloric acid and ammonia, some by burning sulphur and adding ammonia, some by burning paper, magnesium, or sodium. Calcined magnesia and lime were also used, as well as ground charcoal. These three last substances were stirred up by means of a jet of air.

For testing the effects of slight difference of temperature, tubes in some form or other were generally used. These tubes were closed at the front, projected through the back of the dust-box, and were brought close to the glass front for observation under strong magnifying power. The tubes were heated or cooled by circulating water through them, in a small tube passing through their interior.

Suppose the experiments to be begun by introducing a round tube into its place in the dust-box and then filling the box with any dust, everything being then left for some time so that all the apparatus may acquire the same temperature. If the light be now allowed to fall on the box, and be quickly brought to a focus on the tube, it will be found that the dust is in close contact with it on the top and sides, but *underneath* there will be seen a clear space. Close examination will show the particles to be falling on the upper surface of the tube, and coming into contact with it, while underneath a clear space is formed by the particles falling out of it. If the tube is now slightly cooled, a downward current is formed, and the currents of dustless air from below the tube meet under it, and form a dark plane in the centre of the descending current. It is shown that gravitation can, under favourable conditions, produce this separation of the dust quickly enough to keep up a constant supply of dustless air. No increase of effect is produced by a lower temperature. A temperature of − 10° C. makes the dark plane thinner, because it increases the rate of the descending current and carries away the purified air more quickly.

A form of apparatus was arranged to get rid of this separating effect of gravitation. It consisted of an extremely thin and flat piece of metal. This test-surface was placed *vertically* in the dust-box. The air in passing over this piece of apparatus was not caused to take up a horizontal movement at any part of its passage. The result was that even with a temperature of − 10° C. the dust kept close to its surface, and no dark plane was formed in the descending current. The dark plane in the cold descending current seems, therefore, not to be an effect of temperature, but is the result of the action of gravitation on the particles under the body. A dark plane was, however, observed when working with this flat surface when cooled, but it was not formed in dusty, but in foggy air, and was found to be due to the evaporation of the fog particles when they approached the cold surface.

If a very little heat, instead of cold, is applied to the round tube in the previous experiment, then the dark space under the tube rises and encircles the tube and the two currents of clear air unite over the tube and form the dark plane in the upward current. But in addition to this heat has been found to exert a repelling effect on the dust. This was proved by putting the thin vertical test-surface in the dust-box and heating it, when it was found that the dust was repelled from its surface, and a dark plane formed in the ascending current, neither of which effects was obtained with cold. The dust begins to be repelled with the slightest rise of temperature, and the dark space in front of the test-surface becomes thicker as the temperature rises. An experiment is then described in which air flowing up between two parallel glass plates is caused to pass from side to side of the channel by the repelling action of heat at different points.

For testing the effects of higher temperatures a platinum wire heated by means of a battery was used. The platinum wire was bent into a U-shape, the two legs being brought close together. This wire was fixed in the dust-box with the bend to the front, and the legs in the same horizontal plane, the two copper wires to which it was attached being carried backwards and out of the box. By this arrangement a clear view was obtained all round the wire, and other advantages secured. Experimenting with this apparatus it was found that every kind of dust had a different sized dark plane. With magnesia and other indestructible dusts it was very thin, with the sulphate dust it was much thicker, and with the sal-ammoniac dust thicker still. So thick was it with the two latter kinds of dust that the dark planes over the two legs expanded and formed one plane. As the particles could be seen streaming into the dark space under the wires, it was obvious that these large dark planes were not caused by repulsion, but by the evaporation or by the disintegration of the dust particles. When making the experiment in a mixture of different kinds of dusts, the hot wire was surrounded by a series of zones of different brightness, and having sharp outlines. The size of the different zones was determined by the temperature necessary to evaporate the different kinds of dust present, and outside these zones was another, caused by the evaporation of the water from the particles.

---

[1] Abstract of a paper read to the Royal Society of Edinburgh, January 21, 1884, by Mr. John Aitken.

[2] "Essays on the Floating-Matter in the Air," p. 5. (Longmans, Green, and Co., 1881.)

[3] NATURE, vol. xxviii. p. 139.

The conclusions arrived at from these experiments are that the downward dark plane is produced by this separating action of gravitation, in the space under the cold body, and that the upward dark plane is produced (1) by the separating action of gravitation, (2) by the repulsion due to heat, (3) by evaporation, and (4) by disintegration.

The effect of centrifugal force is considered. It is pointed out that as the air, in its passage over a body such as a tube, curves as much in one direction as it does in another, therefore any centrifugal effect produced in the one part will be reversed in the other. An experiment is described in which an air current is caused to curve through 180° in its passage round the edge of a thin plate, and without any curving in the opposite direction, but no decided centrifugal action could be detected.

The motions of the dust particles produced by the repulsion of the hot surface suggested that electricity might play some part in these phenomena. Experiments were made to test this. The hot body was insulated and connected with an electroscope; but no electrical disturbance was observed, nor could any electrification be got from the dust and hot air streaming up from the hot wires. The effects of electrification were studied by insulating and charging the hot surface. The effect was found to be the opposite of the heat effect. If the potential is slight, and the temperature high, the heat is able to keep the dust off the surface of the body and the dark plane district, but if the temperature falls, or the potential is increased, a point is reached when the electrical attraction overcomes the heat effect, and the dust particles break in upon and destroy the dark space.

It was observed that after the dust particles were electrified they tended to deposit themselves on any surface near them, and experiments were made to determine the best conditions for purifying air in this manner. It was found to be best done by causing as rapid a discharge of electricity as possible, by means of points, surfaces being placed near them to increase the electrification of the dust, and to augment the rate of the currents of air which were driven from the points. These surfaces became places on which the dust deposited itself before losing its charge. A large flask was found to be rapidly cleared of a cloud of dust by means of a point—the dust being almost entirely deposited on the inside surface of the flask. If the end of the conductor in the flask terminated in a sphere, but little effect was produced. Electricity has also been found capable of depositing the very fine dust of the atmosphere. The air in a large flask was purified much more quickly by means of the electric discharge than it could have been by means of an air-pump and cotton-wool filter.

It is shown that a wet and hot surface repels dust more than twice as strongly as a hot dry one. From this it is concluded that the heat and moisture in our lungs exert a protecting influence on the surface of the bronchial tubes and tend to keep the dust in the air which is ebbing and flowing through them from coming into contact with their surfaces. This was illustrated by placing a hot and wet surface in a current of dense smoke, where it remained some time without receiving a speck of soot, while a similar surface, but cold, was blackened with the smoke. It is pointed out that on account of the irregularities on the surface of the tubes, and of the more violent movements of the air in the lungs, and on account of curves and projecting edges, the protection in the lungs is not perfect. Still it is thought that this repelling action at these surfaces must have some influence, and it seems possible it may explain some climatic effects, as it is evident that the lungs will be much better protected in such places as Davos Platz, where the air is cold and dry, and the repelling forces at a maximum, than at places like Madeira, where the air is warm and moist and these forces are at a minimum. This point can, however, only be determined satisfactorily by anatomical examinations of lungs which have lived under the different conditions.

In the experiments it was observed that dust not only tended to move away from hot surfaces, but also that it was attracted by cold ones, and attached itself to them. To study this effect glass plates were put in different positions near the hot platinum wire. Very beautiful impressions of the dark plane can be obtained by placing a piece of glass vertically and transversely over the hot wire. The hot air in flowing over the glass, deposits its dust on the surface of the plate leaving a clear line in the middle, indicating where the dustless air of the dark plane had passed. In this way the dust is trapped on the glass to which it adheres with some firmness, and not only the impressions but the dark planes themselves may thus be preserved.[1]

Other experiments to study the repulsion and attraction of hot and cold surfaces were made by placing glass plates on both sides of the hot wire. An interesting result was obtained when the plates were about 1 mm. apart. Using magnesia powder, the particles could be seen rising in the current, and approaching the hot wire; they were then observed to be violently repelled towards the cold surface, to which they adhered. If there was sufficient difference of temperature, not a single particle of dust was carried by the current past the hot wire.

A thermic filter is then described. In this filter the air is passed through the space formed between two concentric tubes. One tube is kept cold by a stream of water, and the other heated by means of steam or a flame. This instrument was shown in action; one end of the filter was connected with a glass flask, in which the condition of the air was tested. So long as the difference of temperature was kept up, and the current not too rapid, the air passing through it showed no signs of producing cloudy condensation on the pressure being reduced, showing that the filter had trapped all, even the invisible dust particles.

Some experiments on the effect of diffusion on the distribution of dust at the surface of a diaphragm are described. When carbonic acid diffuses into a space, the dust comes close to the diffusing surface, but if hydrogen is the diffusing gas, a clear space is formed in front of the diaphragm.

An explanation is then offered of the repulsion of dust by hot surfaces and its attraction by cold ones. It seems possible, that the dust might be repelled in the same way as the vanes of a Crookes' radiometer, by a radiation effect. That this was not the true explanation was, however, proved by placing in the dust-box a polished silver flat test-surface, one half of which was coated with lamp-black, when it was found that the dark space in front of the lamp-black was not any thicker than that in front of the polished metal. It is thought that the repulsion is due to the diffusion of the hot and cold air molecules. The hot surface repels because the outward diffusing molecules are hot, and have greater kinetic energy than the inward moving ones; and as the side of the dust particle next the hot surface is bombarded by a larger number of hot molecules than the other side, it is driven away from the hot surface. The attraction of a cold surface is explained by the less kinetic energy of the outward than of the inward diffusing molecules. Some experiments are referred to, to show that the rate at which gas molecules diffuse indicate that this diffusion effect is sufficient to account for the repulsion and attraction of the dust.

If the explanation here given is correct, then the dust is repelled in the same way as a vane of a radiometer when placed in front of a surface fixed inside the radiometer bulb, and hotter than the residual gas, the principal part of the energy producing the motion being transferred from the hot surface to the repelled surface by the kinetic energy of the molecules, and not by radiation.

In illustration of the tendency of dust to move from hot and to deposit itself on cold surfaces, the following experiments were made. Two mirrors, one hot and the other cold, fixed face to face and close to each other, were placed in a vessel filled with a dense cloud of magnesia, made by burning magnesium wire. After a short time the mirrors were taken out and examined. The hot one was quite clean, while the cold one was white with magnesia dust. In another experiment a cold metal rod was dipped into some hot magnesia powder; when taken out it had a club-shaped mass of magnesia adhering to its end, while a hot rod attracted none.

This tendency of dust to leave hot surfaces and attach itself to cold ones explains a number of familiar things, among others it tells us why the walls and furniture of a stove-heated room are always dirtier than those of a fire-warmed one. In the one case the air is warmer than the surfaces, and in the other the surfaces are warmer than the air. This effect of temperature is even necessary to explain why so much soot collects in a chimney. It explains something of the peculiar liquid-like movements of hot powders, and perhaps something of the spheroidal condition.

For practical applications, it is suggested that this effect of temperature might be made available in many chemical works for the condensation of fumes, and that it might also be used for trapping soot in chimneys. A small trap of this kind was shown. It consisted of a tall metal tube or chimney, surrounded by another tube slightly larger. The products of combustion are taken up the centre tube and down the intervening space. The heat of the gases is thus made to do its own filtering. This apparatus being placed over a smoky lamp, it trapped out most of the soot, and deposited it on the inside of the outer tube. This arrangement of apparatus is too delicate and troublesome for general use, and it is suggested that, as by simply cooling gases in presence of plenty of surface much of its dust is deposited, it might be possible and advantageous under certain conditions to purify air by heating and cooling it a number of times, which could be done at a small expense by means of regenerators.

---

[1] Specimens of these trapped dark planes were shown at the meeting, some of them made of white powder deposited on blackened glass, others of charcoal deposited on opal glass.

Experiments were also made by discharging electricity into the smoke in a chimney. This also produced a marked diminution in the blackness of the escaping smoke. The supply of electricity of sufficiently high potential is however a difficulty for the present.

A VAST DUST ENVELOPE[1]

SCIENTIFIC men have evinced extraordinary interest in the wonderfully brilliant sunsets that have for some time past been observed in different parts of the world. Various theories have been advanced, but all are agreed that the real cause is not yet definitely determined. At the Brevoort House yesterday, a *Tribune* reporter spent a couple of hours with Prof. S. P. Langley, astronomer at Allegheny Observatory, Allegheny, Penn. His views upon the topic of the transmissibility of light through our atmosphere are stated below:

"At first I supposed the sunset matter a local phenomenon, but when the reports showed it to have been visible all over the world, it was obvious that we must look for some equally general cause. We know but two likely ones, and these have been already brought forward. One is the advent of an unusual amount of meteoric dust. While something over ten millions of meteorites are known to enter our atmosphere daily, which are dissipated in dust and vapour in the upper atmosphere, the total mass of these is small as compared with the bulk of the atmosphere itself, although absolutely large. It is difficult to state with precision what this amount is. But several lines of evidence lead us to think it is approximately not greatly less than 100 tons per diem, nor greatly more than 1,000 tons per diem. Taking the largest estimate as still below the truth, we must suppose an enormously greater accession than this to supply quantity sufficient to produce the phenomenon in question; and it is hardly possible to imagine such a meteoric inflow unaccompanied with visual phenomena in the form of 'shooting stars,' which would make its advent visible to all. Admitting, then, the possibility of meteoric influence, we must consider it to be nevertheless extremely improbable.

"There is another cause, which I understand has been suggested by Mr. Lockyer—though I have not seen his article—which seems to be more acceptable—that of volcanic dust; and in relation to this presence of dust in the entire atmosphere of the planet, I can offer some little personal experience. In 1878 I was on the upper slopes of Mount Etna, in the volcanic wastes, three or four hours' journey above the zone of fertile ground. I passed a portion of the winter at that elevation engaged in studying the transparency of the earth's atmosphere. I was much impressed by the fact that here, on a site where the air is supposed to be as clear as anywhere in the world, at this considerable altitude, and where we were surrounded by snow-fields and deserts of black lava, the telescope showed that the air was filled with minute dust particles, which evidently had no relation to the local surroundings, but apparently formed a portion of an envelope common to the whole earth. I was confirmed in this opinion by my recollection that Prof. Piazzi Smyth, on the Peak of Teneriffe, in mid-ocean, saw these strata of dust rising to the height of over a mile, reaching out to the horizon in every direction, and so dense that they frequently hid a neighbouring island mountain, whose peak rose above them, as though out of an upper sea. In 1881 I was on Mount Whitney, in Southern California, the highest peak in the United States, unless some of the Alaskan mountains can rival it. I had gone there with an expedition from the Allegheny Observatory, under the official direction of General Hazen, of the Signal Service, and had camped at an altitude of 12,000 feet, with a special object of studying analogous phenomena. On ascending the peak of Whitney, from an altitude of nearly 15,000 feet the eye looks to the east over one of the most barren regions in the world. Immediately at the foot of the mountain is the Inyo Desert, and on the east a range of mountains parallel to the Sierra Nevadas, but only about 10,000 feet in height. From the valley the atmosphere had appeared beautifully clear. But from this aërial height we looked down on what seemed a kind of level dust-ocean, invisible from below, but whose depth was six or seven thousand feet, as the upper portion only of the opposite mountain range rose clearly out of it. The colour of the light reflected to us from this dust-ocean was clearly red, and it stretched as far as the eye could reach in every direction, although there was no special wind or local cause for it. It was evidently like the dust seen in mid-ocean from the Peak of Teneriffe—something present all the time, and a permanent ingredient in the earth's atmosphere.

"At our own great elevation the sky was of a remarkably deep violet, and it seemed at first as if no dust was present in this upper air, but in getting, just at noon, in the edge of the shadow of a range of cliffs which rose 1,200 feet above us, the sky immediately about the sun took on a whitish hue. On scrutinising this through the telescope it was found to be due to myriads of the minutest dust particles. I was here at a far greater height than the summit of Etna, with nothing around me except granite and snow-fields, and the presence of this dust in a comparatively calm air much impressed me. I mentioned it to Mr. Clarence King, then Director of the United States Geological Surveys, who was one of the first to ascend Mount Whitney, and he informed me that this upper dust was probably due to the 'loess' of China, having been borne across the Pacific and a quarter of the way around the world. We were at the summit of the continent, and the air which swept by us was unmingled with that of the lower regions of the earth's surface. Even at this great altitude the dust was perpetually present in the air, and I became confirmed in the opinion that there is a permanent dust shell inclosing the whole planet to a height certainly of about three miles (where direct observation has followed it), and not improbably to a height even greater; for we have no reason to suppose that the dust carried up from the earth's surface stops at the height to which we have ascended. The meteorites, which are consumed at an average height of twenty to forty miles, must add somewhat to this. Our observations with special apparatus on Mount Whitney went to show that the red rays are transmitted with greatest facility through our air and rendered it extremely probable that this has a very large share in the colours of a cloudless sky at sunset and sunrise, these colours depending largely upon the average size of the dust particles.

"It is especially worth notice that, as far as such observations go, we have no reason to doubt that the finer dust from the earth's surface is carried up to a surprising altitude. I speak here, not of the grosser dust particles, but of those which are so fine as to be individually invisible, except under favouring circumstances, and which are so minute that they might be an almost unlimited time in settling to the ground, even if the atmosphere were to become perfectly quiet. I have not at hand any data for estimating the amount of dust thrown into the air by such eruptions as those which recently occurred in Java and Alaska. But it is quite certain, if the accounts we have are not exaggerated, that the former alone must have been counted by millions of tons and must in all probability have exceeded in amount that contributed by meteorites during an entire year. Neither must it be supposed that this will at once sink to the surface again. Even the smoke of a conflagration so utterly insignificant, compared with nature's scale, as the burning of Chicago, was, according to Mr. Clarence King, perceived on the Pacific Coast; nor is there any improbability that I can see in supposing that the eruption at Krakatoa may have charged the atmosphere of the whole planet (or at least of a belt encircling it) for months with particles sufficiently large to scatter the rays of red light and partially absorb the others, and to produce the phenomenon that is now exciting so much public interest. We must not conclude that the cause of the phenomenon is certainly known. It is not. But I am inclined to think that there is not only no antecedent improbability that these volcanic eruptions on such an unprecedented scale are the cause, but that they are the most likely cause which we can assign."

---

[1] From the *New York Daily Tribune*, January 2. Communicated by Prof. Piazzi Smyth.

THE ORIGIN OF THE SCENERY OF THE BRITISH ISLANDS[1]

THE insular position of Britain, which we are accustomed to regard as an essential and aboriginal feature of the country, is merely accidental, and has not always been maintained. The intimate relation of Britain with the Continent is well shown by the Admiralty charts. If the west of Europe were elevated 200ft.—that is, the height of the London Monument—the Straits of Dover, half of the North Sea, and a large part of the English Channel would be turned into dry land. If the elevation extended to 600ft.—that is, merely the united heights of St. Paul's and the Monument—the whole of the North Sea, the Baltic, and the English Channel would become land. There would likewise be added to the European area a belt of territory from 100 to 150 miles broad, stretching to the west of Ireland and Scotland. A vast plain would unite Britain to Denmark, Holland, and Belgium, and would present two platforms, of which the more southerly would stretch from what are now the Straits of Dover northward to the northern edge of the Dogger Bank. The steep declivity separating the two plateaux is doubtless a prolongation of the Jurassic and Cretaceous escarpments of Yorkshire. It is trenched at either end by marked depressions, of which the western is a magnificent valley through which the united waters of the Rhine and Thames would flow between the Dogger Bank and the Yorkshire cliffs. The eastern gap would allow the combined Elbe and Weser to escape into the northern plain. Possibly all those rivers would unite on that plain, but, in any case, they would fall into a noble fjord which would then be revealed following the southern coast line of Norway. Altogether an area more than thrice that of Britain would be added to Europe. By a total rise of 1,800 feet, Britain would be united to the Faroe Islands and Iceland; while the Arctic and Atlantic Oceans would be separated. From its position on the oceanic border of a continent, Britain has been exposed to a great variety of geological change. In such a position marine erosion and deposit are most active, and a slight upheaval or depression, which would have no sensible effect in the interior of a continent, makes all the difference between land and water. Moreover, there appears to be a tendency to special disturbance along the edge of an ocean. America affords the most marked proofs of this tendency, but in the structure of Scandinavia and its prolongation into Scotland and Ireland there appear to be traces of similar ancient ridging up of the oceanic border of Europe.

There is a remarkable convergence of geological formations in Britain, each carrying with it its characteristic scenery. The rugged crystalline rocks of Norway reappear in the Scottish Highlands; the fertile Chalk, with its smooth downs and gentle escarpment, stretches across to us from the north of France; the great plains of North Germany, strewn with the debris of the northern hills, extends into our eastern lowlands; even the volcanic plateaux of Iceland and Faroe are prolonged into the Inner Hebrides and the north of Ireland.

The present surface of Britain is the result of a long, complicated process in which underground movements, though sometimes potent, have only operated occasionally, while superficial erosion has been continuous, so long as any land has remained above the sea. The order of appearance of the existing features is not necessarily that of the chronological sequence of the rocks. The oldest formations have all been buried under later accumulations, and their re-emergence at the surface has only been brought about after enormous denudation. In its general growth, Britain like the rest of Europe has, on the whole, increased from the north by successive additions along its southern border. The oldest upheavals ridged up the Palæozoic rocks into folds running north-north-east and south-south-west, as may yet be seen in Scotland, in the Lake Country, and in Wales. By a later series of folds the younger Palæozoic rocks were thrown into north and south and east and west ridges, the latter of which still powerfully affect the topography in southern Ireland, and thence through South Wales and Belgium. An east and west direction was followed by the more important subsequent European disturbances, such as those that upheaved the Pyrenees, Jura, and Alps. Some of the latest movements that have powerfully affected the development of our scenery were those that gave the Secondary rocks their general tilt to south-east. It is very doubtful if any part of the existing topography can be satisfactorily traced back beyond middle or older Tertiary time. The amount of erosion of some of the hardest rocks of the country since that date has been prodigious, as may be seen in the fragmentary condition of the volcanic plateaux of the Inner Hebrides.

The main topographical features of Britain may be arranged as mountains, tablelands, valleys, and plains. All our mountains are the effect of erosion on areas of land successively upheaved above the sea. In the development of their forms, the general outlines have been mainly determined by erosion independent of geological structure; while the details have been chiefly guided by structure, but partially also by the rate and kind of erosion. Ruggedness, for example, has resulted primarily from structure, but has been aggravated by greater activity of erosion. The mountainous west, with a greater rainfall and steeper slopes, is more rugged than the mountainous east. The tablelands of Britain are of two orders—1, those of deposit, which may be either (*a*) of sedimentary rocks, horizontal or nearly so, as in the millstone grit and Jurassic plateaux of Yorkshire, or (*b*) of volcanic rocks, as in the wide plateaux of Antrim, Mull, and Skye; 2, those of erosion, where, as the result of long-continued degradation, a series of plicated rocks has been cut down into a more or less uniformly level surface, as in South Wales. By the elevation of such a surface into a high plateau, erosion begins anew, and the plateau is eventually trenched into a system of ridges and isolated hills, as has happened in the Highlands. The valleys of Britain are the result of erosion either (*a*) guided by geological structure, as in what are called longitudinal valleys, that is, valleys which run along the strike or outcrop of formations, as the Great Glen and Glen Spey in Scotland and the valleys of the Trent and Avon in England; or (*b*) independent of geological structure, as in the transverse valleys which embrace the great majority of British examples. Our plains have been produced by the spreading out of *detritus* by the operation of rain and rivers, as in river terraces and alluvial plains; by the sea, as in raised beaches; or by land-ice and floating-ice, as in the glacial drifts of the Lowlands. The existing watershed of Britain is profoundly significant, affording a kind of epitome of the geological revolutions through which the surface of the country has passed. It lies nearer the west than the east coast. The western slope being thus the steeper, as well as the more rainy, erosion must be greater on that side, and consequently the watershed must be slowly moving eastward. Probably the oldest part of the watershed is to be found in the Highlands, where its trend from north-north-east to south-south-west was determined by the older Palæozoic upheaval. Its continuity has been interrupted by the dislocation of the Great Glen. After quitting the Highlands it wanders across the Scottish Lowlands and Southern Uplands, with no regard to the dominant geological structure of these districts, as if, when its course was originally determined, they had been buried under so vast a mass of superincumbent rock that their structure did not affect the surface. Running down the Pennine Chain the watershed traverses a region of enormous erosion, yet from its general coincidence with the line of the axis of elevation, we may perhaps infer that the anticline of the Pennine Chain has never been lost under an overlying sheet of later undisturbed rocks. The remarkable change in the character of the watershed south of the Pennine Chain carries us back to the time when the great plain of the Secondary rocks of England was upraised with a gentle inclination to east and south-east. The softer strata between the harder escarpment-forming members of the Jurassic series and the Palæozoic rocks of the Pennine Chain were worn away, and two rivers carrying off the drainage of the southern end of that chain flowed in opposite directions, the Avon turning south-west and the Trent northwards. By degrees these streams moved away across the broadening plain of softer strata as the escarpments emerged and retreated. At the same time streams collected the drainage from the uprising slope of Secondary rocks and flowed south-eastward. Successive lines of escarpment have since been developed, and many minor watersheds have arisen, while the early watershed has undergone much modification, these various changes pointing to the continuous operation of running water.

SOCIETIES AND ACADEMIES

London

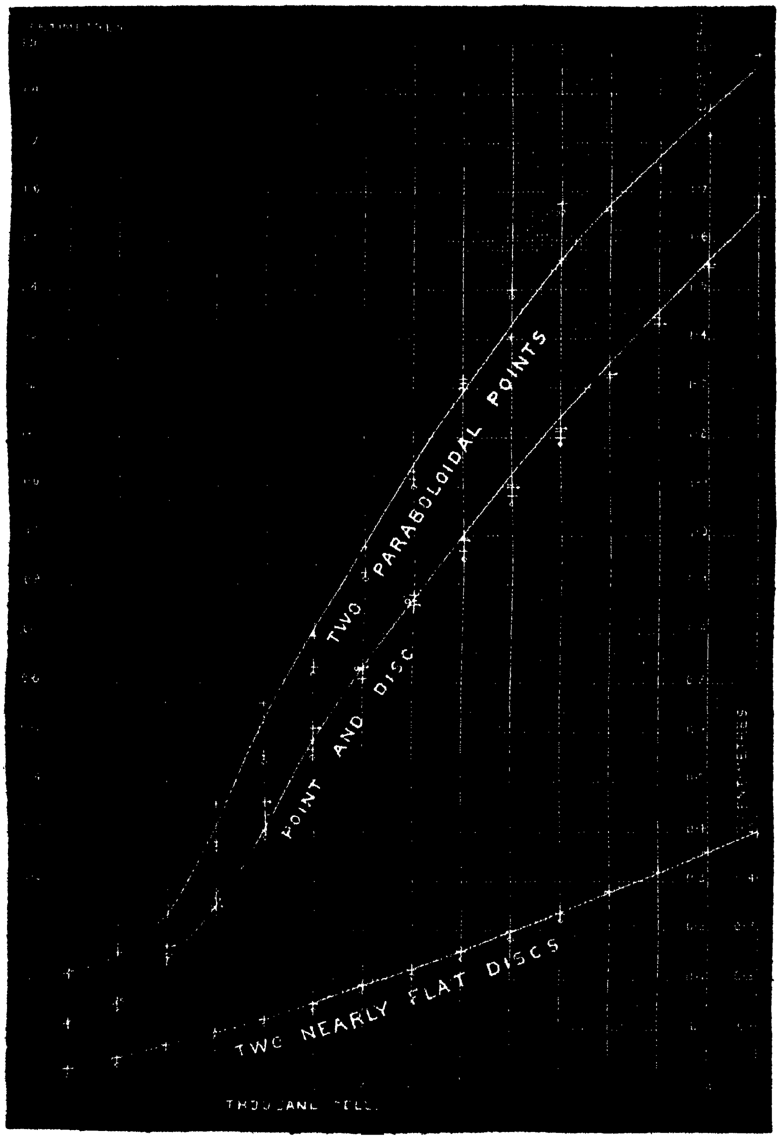
Royal Society, December 13, 1883.—"Experimental Researches on the Electric Discharge with the Chloride of Silver Battery." By Warren De La Rue, M.A., D.C.L., Ph.D., F.R.S., and Hugo W. Müller, Ph.D., F.R.S.

SECOND POSTCRIPT TO PART IV. "PHIL. TRANS.," PART II., VOL. CLXXIV.

Striking Distance.—In a postscript to Part IV. of our researches,[1] we stated that, with 14,400 cells, partly of the rod form, partly of the chloride-in-powder form, the length of the spark between paraboloidal points was 0·7 inch (17·8 mm.), and between a point and disk 0·62 inch (15·7 mm.), and that it does not appear, therefore, that the law of the spark being as the square of the number of cells holds good beyond a certain number.

These results were obtained at the Royal Institution; since the removal of the battery to our laboratory we had not, at the date of the postscript to Part IV. of our researches, charged up the whole of it. Recently, however, we have put the battery in thorough order, by scraping the zinc rods[1] of the cells already charged up and added newly made up cells to bring up the total to 15,000 cells, all of the rod form.

Having the whole 15,000 cells in perfect order, we thought that it would be desirable to make fresh determinations of the striking distance, increasing the potential a thousand cells at a time, between two very slightly convex disks (planes), a point and disk, and two paraboloidal points. These points are one-eighth of an inch (3·175 mm.) in diameter, and three-eighths of an inch (9·525 mm.) long. In the case of a point and disk, the point was like one of those used for two points, and the disk was $1\frac{5}{16}$ inch [3·334 cm.] in diameter. The two planes used were $1\frac{5}{16}$ inch [3·334 cm.] in diameter.



As the points, particularly the negative, are deformed by the discharge, the precaution was taken to touch up the point after each discharge in the shaping-tool, screwed to the mandril of the lathe, mentioned in Part I. of our researches,[2] and thus to restore them to a true paraboloidal form.

Results were obtained which are plotted down in the diagram.

The several results, the different sets being distinguished by plain crosses or crosses with a dot, are laid down on the diagram, Fig. 1, to which are also added other results already published from former experiments; these latter have a ring on one of the members of the cross.

15,450	1·8500	8,351	0·84 ,,	28

An inspection of the diagram, drawn on a reduced scale from the curves as originally laid down, shows that the curve for approximate planes (slightly convex, to insure the centres being the most prominent) is continuously concave, whereas those for both point and disk and two points are concave only for a certain distance, and then turn off and become convex. Moreover, it is seen that the intensity of force per centimetre decreases continuously up to 15,450 volts in the case of planes; but that, in the case of a point and disk, and also in that of two points, the decrease ceases after a certain potential has been reached, and that then it increases so as to become nearly a constant quantity. Between a point and a disk the potential per centimetre at 9,000 volts and beyond is very nearly 9,200; consequently, if the law holds good, to produce a spark 1 decimetre (3·94 inches) long, 92,000 volts, one 1 metre (39·37 inches) long, 920,000 volts,[1] and a flash of lightning 1 kilometre (0·621 mile) in length, a potential of 920,000,000 volts would be required, but this potential would be lessened by the diminution of the atmospheric pressure at the height of a kilometre, namely 607·4 mm. (799,210 M), or a mean pressure of 713·8 mm. (939,211 M) between 1 kilometre and the earth. Taking the mean pressure 939,211 M, it would require 864,000,000 volts to produce a discharge between a cloud (regarded as a point) 1 kilometre high and the earth.

It is extremely difficult to conjecture how a cloud can become charged to such an enormous potential, unless the charged molecules balance each other (as those of a stratum in a vacuum tube may be conceived to do) until a disturbing cause breaks up the arrangement; and then the whole of them are discharged in one direction with their aggregate potential.

We may add that less than 15,000 cells would not have sufficed to make out the fact that the intensity of force to produce a discharge between a point and disk or two points becomes a constant after 9,000 to 11,000 cells has been reached.

The following table gives the ratios of the striking distances between a point and a disk and two points respectively, taking those between two disks as unity. And also the relation between the striking distances between a point and a disk and between two points, taking those between a point and a disk as unity.

Cells	Ratio between point and disk to that between two disks	Ratio between two points and that between two disks	Ratio between two points and that between a point and disk
With 1,000	0·60	0·84	1·40

The striking distances from which the above ratios are calculated are those obtained from the smoothed curves.

January 17.—"Evidence of a Large Extinct Australian Lizard (*Notiosaurus dentatus*, Ow.)," by Sir Richard Owen, K.C.B., F.R.S., &c.

This evidence is based on a small fragment, seemingly of coal, with roots of two teeth adherent thereto, transmitted to the author from the Department of Mines, Sydney, New South Wales; but stated to be from a Pleistocene deposit. The author had

---

[1] To produce a spark between a point and a disk used for example as the dischargers of an induction coil—

In length	It would require in E.M.F. volts
1 inch	23,367
1 foot	280,400
1 yard	841,230

noted that vegetable fossils from the same formation and locality presented a similar jet-black colour, and glistening petrified fracture. The paper details a series of comparisons with known recent and fossil Saurians. The size and striated exterior of the teeth suggested, at first, crocodilian affinity. But closer comparisons, aided by application of the microscopic test to the tissues of both the bone and tooth, led to a conclusion of the affinities of the fossil reptile represented by the fragment of mandible and attached parts of teeth. It was equal in size to the extinct horned lizard *Megalania*, which had an armature of the mouth like that of a tortoise. *Notiosaurus* was a toothed and pleurodont lizard, like the large existing *Hydrosaurus* of Australia, but of more than twice its size.

Linnean Society, January 17.—Sir John Lubbock, Bart., president, in the chair.—Mr. A. S. Pennington was elected a Fellow of the Society.—Dr. R. C. A. Prior exhibited and made remarks on a series of useful timbers from British Guiana. These were all hard woods, among which may be mentioned the "greenheart" (*Nectandra rodiei*); the "ducalibolly," a rare, red wood used in the colony for furniture; "wamara," a very hard wooded tree sixty feet high, used by the natives for clubs, &c.; "letterwood" (*Brosimum aubletii*), useful for inlaying and making very choice walking sticks; "hyawabolly" (*Omphalobium lamberti*), a rare tree of twenty feet high, known commercially as zebra wood.—Mr. H. N. Ridley drew attention to a fasciated branch of holly from Herefordshire, in which certain of the leaf-branches were curiously interwoven.—A presumed portrait of Linnæus, in oil, was exhibited on behalf of Mr. F. Piercy.—A paper was read by Mr. J. G. Baker, viz. a review of the tuber-bearing species of *Solanum*. As they stand in De Candolle's "Prodromus" and other botanical works, the tuber-bearing Solanums are estimated as belonging to twenty distinct species. Mr. Baker thinks that not more than six of those are really distinct, viz. (1) *Solanum tuberosum*, a native of the dry, high regions of the Andes from Chili northwards to Venezuela, reappearing in other varieties in Mexico and the Rocky Mountains; (2) *S. maglia*, an inhabitant of the damp coasts of Chili, as far south as lat. 44° to 45°; (3) *S. commersoni*, a low-level plant of Uruguay, lately introduced as a novelty under the name of *S. ohrendii*; (4) *S. cardiophyllum*, a little-known species from the Mexican highlands; (5) *S. jamesii*, a native of Mexico and the Rocky Mountains; and (6) *S. oxycarpum*, a native of Central Mexico. The two last have the tubers very small. All our cultivated races of potato belong to *S. tuberosum*; but the plants gathered by Darwin in the Chonos Archipelago, and that experimented upon by Solme at Chiswick, are both *S. maglia*. The author attributes the deterioration of the potato partly to its being cultivated in too humid climates, and partly to the tuber having been unduly stimulated at the expense of the other organs of the plant. There are many hundred species of Solanum known which do not produce any tubers, but maintain their ground in the world by their seeds alone, and he urges that, in order to extend the power of climatic adaptation of potato species, (2), (3), and (4) should be brought into cultivation and tried both as pure specific types and as hybridised with the numerous forms of *S. tuberosum*.—The next paper read was by Mr. A. D. Michael, on the "Hypopus" question or life history of certain Acarina. From a careful series of experiments and observations he concludes that true "Hypopi" are not adult animals, but only a stage, or heteromorphous nymphs of *Tyroglyphus* and allied genera. Nor do all individuals become "Hypopi," which latter stage takes place during the second nymphal ecdysis. It seems a provision of nature for the distribution of the species irrespective of adverse conditions. "Hypopi" are not truly parasitic, nor confine themselves to any particular insect. A new adult form described is called by the author *Disparipes bombi*, and he believes there are other species of the genus. Donnadieu's bee parasites are admitted to be adults, though it is uncertain if they are identical with Dufour's *Trichodactylus*.—Dr. M. C. Cooke made a communication on the structure and affinity of *Sphæria pocula*. Its position has hitherto been unquestioned, since originally described by Schweinitz in 1825. Dr. Cooke, however, shows from microscopical examination that structurally it is Hymenomycetal, and not Ascomycetal, being allied to the genus *Polyporus* or *Porothelium*. He designates it as *Polyporus* (*Mesopus*) *poculus*, Schwein., allied perhaps in habit to *P. pendulus*, but in substance to *P. rhipidium*.—A paper by Mr. W. Joshua was read, viz. notes on some Burmese Desmidieæ, in which he figures and describes new and interesting species.—Novitates Capensis was the title of a paper by Mr. Henry Bolus, and mainly confined to diagnoses of new or rare orchids from South Africa.

Institution of Civil Engineers, January 22.—Sir Frederick Bramwell, F.R.S., vice-president, in the chair.—The paper read was on the adoption of standard forms of test-pieces for bars and plates, by Mr. William Hackney, B.Sc., Assoc.M.Inst.C.E.

Edinburgh

Royal Society, January 7.—T. Stevenson, C.E., vice-president, in the chair.—Papers were read on the approximation to the roots of cubic equations by recurring chain fractions, by Mr. E. Sang, and on the researches of M. E. de Jonquières on periodic continued fractions, by Thomas Muir, M.A. The author showed that the results which M. de Jonquières is from time to time communicating to the French Academy are merely particular cases of a more general result which he communicated to the Society some years ago.—A paper was also read on new forms of nerve-terminations in the skin of mammals, by S. Hoggan, M.B., the latter being communicated by Prof. Turner.—A second paper was laid on the table on a diagnosis of the phanerogamous plants of Socotra, by Prof. Bayley Balfour.—A communication was read on the Tunicata of the *Porcupine* Expedition by Prof. Herdman.—An arrangement of the metals in an electro-frictional series was submitted by A. Macfarlane, M.A., D.Sc. As the result of a large number of quantitative experiments, he found that the arrangement of the metals according to the amount of negative electricity produced upon them by a constant amount of friction (without abrasion) is as follows:—Gold, 181; platinum, 136; tin, 126; silver, 102; copper, 100; lead, 62; nickel, 59; brass, 59; iron, 56; aluminium, 50; zinc, 45; magnesium, 43; antimony, 38; German silver, 32; bismuth, 22.

JURASSIC ROCKS UNDER LONDON

ON two previous occasions[1] the attention of the readers of NATURE has been directed to the facts which have been revealed by deep borings in search of water under London. In the first of these communications it was shown how completely the predictions of geologists, as to the nature, succession, and thicknesses of the different strata under London had been verified; and in the second the question of the possibility of finding workable coal-seams beneath the metropolitan area was discussed at some length.

Quite recently, however, a new boring has been put down within the London Basin, which has made known so many new facts of surpassing interest to the geologist, and has at the same time furnished them with new data, tending to modify their former conclusions on some important problems, that it may be well to recur to the subject in the pages of this journal, and to give a short account of these remarkable discoveries.

The growing wants of the town of Richmond in Surrey have caused the local authorities of that place to seek an augmentation of their water-supply by carrying to a much greater depth a well which had some years ago been put down into the Chalk. This has been done by boring by Mather and Platt's flat-rope system, the work being done under the direction of Mr. C. Homersham, C.E., and at the present time a depth of 1308 feet has been attained. Not only is this well actually a few feet deeper than the famous well at Kentish Town, which was carried 1302 feet beneath the surface, but, commencing as it does near the level of the Thames, it reaches, reckoning from the Ordnance datum line, a level more than 150 feet lower than that of any well hitherto sunk within the London Basin.

Up to the present time only insignificant supplies of water have been obtained, but it is to be hoped that as the work is carried on this spirited enterprise may meet with the success it so well deserves. To the student of London geology it has already afforded a number of facts of wonderful novelty and interest.

The succession of strata found in this well was as follows:—

		feet
	Made ground and gravel	10
Tertiary, 243½ feet	London Clay...	160
	Woolwich and Reading Series ...	60
	Thanet Sand...	23½
Cretaceous, 888½ feet	Chalk with flints Grey Chalk Chalk Marl	671
	Upper Greensand...	16
	Gault	201½
	Neocomian (?)	10
	Great Oolite	87½
	New Red Sandstone and "Marl"	60 +

The lines indicate unconformable breaks in the series of strata, and the lapse of enormous periods of time between the deposition of the beds which they separate.

Down to the base of the Gault the order and thicknesses of the several formations was exactly what would be predicted by any geologist conversant with the details of London geology. Some very interesting facts concerning the divisions of the Chalk strata under London have, however, been made out for the first time by the study of the admirable series of "cores" brought to the surface during these boring operations.

But it is with respect to the strata found lying beneath the Gault that the greatest amount of interest has been excited among geologists.

The Gault clay has at its base the usual band of phosphatic nodules, the so-called "coprolites," and beneath this was found a series of beds, ten feet in thickness, the nature of which is peculiar, while their age is somewhat problematical.

These beds appear in fact to consist of materials derived from the wearing away of the rocks on which they repose, but include fragments of other rocks evidently brought from a distance. They contain many "derived fossils," greatly fractured and waterworn, but very few of its organic remains are of the age of the deposit itself, and serve to fix its geological age. From a consideration of the whole of the evidence in this case, however, this series of rocks, ten feet in thickness, may be referred with considerable probability to some part of the Neocomian period. Unfortunately the typical Lower Greensand was wholly wanting, and the expected supplies of water from this source were therefore missed.

But immediately beneath this peculiar and somewhat puzzling stratum, deposits of great interest to the geologist were encountered. They consisted of thick beds of oolitic limestone, with some subordinate beds of clay, fuller's earth, and sandstone, the whole having a thickness of 87½ feet. A few fossils, for the most part very imperfect, were found in the limestone, but one of the clay bands, when carefully washed, proved to be veritable "El Dorado" to the palæontologist. It was seen to be crowded with specimens of Brachiopods, Bryozoa, Echinoderms, and other organisms, all of them in the most exquisite state of preservation. It is evident that these organisms which flourished upon the floor of the sea were killed and overwhelmed by a sudden influx of muddy sediment. The species found in this interesting bed of clay, which is only six inches in thickness, are similar to those which occur in the Bradford Clay of Wiltshire, and the Calcaire de Ranville of Normandy. It is evident, therefore, that the deposit which contains them is of the age of the Great Oolite. These great oolite strata are found to rest directly on the Trias,—the Inferior Oolite, Lias, and Rhætic being absent.

Now no strata of the age of the Lower Oolites were before known to exist under the London Basin, though it is but fair to remember that Mr. Godwin-Austen, in his celebrated essay on the probable existence of coal under London, distinctly pointed out the possibility of the existence of such deposits.

In the boring which in the year 1878 was put down at Messrs. Meux's Brewery in the Tottenham Court Road some anomalous strata about 64 feet in thickness were found lying between the Gault Clay and the Devonian rocks in which that boring terminated. From some obscure casts of fossils detected in these beds, they were, at the time of their discovery, referred to the Neocomian.

---

[1] See NATURE, vol. xvi. p. 2, and vol. xxv. pp. 311, 361.

But a careful re-examination of the question shows that, like the beds above described at Richmond, they certainly belong to the Great Oolite, though they were deposited under shallower water conditions than their equivalents at the latter place, and were perhaps, in part at least, of estuarine origin.

The Trias is another formation which has not hitherto been certainly detected under London. It is true that some geologists think that the rocks reached in the Kentish Town and Crossness borings belong to that formation, but this identification is disputed by some very eminent authorities. Although no fossils have been found in the red and variegated strata of the Richmond boring, yet their mineral characters are such as to leave scarcely any room for doubt that they belong to some part of the "Poikilitic" or New Red Sandstone system. They consist of coarse and fine grained sandstones, often exhibiting false-bedding, which alternate with red and variegated clays or "marls." It will be of great interest to geologists if it can be determined upon what member of the Palæozoic rocks these Triassic strata repose.

The result of the deep boring at Richmond is to show that while the water-bearing strata of the Lower Greensand do not extend so far northward as Richmond, other unexpected deposits do exist beneath that town. During portions of the Triassic and Jurassic periods the great Palæozoic ridge, stretching between the Mendips and the Ardennes, was in part or wholly submerged, and thus we find deposits of these ages along its flanks. The relation of the Great Oolite under the central and southern metropolitan district are strikingly similar to those of the Lower Oolite in the Boulonnais. Taking into consideration the proved thickness of the Upper and Middle Oolites in the "Wealden boring" at Battle, we most be prepared to find the Palæozoic axis, with its possible coal-beds, at a considerably greater depth beneath the surface in the southern half of the London Basin than had hitherto been anticipated.

Although no beds of Middle Oolite age have as yet been found under the London Basin, yet, that strata of this period were originally deposited there, we have a very interesting and curious proof. Among the beds of the Lower Greensand of the North Downs, between Sevenoaks and Farnham, we often find deposits consisting of such coarse materials as almost to merit the name of conglomerates. These consist in great part of waterworn fragments of hard and sub-crystalline rocks, evidently derived from the great Palæozoic ridge lying to the north. Mingled with these pebbles are great numbers of excessively eroded but sometimes still recognisable fossils evidently washed out of beds of Lower and Middle Oolite age. The former, as we have just showed, have now been detected under London; but such is not the case with the latter, which may not improbably have been wholly removed by denudation before the deposition of the Cretaceous strata.

In one of the articles referred to at the commencement of this notice, it was pointed out that not only might coal be found at workable depths under London, but that, when discovered, this coal would probably be of the anthracite variety Now although no beds of coal have hitherto been found in place beneath the metropolis, yet the Richmond boring has yielded striking and unmistakable evidence as to the presence and nature of the coal-seams under the London Basin. In several of the deposits pebbles of coal-measure sandstone with fragments of anthracite have been detected. From this interesting fact it may be justly inferred that while the beds in question were being deposited on the flanks of the old Palæozoic ridge, portions of that ridge consisting of Carboniferous strata and containing seams of anthracite rose above the level of the sea and yielded the fragments mentioned. That the source of these fragments was not very distant may be inferred from the brittleness of anthracite, which certainly could not have travelled far. Thus at last the prediction of geologists has been verified, and coal has been found under London, though as yet unfortunately not *in situ*.

JOHN W. JUDD

MENTAL EVOLUTION IN ANIMALS

Mental Evolution in Animals. By G. J. Romanes, M.A., LL.D., F.R.S., &c. With a Posthumous Essay on Instinct, by Charles Darwin. (London: C. Kegan Paul & Co., 1883.)

IN the present volume Mr. Romanes redeems a part of the promise which he gave us in his "Animal Intelligence." He traces in its main outlines the development of mind in the lower animals. The other part of the promise, to follow the course of mental development in man, will be fulfilled in another work. We think it well that the author has thus divided his task. Each division is of sufficient magnitude to require a separate volume; and though as an evolutionist Mr. Romanes would of course maintain the continuity and identity of the process of mental evolution from its first obscure manifestations in the lower grades of animals up to its highest present point of attainment in civilised man, he would probably allow that the two stages of the process, the sub-human and the human, are sufficiently differenced by the difference in the degree of complexity of the factors involved. To this it may be added that the detailed study of each of these two stages of mental life requires a body of knowledge of its own, a special modification of psychological method, and a particular kind of psychological interest.

In the present work the author has to face a much more difficult task than that which he undertook in his earlier volume. This no doubt had its difficulties. For in what we call the "observation" of mind, whether in our fellow-men or in the lower animals, a process of inference is involved; and when the action to be psychologically interpreted is far removed from the ordinary types of human action, this process is one of peculiar difficulty. But in the earlier work inference or interpretation played a subordinate part. Here, however, it becomes the main problem. In order to connect the facts ascertained and to present a systematic view of mental life as a whole, we must have clear notions respecting the nature of mind in general, as well as of its several phases, which we mark off by the names of the faculties perception, imagination, &c. It is not too much to say that in carrying out the task of tracing the evolution of mind in the lower region an inquirer needs to combine the special aptitudes of a naturalist with those of a psychologist.

Readers of the earlier writings of Mr. Romanes are well aware that he possesses a considerable skill in psychological analysis; and the present volume amply justifies the high expectations in this respect which his other works had excited. He shows acuteness and now and again subtlety. But ingenuity is invariably kept in check by that too uncommon quality, sound common sense. He does not strain after originality, but rather takes pleasure in affiliating his views on the doctrines of recognised masters of the science. The reader has throughout the conviction that the writer has a disinterested enthusiasm for his subject, and cares much more for adding to the store of well-ascertained truth than for adding to his own reputation as a contributor to this result. In all this he seems to have caught something of the spirit of his favourite master, Charles Darwin, of whose valuable work in animal psychology the present volume is to so large an extent a continuation.

At the very outset Mr. Romanes has to face a question which makes unusual demands on the inquirer's sobriety of judgment. What are we to include under the head of mind? How far down in the zoological scale can we confidently maintain that mind is to be found? And by what criterion are we to ascertain its presence? The student of psychology need not be reminded that even competent writers have grown confused in seeking to demarcate the area of mental phenomena, whether as presenting themselves in connection wlth a single organism, or with the sum of organic beings. A trained psychologist like G. H. Lewes used the terms "sensibility" and "sentience" in a way that left his readers perplexed as to whether he was speaking of a psychical phenomenon properly so called, that is, a mode of feeling, or simply of a physiological phenomenon, actions of the nervous system or nervous processes. Mr. Romanes has steered clear of this confusion. He rightly criticises Lewes's use of the term "sensation," and confines it to its proper subjective signification. Mind being thus coextensive with feeling or states of consciousness, the author proceeds to lay down a criterion for ascertaining its presence in any given case. It is as follows:—"Does the organism learn to make new adjustments, or to modify old ones, in accordance with the results of its own individual experience?" Otherwise expressed, it is the manifestation of choice, choice being proved by "the antecedent uncertainty of adjustive action." In laying down this test, however, Mr. Romanes is careful to point out its imperfections. "It is not rigidly exclusive, either, on the one hand, of a possibly mental character in apparently non-mental adjustments, or, conversely, of a possibly non-mental character in apparently mental adjustments." That is to say, it is a rough test sufficient for practical purposes, and eminently in accordance with the dicta of common sense.

After a brief account of the structure and function of nerve-tissue, and of the growing complexity of nerve-structures as evidenced by the double result, compounding of mental elements and compounding of muscular elements, the writer proceeds to discuss what he terms the root-principles of mind. He has already told us that the criterion of mind is choice. He now considers what is involved in the simplest type of choice. Being a mental quality, it must have its physiological correlative. This the author takes to be what he variously calls "the power of discriminating between stimuli *irrespective of their relative mechanical intensities*," the power of "selective discrimination," of "discriminative excitability," &c. It is illustrated by the capability of a sea-anemone which had been surrounded by a turmoil of water, after a time of expanding its tentacles on contact with a solid body. This implies the discrimination of qualitatively unlike stimuli. Each of the organs of special sense has as its function "the rooting out, selecting, or discriminating the particular kind of stimulation to which its responsive action is appropriate." This power of discrimination is regarded as the root-principle of mind. This doctrine has a certain resemblance to the theory of Mr. Spencer and Dr. Bain, that the feeling of difference is the fundamental mode of consciousness. But the author is very explicit in saying that the discrimination he speaks of is a physiological and not a psychological property. Indeed, he allows that it manifests itself in plants, that is to say, much lower down in the scale of organisms than mind can be supposed to reach. It may, however, occur to the reader that the property is not even peculiar to organic structures. Does not a piano manifest just this selective discrimination (to qualitatively unlike stimuli) when its several strings pick out and resonate to the appropriate vibrations of a composite mass of sound? And is it not easy to conceive an artificial mechanism showing such discrimination in a far higher degree than the lower grades of animals? It may be urged, further, that what choice, as previously defined by Mr. Romanes, requires as its correlative is a germ of *conscious* discrimination. A new adjustive action, not provided for by the inherited nervous structures, seems to involve some vague consciousness of a difference between the new and the old, the exceptional and the usual, circumstances. Mr. Romanes might not improbably meet these difficulties by saying that in calling this physiological discrimination the root-principle of mind he simply means to single out the most important property of nerve-structures, the development of which up to a certain point is an antecedent condition of the appearance of mind or consciousness. But even then it would be hard to see why this was exclusively erected into the root-principle of mind to the disregard of another property, retentiveness or memory, which Hering and others have shown to be a property of all organic structure, and the importance of which, indeed, the author seems to allow later on in his work.

In order to complete the author's account of the physiological conditions of mind it is necessary to add that he supposes consciousness to arise when the time occupied by the nervous process, or the interval between sensory stimulation and muscular action reaches a certain magnitude. Mere complexity of nervous actions does not involve consciousness, as we may see in the case of highly compound reflexes. To use the author's graphic language, consciousness involves as its immediate physiological condition a ganglionic "friction" or "state of turmoil." This increase of time "implies that the nervous mechanism concerned has not been fully habituated to the performance of the response required." As more complex organisms are evolved, and the stimuli playing on them become in consequence more varied, this insufficiency of mechanical arrangements and consequent rise of ganglionic friction become more and more marked, and the insufficiency is met by the activity of the higher centres in "focusing many and more or less varied stimuli," which function involves a higher manifestation of the aptitude of discrimination, and as a consequence of this a psychical accompaniment or consciousness.

The author now proceeds to sketch out his general scheme of mental evolution by the aid of a somewhat elaborate diagram. By this last, which is of a tree-like form, we see how out of excitability, the distinguishing property of living matter, there arises, by a double root, contractility, the property of nerve-fibres, and discrimination, the property of nerve-cells, first reflex action, then conscious or voluntary. In branch-like appendages of the stem are represented the successive grades of intellect on the one side, and emotion on the other. To this are added at the sides two finely graduated scales giving the products of emotional and intellectual development. Opposite the numbered divisions of these scales appear the names of those classes of animals, species or larger groups, in which the particular products first distinctly present themselves. Finally the corresponding stages of mental development of the human individual are appended in a parallel scale. It is only fair to Mr. Romanes to say that in thus seeking to mark out by definite stages or levels the progress of mind in the animal series, he is fully aware of the impossibility of assigning hard and fast lines of demarcation. His psychological knowledge tells him that the several faculties, sensation, perception, &c., are not absolutely distinct one from another, but involve common psychical functions. And his clear sense of the limits of our insight into the mind of the lower animals keeps him from dogmatically asserting that a particular faculty or product of mind is not present below a certain zoological level.

Having thus mapped out his ground, Mr. Romanes goes on to investigate its several divisions in detail. The order of treatment is as follows:—(1) sensation, (2) perception, (3) pleasures and pains, memory and association of ideas, (4) perception, (5) imagination, (6) instinct, (7) reason, (8) animal emotions. This does not seem a very good logical arrangement of the subject, or one which grows naturally out of the diagram. It appears, moreover, to make too much of the intellectual side of the animal mind, and too little of the emotional. This strikes one in the cursory treatment of pleasures and pains along with memory, &c., and in the somewhat meagre review of the emotions in the final chapter. The same thing is seen, too, in the elaborate discussion of instinct, in which the highly interesting emotional element in the phenomenon is hardly touched on.

But it is, perhaps, ungracious, in view of the interesting and valuable material with which the author here supplies us, to complain of what he has not given us. To touch on only one or two points of interest, the account of the development of the several varieties of sensation from their simplest rudiments is full and instructive. The fundamental fact in memory, namely, retentiveness, is clearly seized, and it is satisfactorily shown that different grades of memory, *e.g.* mingling of traces of past sensations with present ones, recalling of absent sensations by association, precede the apparently simple but really complex act of perception.

The facts brought forward in proof of the existence of imagination, that is the power of mentally picturing absent objects, even low down in the scale of animals, are interesting and conclusive. The presence in dogs, horses, asses, &c., of what the author calls the third degree of imagination, where the image is not suggested by external objects present at the time, is ingeniously maintained by the facts of dreams, delusions, and evidences of prolonged anticipation, *e.g.* of the stable by the homeward-journeying horse, and recollection, *e.g.* of the lost master or mistress by the pining dog.

The *pièce de résistance* in the volume is, as we might expect, the discussion of the perplexing subject of instinct. To this no fewer than eight chapters are devoted. Here Mr. Romanes shows himself at his very best. We see that he has mastered the wide range of facts involved, and keeps the many varieties of the phenomena steadily in view. We see, too, that he has pondered long and well on his facts, reading what has been said by others on the subject of his meditation. Finally we recognise his thorough sobriety of judgment, freedom from one-sidedness and from everything like speculative extravagance. Mr. Romanes begins by showing that instinct is clearly marked off from reflex action, not merely by the degree of its complexity, as Mr. Spencer says, but by its accompaniment of consciousness. Then he proceeds to illustrate perfect instincts, in which the actions are perfectly adapted to the circumstances of life for the meeting of which the instincts exist, and imperfect instincts, in which the adjustment to the circumstances of the animal's life is less perfect.

This prepares the way for the main problem, the explanation of the origin and development of instinct. There have been two chief theories propounded to meet the case. On the one hand, G. H. Lewes, and also with him apparently Wundt and others, conceive of instinct as a kind of "lapsed intelligence" analogous to the effect of habit as operating during the development of a single human life. Just as we come to do things in a mechanical and semi-conscious way as the result of having frequently done them with full consciousness, so actions of the lower animals carried out with conscious design at first may, as the result of long continuance in succeeding generations and the operation of the principle of heredity, ultimately become instinctive. In opposition to this view, a more humble origin has been assigned to the phenomenon. According to this theory, instinct does not involve intelligence in any stage of the action. Its origin is mechanical. The germ of instinctive action is due to accidental variations which have become fixed and perfected by natural selection. With this view we may take that of Mr. Herbert Spencer, that instincts grow out of reflex actions when these reach a certain degree of complexity, and only involve consciousness in their later stages of development. Mr. Romanes combines these different theories. He allows a certain weight to Mr. Spencer's hypothesis as serving to explain the lowest type of instinctive action occupying the border land between reflex and instinctive actions proper, that is those accompanied by consciousness. But fully developed instincts can only be accounted for by the principle of variation and natural selection, and by that of lapsed intelligence. In the first place, what the writer calls primary instincts, including those of many low animals and certain instincts of higher animals, *e.g.* incubation, arise by the action of the first cause. This is proved by the fact that purposeless habits, tricks of manner, *e.g.* the trick of barking round a carriage showing itself in certain varieties of dogs, occur and are inherited. In the second place, secondary instincts, including many of those of the higher animals, *e.g.* dread and shunning of man, or other enemies, were originally intelligent actions, and illustrate the principle of habit or lapsed intelligence. This proposition, again, is established by showing first, that "intelligent adjustments when frequently performed become automatic in the individual, and next that they are inherited till they become automatic habits in the race," *e.g.* in the tendency of certain breeds of dogs to "beg."

In combining both these principles in his theory of instinct, Mr. Romanes follows his master, Mr. Darwin, and he has derived much assistance from the valuable essay on instinct by that writer, which was written for the "Origin of Species," but, having been withheld from that publication for want of space, now appears for the first time as an appendix to Mr. Romanes' volume. But the author has elaborated the theory sketched out by Mr. Darwin. More particularly he has illustrated at great length how the two causes may combine. He shows how on the one hand, primary instincts may come to be put to better uses by intelligence, and, on the other hand, secondary instincts may be modified and put to better uses by natural selection. The effects of domestication illustrate most clearly this conjoint action of the two principles. With respect to the comparative importance of the two causes, Mr. Romanes seems inclined to look at natural selection as the chief agency, intelligent adjustment being regarded as an auxiliary agency, the chief function of which is to supply to the controlling principle of natural selection an additional class of variations which are from the first adaptive. Mr. Romanes supports his theory by a cumulative chain of argument of very great strength, and he orders the successive steps of it in such a way as to make the reader feel its full force. His main positions seem to us unassailable. The only point we feel inclined to criticise is the limitation of the action of intelligence in the instincts of animals low down in the scale. The author appears to argue on general grounds that these must to a large extent be due to the working of natural selection. But the facts of intelligent modification of instinctive actions cited by him, *e.g.* in the case of the constructive actions of bees, &c., appear to show that the animals concerned possess a considerable measure of genuine sagacity. And while it is no doubt difficult, as the author remarks (p. 191), to attribute to an animal so low down in the scale as the larva of the caddice fly a power of consciously reasoning, it seems, on the other hand, hard to understand how, by the mere play of natural selection unaided by any rudiment of conscious discrimination and adaptation of means to ends, this little creature could have acquired the habit of either lightening its floating case by attaching a leaf to it or weighting it by attaching a small stone according as it becomes too heavy or too light. But the author shows himself so completely the master of his subject, that the reader feels disposed to accept his conclusions in the very few instances in which his individual judgment leans the other way.

JAMES SULLY

OUR BOOK SHELF

An Introduction to the Study of Heat. By J. Hamblin Smith, M.A. (London: Rivingtons, 1883.)

THOUGH the author states in the preface that "he has endeavoured in this book to explain the elementary facts connected with the theory of heat so far as a knowledge of them is required by the University of Cambridge in the general examination for the ordinary B.A. degree," it will be found that he has succeeded in producing a book which is not only admirably adapted to help a student who is preparing for this or any other elementary examination, but which, from the simple nature of the language and the clearness of the descriptions, may be read with advantage by those who have no examination to pass, but who may wish to understand something of the science of heat for its own sake.

The text is composed of short numbered paragraphs, in each of which the author deals with one new fact only, a plan eminently adapted to save the student confusion. These paragraphs may be taken as model answers to imaginary examination questions.

Over two hundred questions are given on those parts of the subject, such as expansion, calorimetry, conductivity and hygrometry, which admit of being put in simple numerical form. Many of these are essentially exercises in arithmetic, and must irresistibly remind the reader of the unlikely questions which he used to have to answer at school. In the questions on thermometers, for instance, an observer seems to have noted the sums, differences, products, &c., of the readings of every kind of thermometer in his laboratory, without noticing what those readings were, and then, when too late, to have met with the necessity of finding from his observations the temperatures which the instruments actually indicated. However, though observations of such a kind are rarely made, the exercises which they furnish will of necessity make those who work them out absolutely familiar with the fundamental principles of the subject.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

The Ear a Barometer

AT a time when I frequently went between Peterborough and London by the Great Northern Railway express trains, I found that the sudden compression of the air produced on entering a tunnel was not only perceptible by the ear, but even unpleasant, and that this unpleasant sensation remained till the open air was reached, when it suddenly ceased. Of course it was natural to suppose that the noise was the primary cause, but I satisfied myself that this had nothing to do with the effect, for on swallowing after entering the tunnel the sensation ceased, but recurred in the opposite sense on leaving the tunnel, when a second operation of swallowing removed it. This showed clearly that what was observed was real.

As far as I remember there was, as measured by the sensation, an increase of pressure, at first sudden, and then gradually rising for a second or two on entering, and a corresponding gradual and sudden decrease on leaving a tunnel.

I did not at the time have the opportunity of taking an aneroid with me to measure the amount of the compression, but intended to try an air thermometer which I thought would be more sensitive to a sudden change of pressure than even the most delicate aneroid.

It is strange that so few people have noticed this sensation in the ears; besides Mr. Horace Darwin I do not know of any one who I may say has been disturbed by it.

During the gale on the 22nd and 23rd inst. it occurred to me to try whether I could get an idea of the pressure that could be felt by the ear. My room faces west, and the wind was beating against the windows; so after shutting the door I opened one of the windows suddenly during a furious gust, at which a small gas-flame bobbed nearly out, and the same instantaneous sensation was plainly felt. On shutting it again the gas-flame started up, but the inverse sensation was not perceptible. The gas-flame stood at apparently the same height with the window shut or open. Its movements were simply due to the starting and stopping of an extra draught in the chimney. On examining the meniscus at the top of the column in a mercurial barometer, the change of pressure was plainly visible, not by a rise and fall of the whole column, but by a change of curvature which was very marked when the window was opened during the stronger gusts. A pocket aneroid showed the same thing perfectly, rising, as far as I could judge, about 1/150 inch in general, but during one very furious blast 1/20 inch; on that occasion only did the shock on the ears seem at all comparable with what I remember to have felt in the tunnels.

It is not necessary to wait for a gale in the right direction to test the ears. I found that if a friend charged the door with his whole strength, much the same compression was produced as by the average gusts of wind. Of course the compression will depend partly on the contents of the room, which were, in the case in question, about 2500 cubic feet.

It is probable that the change of pressure noticed by the ear is greater than that shown by the barometer, for the instantaneous effect on the gas flame was enormous, while the permanent action was barely perceptible; on the other hand, the aneroid showed a permanent displacement with only a very slight recoil. The greater mobility of the gas doubtless corresponds to the great sensibility of the ear.

If the actual change of pressure felt by the ear is 1/150 inch, which corresponds to a change of level of six feet, it might be expected that a sensation would be observed on running up or down stairs. This I have not noticed, the change of pressure being so gradual.

I need hardly add that descending a mine at the high speeds common in the collieries is most painful to me, and is only rendered bearable by continuously swallowing.

The very great and apparently unrecognised difference that there seems to be in the sensibility of the ears of different individuals may be an excuse for occupying so much of your valuable space with what is in other respects a long and uninteresting letter. C. V. Boys

Physical Laboratory, South Kensington

The Remarkable Sunsets

In Nature for December 20, 1883, Dr. James Macaulay has collected (pp. 176, 177) some recorded instances of the wide distribution at former periods of volcanic dust. Perhaps the following may be worth adding. It is to be found in that extraordinary repertory of curious information and suggestion, the "Philosophical Notes" to Darwin's "Botanic Garden" (part ii. 3rd edition, 1791, p. 167). W. T. T. D.

The Rev. Mr. Sterling gives an account of a darkness for six or eight hours at Detroit in America, on October 19, 1762, in which the sun appeared as red as blood, and thrice its usual size: some rain falling covered white paper with dark drops like sulphur or dirt, which burnt like wet gunpowder, and the air had a very sulphureous smell. He supposes this to have been emitted from some distant earthquake or volcano (*Phil. Trans.* v. liii. p. 63).

In many circumstances this wind [the Haimattan] seems much to resemble the dry fog which covered most parts of Europe in the summer of 1780, which has been supposed to have had a volcanic origin, as it succeeded the violent eruption of Mount Hecla and its neighbourhood. From the subsidence of a white powder, it seems probable that the Haimattan has a similar origin, from the unexplored mountains of Africa. Nor is it improbable that the epidemic coughs which occasionally traverse immense tracts of country may be the products of volcanic eruptions; nor impossible that at some future time contagious miasmata may be thus emitted from subterranean fissures in such abundance as to contaminate the whole atmosphere and depopulate the earth (Darwin's "Botanic Garden," part ii. 3rd edition, 1791, p. 167).

We had the sunset display again to-night, but the after-glow was much less prolonged, suggesting that the stratum of dust and crystals is slowly settling down. But repeated flashes of lightning and peals of thunder, in a place where storms, at the usual time of year for them, are very infrequent, seem to suggest also the question whether the ash is not brought within the sphere of rain-clouds rather by loss of electricity than the influence of surface-gales. At the same time the large fluctuations of pressure seem to tell, on the contrary, that the whole column is affected to unusual altitudes. Since I have been a reader of journals I have seen nothing more enthralling in its interest than the contributions made, week by week, to Nature on this subject from all parts of the world. It marks an era in observation from which we may hope great things in the future.

Bregner, Bournemouth, February 2 Henry Cecil

Referring to the latter part of Mr. Hawell's letter in Nature, January 24 (p. 285), there seem to be several different ways in which volcanic dust might affect the temperature, and though all of them seem likely to have but small effect, the quantities they affect are so vast that a very small percentage may form a very considerable quantity.

1. The volcanic gases would form at first a stratum much warmer than would be natural to the heights at which they would rest, and would thus retard the outward flow of heat from the earth.

2. The volcanic dust, forming an unusually high stratum of opaque matter, would intercept rays from the sun that would be otherwise lost to the earth.

3. The volcanic dust would act as a screen to prevent the earth losing heat by radiation, while it would also (4) act as a screen to prevent the sun's rays reaching the earth; but in so doing would make the dust stratum warmer, and so would aid cause No. 1.

The indirect effects, as influencing evaporation and condensation, and the formation of clouds, are probably greater than the direct, but are more difficult to analyse.

December 3.—I have noticed that December 3 was generally remarkably cloudy. Here, however, it was conspicuous as the day on which all the most marked features of the sunsets culminated. At 4.45 the green and pink glows covered the western half of the sky, and the rest of the sky was filled with a purple glow of like character, while the crescent moon was green. These glows had to a great extent faded at 5; and though the phenomenon lasted late, I can give no more details, as I took no notes, not being able to give it continuous attention.

37, The Square, Ripon, January 28 W. W. Taylor

Christian Conrad Sprengel

Speaking of Christian Conrad Sprengel's discoveries, Dr. H. A. Hagen says (Nature, vol. xxix. p. 29):—"In Germany these discoveries were well known to every naturalist during the whole century. Certainly between 1830 and 1870 at every university in Prussia the same facts were taught as well-known facts of the highest importance, and of course known by every student." From the complete want of papers relating to the facts observed, and the theories proposed by Sprengel in the German botanical and entomological periodicals published before the time of Darwin, strangely contrasting with the profusion of such papers in modern botanical literature, one might have been led to a very different conclusion, viz. that Sprengel had fallen into almost complete oblivion in Germany also, and that hardly any professor in any of the universities of Prussia and of Germany in general duly appreciated and taught his discoveries before Darwin's time. And this, I think, is really the case. Certainly at the University of Berlin in 1841, neither Lichtenstein, in his lectures on zoology, nor Kunth in those on botany, ever spoke of Sprengel and his work, nor did Erichson in his course on entomology. At the University of Greifswald, in 1842, the professor of natural history, Hornschuch, never mentioned Sprengel's discoveries. In 1848 my brother, Hermann Müller, began the study of zoology and botany at the University of Halle, where he never heard of Sprengel, with whose work he became acquainted only much later through Darwin's books. Thus it appears that between 1840 and 1850, in three at least of the six universities of Prussia, Sprengel's work had fallen into the most complete oblivion. Now it is improbable in the highest degree that the several professors of natural history in these universities should have ceased, unanimously and at the very same time (1841) to teach what, between 1830 and 1840, they had taught "as well known facts of the highest importance." Hagen's statement, therefore, needs some further proof before it can be accepted.

If in Germany Sprengel's discoveries had been "well known to every naturalist during the whole century," the opinion that his treatise had been unduly neglected until it was, as it were, re-discovered by Darwin, could never have prevailed, as it appears to do, among German botanists, and Prof. Eduard Strasburger could never have written the following lines, with which I may appropriately conclude this letter: "Until 1860 and some years afterwards in any catalogue of old botanical books, the work of Conrad Sprengel, published in 1793, 'Das entdeckte Geheimniss der Natur im Bau und in der Befruchtung der Blumen' might be found at the price of about 15 sgr. (1*s.* 6*d.*), and I myself bought it there at that price as a curiosity, for the sake of its strange title. In the 220th catalogue of Friedlander (1873) the price of the same book is 3 thlr. 20 sgr. (11*s.*) This rise in the price of Sprengel's book shows very strikingly the change through which in the meantime it has passed in our appreciation. For only during the last ten years, after it had remained *wholly unnoticed* for nearly seventy years, the old book has come to be duly valued. It was Charles Darwin, who by his excellent book on Orchids . . . revived the questions treated by Sprengel" (*Jenaer Literatur Zeitung*, 1874, article 140.) Fritz Müller

Blumenau, Santa Catharina, Brazil, December 15, 1883

Diffusion of Scientific Memoirs

Prof. Tait appears to have misunderstood my object in writing the letter published in your issue of January 24 (p. 287). It refers distinctly to his letter of December 27, and not directly to the review which began the correspondence. In that letter Prof. Tait stated publicly that he had not received certain publications of the Cambridge Philosophical Society. I desired, as secretary, to explain that it was not due to the neglect of the officers of the Society. He also says:—"Nature would do a real service to science by collecting statistics as to the numbers of different centres . . . at which the *Transactions* of various scientific societies were freely accessible in 1883 (say) and also in 1853." It was in my power to give the statistics for "*Transactions* or *Proceedings* or both" for the year 1883; in answer to part of Prof. Tait's suggestion I did so. There is no reference in my letter to the year 1854, so that Prof. Tait is not correct in stating (Nature, January 31, p. 311) that the question between us is, "What was the state of matters in 1854?" The year 1869 was the earliest for which, with the data ready to hand, I could obtain the numbers, I therefore gave statistics for that year in addition; I had no knowledge of what may have been the case in 1854, and I said nothing about it. Prof. Tait referred to a malady and suggested a cure. I merely wished to show that the cure had already been applied. My remarks were addressed solely to that point, and were not "beside the question." Prof. Tait, in your last issue, has an elaborate argument to prove that about one-third of the centres receiving publications receive *Proceedings* only. In this he is entirely mistaken. At present the number of such centres is 6; in 1854 it was 0. The history of the case is as follows. Until the year 1843 the Cambridge Philosophical Society published no *Proceedings*. Between that year and 1864 short accounts of the papers read and of the discussions were published in the *Phil. Mag.*, and separate copies were supplied to the Society. In 1864 these were collected, and form vol. i. of the *Proceedings*. At the time they were not circulated separately; circulation was given them in the *Phil. Mag.* In that year the arrangement with the *Phil. Mag.* came to an end, and notices of the same kind were printed by the secretaries and distributed to *resident Fellows*. Almost without an exception all the important papers published by the Society appeared in the *Transactions*. There was no need therefore to circulate *Proceedings*, and it was not done. This practice was continued up to 1876, when the second volume of the *Proceedings* was closed, and a new system begun. Thus up to 1876 *all centres* receiving publications *necessarily received Transactions*, and as a matter of fact nothing else. A few copies of vols. i. and ii. of the *Proceedings* have since been issued. Vol. iii. of the *Proceedings* was commenced in 1876, and both it and succeeding volumes contain in full the shorter or the less important communications made to the Society, as well as abstracts of matter published in full in the *Transactions*. Vols. iii. and iv., then, of the *Proceedings* have, as a general rule, been sent with the *Transactions*, and the centres have usually, since 1876, received both. Within the last few years, however, 6 centres have been added to the list which receive the *Proceedings* only. Thus in 1883 (omitting the honorary Fellows) 114 centres received *Transactions* only, or *Transactions* and *Proceedings*, in most cases the latter, and 6 received *Proceedings* only; while *in* 1853 *all the publications distributed were Transactions.* I do not pretend to know what the number of centres was at that date, and my first letter made no direct reference to it. Nothing in that letter, however, supports the arguments adduced by Prof. Tait to prove that "it follows from Mr. Glazebrook's data that the number of centres in 1854 must have been about 40 only."

R. T. Glazebrook,
Secretary of the Cambridge Philosophical Society
Cambridge, February 4

Brooks' Comet

I send you a sketch of Brooks' comet, in which an attempt is made to represent a remarkable change which took place in the comet about January 13. On that evening the well-defined and almost circular envelope which is represented in the figure was entirely wanting when the comet was seen on previous occasions. The nucleus was much more condensed and star-like than at any time before. The envelope was of nearly uniform brightness, with a perfectly defined outline, which was easily measured. It seemed to be produced by two fan-shaped emanations from the nucleus, which, curving backward toward each other, met at the outer edges, leaving a darker elliptical space on each side of the nucleus, the space on the north side being the darker, and the preceding fan-shaped portion having an extension on the north side. A line drawn through the middle of the dark spaces would be perpendicular to the axis of the tail.

The diameter of this envelope was 1′ 20″, while the diameter of the outer nebulous envelope, as far as it could be readily traced, was about 6′ 9″. The spectroscope showed a bright continuous spectrum, which was surprisingly strong in the red, which completely masked any lines. As the comet had not been seen here for several days previous to the 13th, this appearance may have been of considerable duration. Clouds prevented another view until January 17, when the inner envelope had entirely lost its sharp outline, and the following portion had disappeared, leaving a corresponding dark space, while the preceding portion had increased its angular dimensions and revolved through an angle of about 60°.

This is the appearance it presented, though the change may have occurred in a very different manner. The 26-inch equatorial did not bring out any additional details. The distance from the following side of the nucleus to the outer edge of the inner envelope was about 32″, whereas it had been 40″ on the 13th, taking half the diameter of the envelope on that occasion to represent the corresponding measurement on the 17th.

A very marked increase in the length of the tail of the comet occurred between December 27 and 28. For about one-third of its length the tail was broad and fairly uniform in brightness; from the middle of this broad portion issued two long bright streams, one being longer and brighter than the other. The total length was about 4°. W. T. Sampson

"Mental Evolution in Animals"

The appearance of Mr. Romanes' new book with the above title reminds me of a reference in his work on "Animal Intelligence" to an observation of my own. I have intended for at least twelve months past to write you about the matter, but as Mr. Romanes' new book is practically a continuation of his former work, you will probably not conclude that I have procrastinated too long.

On page 251 of "Animal Intelligence" Mr. Romanes quotes my story of a skate in the Manchester Aquarium. The fish in question, unable to seize a morsel of food lying in the angle formed by the glass front and bottom of the tank, "raised himself into a slanting posture, the head inclined upwards and the under surface of the body towards the food," and, by waving his fins, caused a current in the water which lifted the food straight to his mouth. Mr. Romanes adds that this observation is practically worthless "from the observer having neglected to repeat the conditions in order to show that the movements of the fish were not, in their adaptation to these circumstances, purely accidental."

I quite agree with Mr. Romanes that such observations should be tested in every possible way, and I should have been only too glad to repeat the conditions of this and other observations had I been able to do so. The fact is, however, that as neither the directors nor the curator of the Manchester Aquarium were willing to call in the aid of those extra attractions which you London people seem to have successfully employed in the case of the Westminster institution, the Manchester Aquarium came to an untimely end, and thus my observations were cut short. There are, however, two comments which I should like to make. On p. 351 of "Animal Intelligence" (the coincidence in the numbering of the respective pages may help the reader's memory), Mr. Romanes quotes a story by Mr. J. S. Hutchinson concerning a Polar bear at the "Zoo." A bun was thrown into a pond, and fell "at the angle" beyond the reach of the bear. The animal thereupon "commenced stirring the water with its paw, so that it established a sort of rotatory current which eventually brought the bun within reach." This story was communicated to Mr. Romanes privately, and my skate story was published in your columns four years before Mr. Romanes published his book (see NATURE, vol. xix. p. 160). No repetition of the conditions is mentioned in the case of the bear, yet Mr. Romanes speaks of the story as "a most remarkable observation." In justice to Mr. Romanes I must add that he appears to accept the bear story as a proof of intelligence in that animal because it corroborates a similar story communicated to Mr. Darwin by another observer. I feel, however, that I have a right to back my skate against either of the bears named, for the following reasons. Had I repeated the conditions in the case of the skate with precisely the same result, it would have appeared as though the skate acted in obedience to inherited habit, or instinct, and even the similar conduct of the bears suggests this inference in their case. On the other hand, had a second trial with the skate failed, it would not have been proved that the first case was accidental, and therefore not the result of a "happy thought" on the part of the skate; for it might still have been contended that the skate, like a man, might display presence of mind on one occasion, and not on another, and the chief interest of the incident lies in the assumed spontaneity of the action. Finally, if Mr. Romanes will reflect upon the attitude of the fish as described in my narrative, I think he will see that the movements could not be "purely accidental." For, from the position of the skate's eyes, it follows that, when in the slanting posture described, he *could no longer see the food*. Yet he opened his mouth and adroitly caught it, the waving of the fins and the opening of the mouth being necessarily rapidly consecutive actions. This fact seems to me to show that he *expected* the food to rise in the way in which it did rise. F. J. FARADAY

Manchester, January 21

YOUR correspondent seems to think that I had some particular spite against his skate, and quotes my indulgence to a bear as proof of inconsistency. But the two cases are very different. Even apart from the unconscious corroboration to which he alludes (and which as evidence of a fact I consider better than even verification by the same observer), we must remember that the stirring of water for a long time in the same direction with its paw is not quite so habitual an action on the part of a bear as is the ordinary swimming movement on the part of a skate. As for any difficulty which the skate may have had in seeing the food approach its mouth, surely the fact of its opening its mouth when the food was near enough to grasp is no better evidence of design than of accident. In either case, under the conditions, and more especially the "attitude," described, the seizure of the food at the proper moment can only be ascribed to the sense of *smell*, which in the skate is so highly developed. Lastly, why does your correspondent begin by saying that verification would have been desirable, and end by arguing that it would have been of no use? Even if the experiment had failed on repetition, he says, his inference would not thereby have been negatived. If this is so, assuredly there would have been no object in repeating the conditions. I once told a terrier to fetch me the ace of hearts from a pack of cards, and he did it. I happened previously to have known that the ace of hearts was the top card. Suppose I had repeated the experiment fifty times, and the dog had every time brought the wrong card, should I have been justified in attributing the first success to a "happy thought"?

GEORGE J. ROMANES

The Storm of January 26

I SEND you inclosed particulars of the great storm of January 26 and 27 as observed at Newport, opposite Dundee. Another observer six miles to the north-east of Newport took readings which corresponded almost exactly with those at Newport for the fall, but were thirty to forty minutes later for the rise. They were as follows, being reduced and corrected:—

Hour	Inches	Hour	Inches
2.15 p.m. Saturday,	28·429	11 p.m. Saturday,	27·385
3.15 " "	28·218	11·15 " "	27·385
4.15 " "	28·036	3 a.m. Sunday,	27·665
6.15 " "	27·834	6 " "	27·922
8.15 " "	27·598	9 " "	28·143
10.15 " "	27·406	11 " "	28·230

Dundee, January 30 DAVID CUNNINGHAM

Ozone at Sea

DURING my voyage hither from London in the *Maranoa*, viâ the Canal, and calling at Malta, Aden, and Colombo, I was surprised at the low values for ozone as registered by Moffat's tests, which I pinned to the "uprights" in Stevenson's thermometer screen. I tried periods of exposure varying from half an hour to twenty-four hours, and the highest value noted was but 5·6 for eight hours (scale 0 to 10). The test papers, however, were always tinted, more or less, sometimes to 3·0 in half an hour, whereas tests exposed at the same time and examined when eight hours had elapsed, only gave 4·6. At Ben Nevis and Fort William, and in the moorlands of Staffordshire I have recorded far higher ozone values than at sea under the same force of wind and like periods of exposure. From my long experience of these tests I cannot consider them satisfactory; but in the absence of a more reliable method I would strongly suggest that they would give results more intercomparable if uniformly exposed for an agreed hourly period, especially at the various land stations. CLEMENT L. WRAGGE

Adelaide, South Australia, December 22, 1883

Meteor

AT 9.55 p.m. on Sunday, January 27, I saw a meteor start from a point in Taurus, near to Saturn, and fall vertically a distance of 20°, and then burst with a brilliant flash, giving off several colours that almost instantaneously died away. The meteor was visible about three seconds, and increased greatly in brightness from the time first seen until it burst. It was the most brilliant meteor I ever saw, and its greatest brightness much exceeded that of Venus. E. HOWARTH

Museum, Sheffield, February 5

Ravens in the United States

OUR Natural Histories say *Ravens* are common all over the United States, but I have never met any one who was aware of having ever seen one. Are they common in Westchester County, near the Hudson, and confounded with crows?

New York, January 11 MANHATTAN

Unconscious Bias in Walking

THE thought has occurred to me that "unconscious bias in walking" may be the result of inequality in the length of the lower limbs caused by the manner in which young children are carried. Each person appears to nurse solely on one arm; I think the right is more frequently employed. I have noticed when a child is held in the arm the side which is nearer the nurse appears to be in a somewhat cramped and unnatural position, the leg more or less bent, while the outer side is comparatively straight and free. Would not this, while preventing the full play of the muscles of the inner leg, tend to arrest to some extent its proper development at a time when growth is very rapid, and thus cause that difference in the length and strength of the limbs remarked by your correspondents? SARA S. OWEN

4, Soames Street, Grove Park, S.E., February 2

ON THE HEIGHT OF THE AURORA BOREALIS

IT is with pleasure that I respond to the invitation of NATURE to give an account of the work of the Danish Meteorological Station, which was maintained, under the international scheme, at Godthaab in Greenland, in 1882-83, and of which I had the honour of being the chief. I intend, in the present article, to confine myself to the aurora borealis.

The results, which have been obtained from calculations of the height of the aurora borealis in the temperate zone, which lies south of the so-called auroral belt, all agree in fixing the minimum height of the aurora very high, as the auroræ seem to be confined to the part of the atmosphere where its density is only a fraction of that at the surface of the sea. However different the value may have been of the heights of the auroræ observed outside their true zone, the average of the minimum heights is hardly under two hundred kilometres. On the other hand, the observations in the Arctic regions show that the auroræ may descend to much lower elevations above the earth's crust, and that they may even reach down into regions of the atmosphere where the density is about the same as on the surface of the sea.

Dr. S. Fritz has thus, at Ivigtut in South Greenland, in February and March, 1872, measured auroræ the lower edges of which were only from 50 to 200 metres above the level of the sea, while in nearly every monograph of the aurora borealis cases are cited in which the auroræ appear to have reached much further down in the atmosphere. I may further mention some instances, which have, by the bye, not been made public before, observed by the eminent zoologist, Prof. Steenstrup, and which he has permitted me to publish here.

During Prof. Steenstrup's sojourn in Iceland, 1839-40, he saw, on several occasions, auroræ which hid the top of the mountain Esia, some 600 metres in height, lying behind Reykjavik. He further states that he has seen auroral streamers between the masts of a ship, in such a manner that they disappeared where there were sails, and reappeared where the space was free. The Professor asserts even that on one occasion, on January 28, 1840, when walking between Reykjavik and Bessastad with the chief magistrate, Herr Tvede, and Judge Jonasson, he, as well as these two gentlemen, saw auroral streamers appearing *between themselves*. The phenomenon was not a solitary one, but occurred three or four times during this walk, and in spite of the pedestrians keeping about a yard from each other.

Although many estimates of the low descent of auroræ in the Arctic regions may have been due to optical illusions, specially through irradiation, one cannot, even from a casual observation of this magnificent phenomenon, but come to the conclusion that, while some auroræ lie in the same great, indefinable distance from the observer as those observed in the temperate zone, there are others whose whole appearance has the character of being a phenomenon of a purely local nature. During our stay at Godthaab this point had my special attention, as it appeared to me of importance to demonstrate by measurements as accurate as possible whether this subjective impression answered to the true facts.

To this end the Danish international station at Godthaab, 64° 10′ 36″ N. lat. and 51° 40′ 0″ E. long., has, during October and December, 1882, effected a series of measurements. The site of the station was particularly suited for the solution of the problem, as it lies just at the northern border of the great Arctic auroral belt, *i.e.* in a place where the auroræ appear with all the peculiarities which distinguish them in their true zone.

The distance between the two points of observation, separated by the Godthaab Fjord, was 5·8 kilometres, and the direction between them coincided with the magnetic meridian. The two instruments used for the measurements, exactly similar in construction, were arranged as universal instruments. Instead of a telescope, a tube was employed, which had in one end a small opening, and in the other a metal cross of very fine wires. In order that the errors in the observations should not affect them very much, measurements were only made in the vertical plane between the two points of observation. The placing and reading of the instruments were effected by means of pre-arranged fire-signals, and only those measurements of which the reading signals were instantaneously answered, and for which the time of reading exactly coincided, were recorded. Only the lower edges of the auroral bands were measured, as these are nearly always the most clearly defined.

We have, during our evenings of observation, measured the height of thirty-two auroral bands. The subjoined figures, showing the result of these, demonstrate that the lower edge of the band certainly descends very low. Thus of the thirty-two auroræ measured by this method ten only had a parallax under 1°, for six the parallax was between 1° and 2°, four had a parallax of between 3° and 4°, two one between 5° and 6°, four one between 7° and 8°, while we measured six of 10°, 14°, 15°, 17°, 86°, and 143° respectively.

Leaving the auroræ whose parallax was under 1° out of the calculation, I have found the following heights for the other twenty-two lower edges:—

1	67·81 kilometres.	12	7·43 kilometres.
2	59·60 ,,	13	6·16 ,,
3	54·73 ,,	14	5·28 ,,
4	46·94 ,,	15	3·72 ,,
5	45·04 ,,	16	3·69 ,,
6	38·09 ,,	17	3·22 ,,
7	29·81 ,,	18	2·87 ,,
8	19·14 ,,	19	1·99 ,,
9	9·76 ,,	20	1·96 ,,
10	9·40 ,,	21	1·35 ,,
11	7·67 ,,	22	0·61 ,,

The three heights of 1·99, 2·87, and 3·22 kilometres belong to the same aurora as that whose edge was measured at an interval of two minutes between each measurement. The two auroræ of 1·35 and 0·61 kilometres stood both above the fjord between the observatories. From the southern one they were seen at an altitude of 13°·6 and 30°·3 respectively above the northern horizon, while at the northern station they were 80°·5 and 7°·25 respectively above the southern horizon. These two and the above-mentioned third, the height of which was measured three times, had the appearance of curtains with large folds, or of bunches or wreaths of streamers lying close together, separated by darker, faintly-shining spaces, but connected below through a common band. The others were bands or arcs without radiating streamers. The edges measured were all nearly at right angles with the magnetic meridian. Only the height of those edges which were distinctly defined, and whose course did not deviate greatly from perpendicularity on the magnetic meridian, were measured.

I must further, as regards the small height of the auroræ observed at Godthaab, state that not only three observers besides myself, but even a student as conversant with auroral phenomena as Herr Kleinschmidt, all agree that auroræ were seen *below the clouds* on several occasions during the winter of 1882-83. On this point we do not entertain the least doubt.

In conclusion I will describe some observations made on several occasions during our stay at Godthaab of the peculiar type of the aurora known as phosphorescent auroral clouds.

On September 21, 1882, Herr C. Petersen, one of my assistants, observed, at 9.45 p.m., an aurora appearing as a lustrous green light behind the nearest hills. The top of the mountain, "Sadlen," 1200 metres in height, was distinctly seen *above* the lustrous plane. The phenomenon rapidly disappeared. At 10.45 a light was seen in the south, which resembled that of dawn, and contracted into a faint shining cloud, oblong in shape, which oscillated slowly before the mountains "Hjortetakken" (1200 metres) and "Store Malene" (800 metres) at a distance of 8 to 12 kilometres from the station. The tops of the two mountains were distinctly seen *above* the luminous cloud, while at times small but intense spots of light developed themselves in it. When the cloud, at 11.45 p.m., had moved in front of the mountain "Lille Malene," the light became more intense, and had the appearance of a lustrous white cloud of smoke rolling up the hill to north-east. When the cloud travelled over the hill, the light became yellow, and was bordered by a coloured rim. At 11.10 it shot three faint red streamers up towards the zenith, and then the whole disappeared.

The following phenomenon was observed by the writer of these lines:—On November 14, 1882, at 6 a.m., I observed an auroral band without streamers through Vega, the Great Bear, and the Twins, while another stood parallel with this further west. From the "Store Malene" I now saw a peculiar shining white cloud descend into the fjord below. It descended in long, straight, shining bands. In a few minutes the mountain in question, as well as "Hjortetakken" were completely hidden in the cloud. A little further east the cloud possessed greater intensity, while on the plain at the foot of the hill on which the observatory stands, two luminous gatherings were seen, which seemed to rest on the snow, with a strongly phosphorescent light. These two gatherings, which were at first isolated, now came in contact with the above described cloud with long luminous bands radiating from the latter. By opening the slit of the spectroscope as much as possible and simultaneously keeping foreign light from the eye, I beheld the auroral line faintly but clearly defined. The cloud now began to disappear without oscillation, when suddenly a number of horizontal openings formed in it, through which the mountain stood forth. In the next second all had disappeared.

I admit that, as regards the last described phenomenon of the lustrous cloud, it might be explained as being caused by the reflex of the auroræ which were simultaneously visible; but such an explanation is not applicable to the one first described. It would be very interesting to learn if other observers have noticed this form of the aurora. ADAM PAULSEN

Copenhagen

THE EFFECTS OF THE WEATHER UPON DEATH RATE AND CRIME IN INDIA

SOME time ago a very interesting series of articles, by Mr. Buchan, upon the connection between certain meteorological conditions and the zymotic diseases, as illustrated by the mortuary returns of the London district, appeared in NATURE. Happening to have undertaken, at the request of the provincial superintendent of census operations, certain investigations concerning the life statistics of the population of the North-West Provinces and Oudh, just about the time when Mr. Buchan's articles appeared, it occurred to me that it would be worth while to see whether any similar concomitant variations of meteorological conditions and causes of death could be detected in India. The results arrived at are so curious, and at the same time so definite, that I think they may be of interest to readers of this journal.

At starting, however, it should be observed that, though the mortuary returns of the province with which I am connected are probably the best in India, they are still very far from complete. The agency employed for registration is that of the village *chaukidár* or watchman, who is supposed to take note of all births and deaths which occur in his village (aiding his memory, if necessary, by variously cut notches on a stick) and to report these weekly at the nearest police station. From such an agency nothing like an exact account of the causes of death can be expected; hence in the detailed tables given below I have confined my attention to the four most obvious causes—small-pox, cholera, suicide, and wounds. Even as regards the number of deaths registered a considerable defect may confidently be anticipated, owing to lapses of memory on the part of the *chaukidár*. This defect has been found by Dr. Plauck, the Sanitary Commissioner, to amount to about 20 per cent. of the whole on the average of a large number of cases personally examined by him in various parts of the province. The proportion thus obtained is confirmed by a comparison of the deaths actually registered with the death rate arrived at in the last census report. During the five years, 1878-82 (the only ones for which complete returns are obtainable), the deaths registered appear, from figures supplied by Dr. Plauck, to have numbered 7,311,013. The average population during the five years having been about 45,000,000, this gives an annual death rate of 32·5 per thousand. Now in Mr. White's report on the census of 1881 it is shown that the distribution of the population according to age, and the observed death rate among certain tribes and castes suspected of practising infanticide, and therefore placed under strict police surveillance, point to 40 per mille as the probable rate of mortality for the general population. The unrecorded deaths therefore amount on the average to 7·5 out of 40, or 19 per cent. of the total—almost exactly the same defect as Dr. Plauck arrived at by his personal investigation of special cases.

It follows that, though the returns collected by the rude illiterate agency employed are not strictly accurate, the totals arrived at probably on the whole bear a nearly constant proportion to the true number of deaths, the population dealt with being sufficiently numerous to eliminate any individual peculiarities of the agents.

The death rate varies enormously from year to year, as may be seen from the table of the total number of deaths recorded, here given in full:—

Number of Deaths from all Causes Registered in the North-West Provinces and Oudh during the Five Years 1878-82

Year	Jan.	Feb.	March	April	May	June	July
1878	137,161	140,173	143,760	157,326	136,867	120,767	91,677
1879	75,387	62,837	71,874	87,302	100,040	83,802	73,120
1880	116,366	72,030	69,250	72,534	76,622	78,200	56,502
1881	95,226	91,011	97,829	124,831	115,683	86,083	81,609
1882	114,220	92,472	96,596	107,628	119,714	114,382	122,110
Total	538,360	458,523	479,309	549,621	548,926	483,234	425,018

Year	Aug.	Sept.	Oct.	Nov.	Dec.	Annual total
1878	113,701	120,607	138,997	127,656	93,032	1,521,724
1879	131,702	196,135	429,115	369,390	233,795	1,914,499
1880	74,127	87,618	91,218	99,459	93,264	987,190
1881	86,316	109,837	181,519	180,683	151,846	1,402,473
1882	151,779	159,604	156,065	128,040	122,517	1,485,127
Total	557,625	673,801	996,914	905,228	694,454	7,311,013

The deaths recorded average a little under a million and a half per annum, but in 1880 they were less than a million, and in 1879 nearly two millions. In that disastrous year one district or county, that of Aligarh, lost nearly half a million of its population. The chief difference between 1879 and 1880, from the meteorological point of view, was that in 1879 the monsoon rains were unusually heavy, while in 1880 they were so scanty that for a long time grave apprehensions were entertained of another famine, like that which followed the drought of 1877. The year 1877 (which does not appear in the table) was an extraordinarily healthy one, but the effect of the scarcity produced by the drought of that year is seen in the high mortality of the first six months of 1878.

The first rough generalisation suggested by the table is that dry years are healthy and wet ones unhealthy. That this is generally true is well known to residents in the country. Among the natives also I have heard it said that one must choose between health *plus* famine and abundance *plus* fever. It would nevertheless be false to infer that in India mortality is due to rain; for we have only to compare the figures for the several months to see that on the average, and in almost every single year, the month in which fewest deaths occur is July, which happens to be just the rainiest month of the twelve. Rain is no doubt one of the indirect causes of death; but it seems to produce unhealthy effects by increasing the humidity of the air and hastening the growth of rank vegetation, which, decaying at a time of the year when the air is almost perfectly still over the Indian plains, produces that noxious condition of the lower atmospheric strata known by the name *malaria*. Compared with the deaths from malarial fevers, those due to cholera, small-pox, and other epidemics count almost as nothing. Hence, though these epidemics have their particular seasons of maximum and minimum, their effect is completely hidden in the general mortality table under the great annual variation which culminates in October and November.

Besides rainfall, atmospheric humidity, and wind velocity, other meteorological causes which presumably have some effect upon health are the mean temperature and the daily range of temperature—the last, according to the prevalent opinion amongst Indian medical men, who are fond of attributing almost every ailment to nocturnal chills, being a most important cause. The next table gives approximate monthly mean values of all these meteorological elements for the North-West Provinces and Oudh, exclusive of the Himalayan districts, which are very sparsely populated.

Mean Values of Certain Climatological Factors in the North-West Provinces and Oudh

Month	Mean temp.	Daily range of temp.	Relative humidity	Rainfall	Wind velocity per diem
	°	°	%	inches	miles
January	59	28	62	0·8	54
February ...	64	28	57	0·5	71
March	75	29	46	0·3	83
April	85	32	37	0·2	90
May	90	28	43	0·7	93
June	91	20	52	3·8	108
July	85	14	75	11·4	95
August	84	14	77	9·5	80
September ...	83	16	74	6·6	70
October ...	77	27	62	1·3	47
November ...	67	32	55	0·1	35
December ...	60	30	61	0·2	40
Year... ...	77	25	58	35·4	72

Before proceeding to estimate the relative effects of these factors upon the death rate, it will be found convenient to convert the totals given in the first table into mean rates per annum. The mean number of deaths per annum for each million of population is 32,493, and this number is distributed over the months as follows, when the months are all reduced to the same length:—

Jan.	Feb.	March	April	May	June
2351	2201	2093	2480	2397	2181
July	Aug.	Sept.	Oct.	Nov.	Dec.
1855	2435	3040	4352	4083	3025

It has already been pointed out that the effect of the rainfall upon health is very indirect, and therefore need not be taken into account here. The relative effects of the other factors in the second table may be calculated approximately by the formula—

$$d = \alpha t + \beta r + \gamma h + \delta v.$$

Here d, t, r, h, and v respectively denote the variations of the death rate, the mean temperature, the range of temperature, the relative humidity, and the wind velocity each month from their mean annual values. From the twelve equations of this form, furnished by the monthly means, we get the following most probable values for the coefficients, viz.:—

$$\alpha = 79·7 \qquad \beta = 113·6$$
$$\gamma = 43·4 \qquad \delta = -35·6$$

If there be any approach to truth in the assumed proportionality between the variations of the death rate and of these climatological elements, it therefore appears that a mere rise of temperature within the limits observed produced comparatively little effect, one degree of increase in the mean temperature increasing the deaths about 80 per million per month, or rather less than one per thousand per annum. The variations of the diurnal range have a much greater effect, while the change of the death rate due to varying humidity is even less than that due to temperature changes.

The relation between the death rate and the movement of the wind is inverse, the proportionate increase of deaths being 35·6 per million per month for a decrease in the velocity of the wind amounting to only one mile in twenty-four hours. In the months of October and November, when so-called *malarial* diseases attain their maximum, the air is almost absolutely still; and there can be very little doubt that if a moderate breeze were occasionally to spring up at this time of the year, so as to dissipate the *malaria*, or at all events mix it with good air from other districts or from above, the effect would be an immediate decrease of the death rate.

As regards special causes of death, I have already stated that I have confined my attention to those cases in which the *chaukidár* may be trusted to make a correct diagnosis. Small-pox, a disease now happily almost banished from Europe, but still carrying off many thousands of victims annually in India, is one of these almost unmistakable causes. The average number of deaths from this disease during the five years was 59,240, distributed as follows:—

Jan.	Feb.	March	April	May	June
3195	3830	6611	12,561	13,790	9140
July	Aug.	Sept.	Oct.	Nov.	Dec.
4855	1924	742	366	536	1690

The deaths from this cause, numerous as they are, are fewest in the months when the general mortality attains its maximum. The meteorological causes which favour the spread of small-pox appear to be heat, drought, and possibly also an unusually high wind velocity, the solid particles which constitute the contagion being presumably blown about by the wind. The relative effects of these may be roughly computed from the totals for each quarter, using the formula—

$$n = N + \alpha t + \beta (100 - h) + \gamma v;$$

n being the recorded number of deaths in any month; N the number that would occur under the hypothetical conditions of a still, saturated atmosphere at 0° F.; and t, h, and v standing for the temperature, humidity, and wind velocity respectively. The coefficients thus found are $\alpha = 91$; $\beta = 237$; $\gamma = 97$; the condition most favourable to the propagation of small-pox appearing therefore to be dryness. The number N, for the unattainable conditions assumed, comes out negative.

Another disease which the village watchman may be trusted to recognise in most instances is cholera. Cases of severe diarrhœa are doubtless frequently returned as cholera, but this does not sensibly impair the value of the registers, since the two diseases are usually prevalent about the same time. The mortality from cholera is subject to an annual variation quite as distinct as that of small-pox, but there are two maxima, in April and August, with a slight diminution between these months. The averages for the five years are :—

Jan.	Feb.	March	April	May	June
317	338	1304	9027	6541	6344

July	Aug.	Sept.	Oct	Nov.	Dec.
5735	8129	4839	4665	1514	426

From the records of the army, police, and jail departments, extending over a longer series of years, it appears that the maximum mortality from cholera usually occurs in the rainy season. The secondary maximum in April becomes the principal one in this table on account of the excessive prevalence of cholera in April 1880. This epidemic was popularly attributed to the immense number of Hindu pilgrims assembled at the great religious fair of Hardwár, the disease having been caught from some infected persons in the crowd and spread abroad over the country as the pilgrims returned to their homes. The Sanitary Commissioner with the Government of India, however, does not accept this view, but seems to attribute the disease or its dissemination to some occult atmospheric influence. Whatever may ultimately prove to be the nature of the disease, there can be little doubt that in the North-West Provinces it is to a great extent dependent upon heat and moisture, being almost unknown in the cooler months of the dry season. To estimate the relative effects of these two atmospheric conditions, we may employ the formula—

$$n = N + \alpha t + \beta h;$$

the letters having similar significations to those mentioned with the previous formula. Combining the months in groups of four, commencing with December, we get three equations which give the following approximate results :— $\alpha = 281$; $\beta = 45$; $N = -20{,}076$. The principal effect is that due to high temperature ; while at the temperature assumed for N—zero F.—that number comes out negative. That is to say, in a perfectly dry atmosphere cholera would disappear at a temperature considerably above freezing, about 70° F., in fact, if we may judge from these tables. In the cold weather months, indeed, cholera never assumes epidemic proportions in the North-West Provinces ; but when the poison, whatever it may be, is widely disseminated, as in the beginning of 1882, after the great *mela* or religious fair at Allahabad, it remains nearly quiescent, manifesting itself only in a few sporadic cases until the commencement of the hot weather in April, when it breaks forth with alarming rapidity.

Deaths by violence are also, as a rule, unmistakable. In the Sanitary Commissioner's tables two causes of death are given which both come under this head—suicide and wounds—the latter presumably including only the results of murder and manslaughter, as there are separate headings for accidents and wild beasts. The average numbers of these deaths recorded each year are—

	Jan.	Feb.	March	April	May	June
Suicide ...	105	109	196	268	246	248
Wounds ...	105	94	105	119	125	128
Total ...	210	203	301	387	371	376

	July	Aug.	Sept.	Oct.	Nov.	Dec.
Suicides ...	246	242	269	250	151	100
Wounds ...	132	154	145	135	115	98
Total ...	378	395	414	385	266	198

Both series exhibit a distinct annual variation, notwithstanding some irregularities which would probably disappear if we had larger numbers to deal with, and in both the phases are similar, the minimum being reached in the middle of the cold weather, and the maximum in the hot season and rains. Both forms of death by violence are, in fact, manifestations of the same cause, irritability of temper ; for suicides in India are, as a rule, not the result of a fixed melancholia, three-fourths of the cases being those of young married women, who, finding life unbearable under the daily and hourly sting of the mother-in-law's tongue, end it at last by jumping down a well.

The monthly totals given in the last table may be approximately represented by the formula—

$$n = \alpha (t - x) + \beta h,$$

since they seem to depend both on temperature and humidity. In this formula x would be the temperature at which crimes of violence would disappear. Grouping the months in fours, commencing with November, we get three equations which give $\alpha = 7{\cdot}2$, $\beta = 2{\cdot}0$, and $x = 48{\cdot}4°$ F. Crimes of violence in India may therefore be said to be proportional in frequency to the tendency to *prickly heat*, that excruciating condition of the skin induced by a high temperature combined with moisture. Any one who has suffered from this ailment, and knows how it affected his temper, will readily understand how the conditions which produce it may sometimes lead to homicide and other crimes. And any one who has been in India in the cold weather and seen to what an abject condition the ordinary native is reduced by a temperature of 60° or so can believe that there is probably some truth in the arithmetical result above given, that about 48° crimes of violence would disappear, for at such a temperature nobody would possess a sufficient store of energy to enable him to commit crime of any graver description than petty larceny.

S. A. HILL

ALGÆ[1]

THE new work of Dr. Agardh, forms the third part of a series of monographs of algæ, two parts of which have already appeared. The first part contains the genera Caulerpa, Zomaria, and certain groups of Sargassum ; the second contains the Chondariaceæ and Dictyoteæ. The Ulvaceæ form the subject of the present monograph. This work should have special interest for algologists, from the circumstance that in it the author has expressed his views, and the reasons on which they are founded, concerning the much-debated question whether Bangia, Porphyra, Goniotrichum, and Erythrotrichia belong to the Florideæ or to the Ulvaceæ. The fact that Dr. Agardh still retains them among the Ulvaceæ is a sufficient proof that he is not convinced by the perusal of Dr. Berthold's work (noticed in NATURE, vol. xxvii. p. 385), and the statement of the latter that they belong to the Florideæ.

Dr. Agardh discusses the subject at some length, calmly and dispassionately ; and, considering his immense experience in the study of algæ, his opinion is deserving of much consideration. It may be as well to give the reader some idea of the arguments upon which the author has grounded his opinion. He relies principally, it will be seen, upon the assumed difference of the reproductive organs in the Ulvaceæ and in the Florideæ, namely, on the sporidia endowed with motion (zoospores) in the true Ulvaceæ ; and on the antheridia, cystocarps, and tetraspores of the Florideæ ; the antheridia and cystocarps being considered by Thuret and others as sexual, the tetraspores as asexual.

---

[1] "Til Algernes Systematik." Nya bidrag af J. G. Agardh (Tredje afdelningen). Lunds Årsskrift, tom. xix.

Dr. L. Rabenhorst's "Kryptogamen-Flora von Deutschland, Oesterreich, und der Schweiz." Zweiter Band : "Die Meeresalgen Deutschlands und Oesterreichs." Bearbeitet von F. Hauck. 4–6 Lieferung. (Leipzig : Eduard Kummer, 1883.)

Dr. Agardh points out that the organs with powers of motion, observed by Derbès and Solier, are scarcely to be referred to the Florideæ, because in their eruption from the plant, as well as in their movements, they have an appreciable analogy with the organs of Prasiola, described by the author in a new species, *P. cornucopiæ* (see Table III., fig. 74, *e, f, g*).

On the other hand, Dr. Agardh shows that the chief consideration which induced some algologists to remove Bangia and Porphyra from the Ulvaceæ to the Florideæ was derived from the quaternate division of the cells, which was thought to be analogous to the quaternate division of the tetraspores in the Florideæ. He points out that Janczewski and Thuret had observed that it was not tetraspores, but octospores, which resulted from the division in Porphyra; and he calls attention to the fact that the so-called octospores are themselves repeatedly divided into new generations of tetraspores and octospores, in the same manner as the cells or cell-contents in Prasiola, Tetraspora, Palmella, Monostroma, Ulva aureola (*Ilea fulvescens*), and some species of Enteromorpha divide; thus showing an analogy with these plants rather than with the Florideæ.

The author observes that if the organs of Porphyra be considered analogous with the tetraspores of the Florideæ, these organs, according to some authors, should possess different functions, the tetraspores being deemed neutral in the Florideæ, but the octospores sexual in Porphyra. If, he says, those organs which in Porphyra are called antheridia agree with the antheridia of the Florideæ; if, also, those 4-partite organs which constitute spores are to be compared with the tetraspores of the Florideæ; there still remain in Porphyra and Bangia no organs which can be considered identical with the capsular fruit of the Florideæ. If, therefore, those organs which form the principal characteristic of the Florideæ are absent, it is evident that Bangia and Porphyra are far inferior to the Florideæ, and that very distant affinities must be sought for them. Moreover, if those organs which are neutral in the Florideæ become sexual and female in Porphyra, this rather seems to indicate divergence than affinity.

With regard to Bangia, Dr. Agardh observes that the filaments of this plant growing together in patches, as already observed by Dillwyn and others, always vary in thickness and in appearance, and that this difference of appearance may have suggested the idea that they were of various kinds (male and female filaments). According to Dr. Agardh, these differences are merely differences of age; and the so-called special organs are to be considered rather as different states during the evolution of the fructification, than as distinct organs.

Reviewing the statements of different algologists with regard to the fructification of these plants, the author shows from their published works that much difference of opinion existed among them. Thus, according to Derbès and Solier, those organs in Bangia which they considered as male are said by them to be endowed with lively motion; while Thuret and Reinke, referring to the same organs, say that they are motionless. Again, the author observes that Janczewski, alluding to the octospores of Porphyra, says that they have an amœboid motion; Thuret, on the contrary, states that they are motionless.

After quoting Thuret's description ("Etud. Phyc.") of the processes of fructification in Porphyra, Dr. Agardh cites the following passage referring to the antheridia: "La division s'arrête plus tôt pour les spores et se prolonge davantage pour les antheridies; mais il n'y a pas de différence fondamentale dans le procédé. On en a la preuve dans les cas anormaux, déjà mentionnés par M. Janczewski, ou le contenu d'une même cellule primitive se change, partie en spores, partie en corpuscules mâles." So remarkable does this statement appear to Dr. Agardh that he quotes it also in the note to p. 26, where he thus comments on it: "Quomodo ii, qui hoc observarunt, sibimetipsis persuaserint eam partem contentus, quæ organis perhibitis fœmineis constaret, sub stadio evolutionis paulo posteriore in organa mascula non transmutaretur, mihi non liquet."

Leaving this subject to the consideration of algologists, the more general features of the work may now be noticed.

Dr. Agardh arranges the Ulvaceæ under the following genera: 1, Goniotrichum; 2, Erythrotrichia; 3, Bangia; 4, Porphyra; 5, Prasiola; 6? Mastodia; 7, Monostroma; 8, Ilea; 9, Enteromorpha; 10, Ulva; and 11, Letterstedtia.

Of these genera Mastodia and Letterstedtia are natives of the Southern Ocean. Ilea, of which one species only is known, *I. fulvescens* (*Ulva aureola*, C. Ag.), is a small tubular plant which grows at the mouths of some Swedish rivers. The cells of which it is composed are arranged in series of fours, as in Prasiola, but the colour is dusky as in Dictyota.

The other genera, of which many species are natives of these shores, will have more interest for British algologists. *Prasiola marina*, Crouan, which Dr. Agardh unites with *P. stipitata*, has been recently found in Scotland and in Devonshire; and the *Ulva calophylla* of Greville, and *Ulva crispa*, have been removed to Prasiola.

Of the twenty species of Monostroma, five, namely, *M. bullosum*, *M. laceratum*, *M. quaternarium*, *M. latissimum*, and *M. wittrockii* have been found on our coasts. To these Dr. Agardh adds another species, *M. lactuca* (*U. lactuca*, C. Ag.), which he considers identical with *M. undulatum* of Thuret, and probably with *M. pulchrum*, Farlow, of the east coast of North America. While thus transferring the specific name *lactuca* to a Monostroma, the author excludes it from Ulva, where it has been a sourse of confusion.

With regard to Porphyra, Dr. Agardh agrees with Dr. Greville in considering *P. linearis* as a distinct species; and he mentions *P. amethystea* as a native of England. Harvey had stated that the latter had been found on the west coast of Ireland, but the plant appears to have been unknown to him, and has not been found until recently, when Mr. G. W. Traill met with it on the east coast of Scotland. The arrangement of the cells in the plant is very beautiful.

In accordance with the views of most algologists, *P. vulgaris* and *P. laciniata* are united by the author; but he has changed the name of the plant to *P. umbilicalis* ("L. Sp.," ed. 2, 1633), of which he describes several forms. In his views of the structure of this alga, Dr. Agardh is at issue with Janczewski and Thuret. The last-mentioned authors state that the vegetative structure of the plant is always monostromatic, and that it is in the fruitful parts only that the cells are arranged in two series. Dr. Agardh, on the contrary, says that the alga is at all times distromatic. A reference to Plate II., fig. 61, *t*, will show that the two strata seen in the transverse section do not exhibit that subdivision of the cells which constitutes the fruit.

Dr. Agardh agrees with M. le Jolis in removing the *Ulva linza* of Harvey to Enteromorpha, where it takes the name of *E. linza*. Of Ulva, seven species only are enumerated. Under *U. rigida* there are no fewer than twenty-four synonyms. While, however, the author deserves thanks for clearing away so many reputed species, he describes many forms of this very generally distributed alga.

Enough has now been said to show the interest this work should have for algologists. It is illustrated by four plates, beautifully executed, containing 124 figures. Although the title is Swedish, the work is written in Latin.

Of Rabenhorst's "Kryptogamen-Flora," Nos. 4, 5, and 6 of Part II., in which the marine algæ are described by M. Hauck, have recently appeared. Numbers 4 and 5 treat of the Florideæ, which are concluded in the sixth part. Then follow the Phæophyceæ; but before touching on these, a few points relative to some of the Florideæ call for observation.

M. Hauck tells us that in Gelidium the cystocarps are of two kinds—(1) those in which the placenta is basal, and have consequently only one series of gemmidia; (2) those in which the placenta is central, on both sides of which the gemmidia are placed. M. Hauck does not seem to be aware that the former were long ago separated by Dr. Agardh from Gelidium, under the name of Pterocladia, the typical species of which is *Pt. lucida*, a very common alga in the Southern Ocean. The *Gelidium capillaceum*, described at p. 190, is a true Pterocladia, and has been described as such by M. Bornet under the name of *Pt. capillacea*. M. Hauck mentions this name among the synonyms of *G. capillaceum*, and at p. 191, fig. 82, he gives us copies of M. Bornet's figures of the cystocarps of this plant, and also of Gelidium; thus showing the characteristic differences between the two algæ; it is therefore surprising to find that M. Hauck still retains the old name of the plant, and places it under the genus Gelidium.

The cystocarpic fruit of *Dasya punicea*, apparently unknown in the Adriatic, was found on our southern coast as long ago as 1859. Before that time a specimen bearing cystocarps was collected by Miss Catlow in Jersey, and Dr. Harvey gave to it the provisional name of *Dasya catlowviæ*. There is considerable difference in the aspect of the plants which bear cystocarps and those which bear stichidia; so much so, that they have been taken for distinct species. British specimens of this plant are much larger than those of the Adriatic.

M. Hauck describes the tetraspores of *Melobesia corallina* as "zweitheilig," and he refers to Solms' "Corallinenalgen des Golfes von Neapel," Table III., fig. 23. Now, on turning to this figure in the work of Graf Solms, it will be seen that the tetraspores are 4-partite. It is true that they have been described by MM. Crouan and Areschoug as dipartite, but, according to the observations of M. Rosenoff in his very interesting "Récherches sur les Melobésiées," p. 45, there seems good reason to believe that, although tetraspores are often found divided into two parts only, the complete number is four.

With regard to *M. macrocarpa*, M. Hauck is apparently right in uniting it with *M. pustulata*, and also in considering *M. corticiformis* as a synonym of *M. membranacea*.

In a former number of his work, M. Hauck had stated that the tetraspores of Nemaleon were unknown. They had, however, been described by Dr. Agardh in "Sp. Gen. et Ord. Algarum," vol. ii. p. 417, and again in the "Epicrisis," p. 507; but the author did not, in either work, state in which species he had found them. Some uncertainty, therefore, existed on this point; and Thuret was of opinion that up to his time there had been no trustworthy record of the discovery of the tetraspores of Nemaleon. It would have been easy to solve the doubt by an appeal to Dr. Agardh, who is always ready and willing to impart information, but no one seems to have thought of adopting this course. The writer is glad to be able to mention, on the authority of Dr. Agardh, that he (Dr. Agardh) found tetraspores on a plant of *Nemaleon multifidum* from Copenhagen, but he had met with them only once. It is hoped that this statement will finally settle the question.

The description of the second division of the marine algæ, Phæophyceæ, is begun at p. 282 with the Fucoideæ; these are followed by the Dictyoteæ, and after these follow the Phæozoosporeæ. Each order is preceded by a careful description of the structure and fructification of the plants included in it, and an enumeration of the genera; in the case of the Phæozoosporeæ, a short diagnosis of each family is inserted. We are glad to see, from the long list of synonyms appended to the description of many plants, that M. Hauck has greatly diminished the number of species, especially of those from the Adriatic.

British algologists will find in the later numbers of this work, as well as in those which preceded them, much that is interesting and instructive. The succeeding numbers will be welcome. It is hoped that they will be followed by a good index, which will add very much to the value of the work.

MARY P. MERRIFIELD

METEOROLOGICAL OBSERVATIONS FROM BEN NEVIS

A WEATHER REPORT from the Ben Nevis Observatory is now published daily, which gives the observations made at 9 a.m. and 9 p.m., these being the hours adopted by the Meteorological Societies of the British Islands, to which are added the highest and lowest temperatures, the amount of rain and snow in all cases where it is possible to measure it, the height of the snow on the plateau, measured by the snow gauge, the hours of sunshine, taken directly from the sunshine recorder, and the quantity of ozone, droughts, changes of wind, auroras, glories, halos, electrical and other phenomena, recorded as they occur. The record is strictly one of observations, and as these are made at the usual observing-hours, British meteorologists and all persons interested in the weather are thus afforded the means of comparing their own observations with those made at Ben Nevis Observatory, which is by far the most valuable high-level station we possess, as furnishing data of the first importance in the study of the weather changes of Europe. In the winter climate of the Ben, the problem of hygrometric observation is beset with formidable difficulties. With a view to the practical solution of these it is part of the winter's programme that Mr. Omond conduct a series of investigations with a hygrometer of a novel description specially designed by Prof. Chrystal for the purpose. In the meantime, and until the problem be solved, the word "Sat," meaning saturation, is entered in the wet bulb column in all cases when the wet does not read lower than the dry bulb, it being evident that in such cases the air is all but, if not altogether, saturated. Indeed, a saturated atmosphere at all temperatures may be almost regarded as a persistent feature in the climatology of the Ben. Occasionally, however, as recently happened about Christmas and the New Year, a sudden change sets in, the clouds clear away, the sun blazes out in a sky of marvellous clearness, and a dryness of air comes on such as is rarely if ever experienced at lower levels. In these circumstances the dry and wet bulb readings separate to a degree so extraordinary that Glaisher's tables are no longer of any use in calculating the humidities of the air. As the periods of sudden and intense dryness of the atmosphere are intimately connected with the anti-cyclonic systems prevailing at the time in north-western Europe, it is not improbable that a careful record and study of them will lead to a more exact forecasting of some of our most important weather changes.

By and by the observations, combined with those made by Mr. Livingstone at the low-level station at Fort William, will furnish the data for ascertaining what is the normal distribution of pressure, temperature, and humidity in the stratum of the atmosphere between the top of Ben Nevis and the level of the sea at its base. These being once determined, all deviations therefrom, whenever occurring, will be readily seen. When the departures from the normals to subsequent changes of weather have been further investigated and their relations more accurately determined, the high expectations formed regarding the part to be played by the high-level station on Ben Nevis in contributing important data towards the forecasting of the weather of the British Islands will doubtless be realised. It must not, however, be forgotten that this intensely practical problem is an excessively difficult one, requiring for its successful prosecution no small expenditure of time, labour, thought, and money.

NOTES

THE Royal Society at their last meeting elected the following five *savants* foreign members:—Anton de Bary (Strasburg), Carl Gegenbaur (Heidelberg), Leopold Kronecker (Berlin), Rudolph Virchow (Berlin), Gustav Wiedemann (Leipzig).

WE are informed that it has been arranged that Sir William Thomson will give, at Johns Hopkins University during the first twenty days of October next, eighteen lectures on "Molecular Dynamics."

CAPTAIN W. J. L. WHARTON, R.N., at present in command of H.M. surveying vessel *Sylvia*, has been selected to succeed Capt. Sir F. Evans, K.C.B., as Hydrographer to the Navy.

ON Tuesday afternoon, at Oxford, Convocation witnessed in the Sheldonian Theatre the most exciting scene that has been enacted in the University since the opposition to Dean Stanley as Select Preacher. Last summer Convocation passed by a small majority a vote of 10,000*l.* for a new physiological laboratory. The vote was opposed by the anti-vivisectionists and by some on the ground of economy. A memorial got up by Mr. Nicholson against vivisection having produced no effect on the Council, the opponents of Prof. Burdon Sanderson determined to oppose the decree brought before Convocation on Tuesday for empowering the sale of stocks for the 10,000*l.* voted last June. The decree was supported by the Dean of Christchurch, Dr. Acland, and the Warden of Keble, and was opposed by Prof. Freeman and Mr. Nicholson. After a stormy debate the vote was carried by 188 votes against 147. The result was received with enthusiasm, and Oxford is to be congratulated on it. To what shifts Dr. Sanderson's opponents were put may be seen from what the *Times* calls "the most astonishing speech" of Mr. Freeman the historian, "who afforded a curious example of the confusion of thought into which even intelligent men may be led by an over-indulgence in sentiment. It would be as reasonable, said Mr. Freeman, for the historian to illustrate the festivities of Kenilworth by an actual bull-baiting as for the physiologist to experiment upon living animals. Mr. Freeman, in his zeal to establish the scientific character of the historian, forgets the difference between description and discovery, and ignores the fact that the physiologist, at least under the existing law, makes his experiments not for the instruction of pupils, but with a view to discover what is as yet unknown. A more curious article in the indictment against vivisection we have not met with since the celebrated letter in which Sir George Duckett told the Royal Commission that he had no evidence to give, but that he considered vivisection 'an abomination introduced from the Continent going hand in hand with Atheism.'" The *Times* in its leader on the subject treats it sensibly and moderately. "All those who are open to argument have been long ago convinced that science cannot proceed on her beneficent way without the aid of experiments, some of which must be painful; and those who are not open to argument, and those who believe, like some of the wiseacres whose opinion is on record, that 'medical science has arrived probably at its extreme limits,' are not likely to be convinced by anything that can be said or by any facts that can be brought against them. Parliament, on the recommendation of one of the strongest Royal Commissions ever appointed, has legislated in the matter, and physiological experiment is now under limitations as severe as it is possible for it to be consistently with any kind of progress in discovery. Abuses are of the rarest occurrence. Men like Dr. Sanderson are not only humane, but they are conscious that public opinion is awake on the matter, and their discretion as to what should be done and what should not is absolutely to be trusted. It is to be hoped that the sensible action of Convocation will not only encourage the Waynflete Professor to proceed as his scientific conscience may guide him, but will convince the well-meaning but irrational opponents of scientific freedom that further action on their part would be not only vexatious but unsuccessful."

BY the election of Dr. J. H. Gilbert to the separate chair of Rural Economy, Oxford has gained a man of European reputation, whose advent to the professoriate all parties will welcome.

DR. P. P. C. HOEK, of Leyden, writes to inform us of the death of Prof. Dr. H. Schlegel, Director of the Royal Museum of Natural History at Leyden, on January 17 last. Schlegel was born in 1804 in Altenburg (Saxony). It was intended to make him a brazier, but on his paying a visit to Vienna about 1824, his love for natural history was awakened. He came to Leyden in 1825, and tried to obtain an appointment as traveller for the Museum of Natural History, of which Dr. Temminck was then superintendent. He did not receive that appointment, but stayed in the Museum as preparator. He remained in this position until he was nominated conservator in 1839. He was appointed to the post of Director of the Museum in 1858 after the death of Temminck. Schlegel was doctor *honoris causâ* of the Leyden University, member of the Royal Academies of Sciences of Amsterdam and Berlin, &c. The Leyden Museum of Natural History, well known to every zoologist, has become under Schlegel's superintendence one of the richest in existence. For descriptive zoology, and especially that of the vertebrata, (reptiles, birds, and mammals), Schlegel was a first authority; the number of papers and monographs published by him in these groups is very considerable, and their scientific importance great.

THE death is announced of M. Richard Cortambert, *fils*, at the age of forty-eight years. He was attached to the geographical department of the National Library, and, in company with his father, had published many geographical works.

ADMIRAL MOUCHEZ read a paper before the Paris Academy of Sciences at the sitting of February 4, in which he stated that it was impossible to make any observations with large instruments in the old establishment at present the headquarters of French astronomy. He proposes to erect a new observatory on a site in the vicinity of Paris. Admiral Mouchez states, moreover, that to find the money required it would be advisable to sell the new grounds which were annexed to the Observatory in the time of Leverrier. The extent of this land is about 28,000 square metres, and the Admiral states that the sale might realise 4*l.* per metre. This ground was given to the Government by the City of Paris, which sold it for the nominal price of 4*l.*; it is supposed that the Municipal Council will oppose the scheme, which has come to light quite unexpectedly.

BY the last mail from Iceland we have received a communication from Dr. Sophus Tromholt, dated Reykjavik, middle of December, in which he informs us that the weather had till then been mild and very unfavourable for his researches, in consequence of which he defers to the next mail giving to NATURE an account of his studies in the island. By the same mail apparently the reports which have lately been circulating in the Scandinavian press of terrific eruptions in the island have also arrived. It is stated in private letters that in November two enormous columns of smoke were seen in the direction of the great Vatnajökull, and that ashes had fallen in the Seidisfjord. According to the direction it seemed as if this eruption was far more easterly than that occurring in the spring. In connection herewith it may be of interest to call attention to the note published in NATURE (vol. xxix. p. 135), in which it is reported that on the night of

November 17 the snow in the valley of Storelo, in Central Norway, between 61° and 62° N., became covered with a layer of gray and black dust. It is, however, remarkable that Dr. Tromholt's communication contains no reference whatever to any volcanic eruption.

WITH reference to the Krakatoa eruption, Prof. Alph. Milne-Edwards read at the Paris Academy of Sciences, on January 28, a letter from a correspondent in Réunion, in which it is stated that the intensity of the sky-tints was always greatest where the showers of volcanic ashes had been observed. Thus the path of the volcanic cloud can be traced step by step, and its trajectory found to be that of an ordinary cyclone. M. Wolf showed how a study of the curves registered by the barometer establishes two atmospheric waves starting at the same time from Krakatoa, one towards the east and the other towards the west; the former to reach us had to traverse 11,500 kilometres, and the latter 13,500. M. Wolf showed that the rate of progress was that of sound, and on the basis of this and the distances, he found the eruption to have taken place on August 27, at 11h. 43m. a.m.

THE Birmingham Town Hall was crowded on Sunday night, January 27, to hear a lecture from the Rev. W. Tuckwell on "Natural History for Working Men." He dwelt upon the difference between the homes of the working man and his employer, the first being destitute of the beauty and the resource with which the latter overflowed. One resource at any rate he could recommend to them in the study of natural history. Illustrations were drawn from the modification of the sap in their window-plants, the rise of the fluid in their trees, the structure of the spiders' webs on their walls, the transformation of insects in their water-butts; from the heavenly bodies within their gaze, Mars with his polar ice-caps, Jupiter with his moons, the sun with his spots, the moon with her craters, the nebular clusters, and the falling meteorites, to show that enveloping and pressing on us everywhere were miracles of creative and developing energy, surpassing a thousandfold the wonders of human enterprise, and that we walked amongst them unheeding and uninquiring. Instances were given of working men who had been discoverers and happy workers in these subjects, some unknown to fame, others, like Charles Peach, Robert Dick, and Thomas Edwards, the heroes of widely read memoirs. Instructions were detailed for setting up aquariums, collecting fossils and insects, preserving plants, stuffing birds, buying microscopes or telescopes with one year's saving from the public-house. A good museum should be examined; and a visit to Oxford on the next bank holiday was proposed. Annual *soirées* were recommended, at which the collections and constructions of the past year might be exhibited. The lecture ended with a few words of religious feeling arising out of the subject, which were received with deep sympathy by the audience. Thanks were proposed by Mr. Jesse Collings, M.P., Mr. Lawson Tait, and Rev. E. F. MacCarthy. The lecture will shortly be published.

IN connection with the forthcoming International Health Exhibition, it is desired to illustrate as far as possible the relations of meteorology to health, and for this purpose a special sub-Committee has been formed. It is hoped that the Royal Meteorological Society will establish a typical climatological order station, provide the complete equipment, and supervise the same. This will be arranged on a level grass space about thirty feet square, which space will be railed in, and provided with a gate through which a limited number of the public can from time to time be admitted. The attendant will take daily observations from the instruments, which will be exhibited in diagrams, and a copy of them furnished to the editorial department of the Exhibition, for publication in the daily programmes and also as a *communiqué* to the press. It is hoped that a series of large diagrams illustrative of the climatal conditions prevailing in various parts of the world may be exhibited. Besides the collective exhibit above described, space will be provided for the exhibition of instruments by manufacturers, inventors, and others who may desire to show them. Attention is particularly directed to the fact that the Committee specially invite the exhibition of meteorological instruments bearing upon the relations of climatology to public health. The Committee also appeal to authors of papers upon the relations between health and disease, rainfall, percolation, evaporation, and flow from ground, and other subjects embraced by the Exhibition, and invite them to exhibit diagrams, models, and apparatus illustrative of their researches.

BULLETIN No. 3 of the Entomological Division of the U.S. Department of Agriculture (Washington, 1883), when stripped of the "red-tape" that appears to be even more necessary on official documents in the States than it is in this country, is of more than usual interest. The notorious "army-worm" appears in a new character, viz. as destructive to cranberries, which form an important feature in the productions of the States. Various additional enemies to forest-trees are treated on by Dr. Packard. A long chapter (by Drs. Anderson and Barnard) is devoted to the "cotton-worm," in which (in addition to interesting biological information) elaborate contrivances for distributing arsenical solutions are described. Dr. McMurtrie contributes an exhaustive report on the examination of raw-silk "grown" in the States. From a scientific point of view the most valuable article is a posthumous one, by the late Dr. J. S. Bailey, on the North American *Cossidæ* (or "goat-moths"), illustrated by two very excellent plates.

WE cannot speak too highly of the work and management of the Sheffield Free Libraries. One-quarter of their rate is mortgaged to meet the debt incurred at starting; yet more than one-seventh of its entire amount is spent in books. Practically this is more than one fifth of the available income; and since, besides the central library, there are three large active branches as well as a museum and observatory, it shows a careful economy in the expenses. The committee regret in their report that their income will not allow them to further increase their premises in both size and number. In many libraries the income is almost swallowed up in the expenses of a single costly establishment. The management of Sheffield, therefore, combined with the excellence of the collection of books which its catalogue displays, deserves support from any who feel an interest in intellectual progress or wholesome and harmless recreation.

THE Norwegian naturalist, Dr. S. A. Buch, has been commissioned by his Government to prosecute practical scientific researches as to the herring fisheries of Norway during the present year, according to the instructions of the Society for Promoting the Norwegian Fisheries in Bergen.

ON January 24, at 11.25 p.m., a splendid meteor was observed at Husqvarna in Sweden. The meteor passed rather slowly in a southerly direction, leaving a lustrous trail behind about a yard long. It was nearly the size of an ordinary cheese-plate. After a few seconds it burst with a loud report, emitting a light green lustre. The fragments seemed to turn red and soon vanished.

WITH the January number the Austrian *Monatschrift für den Orient* has increased its size, and introduced illustrations. It is also promised that scientific supplements will be occasionally issued.

MESSRS. HODDER AND STOUGHTON have issued a translation of the first volume (the only one yet published) of Dr. Rein' work on Japan—"Japan: Travels and Researches undertaken at the Cost of the Prussian Government"—of which we were able to speak in high terms in reviewing the original German edition. Altogether it is probably the most solid contribution which has been made to a knowledge of Japan and its people; the translation seems to us to be well done.

THE next evening lecture of the Society for the Encouragement of the Fine Arts will be delivered by Mr. Lennox Browne, at the rooms of the Society in Conduit Street, on February 14. It will be entitled "Science and Singing," and will be elucidated by vocal and other illustrations.

FROM the *Adelaide Express and Telegraph* of December 31, 1883, we learn that Mr. Clement L. Wragge was about to start an astronomical and meteorological observatory on his own account on the banks of the Torrens. Observations of the usual meteorological elements were to be commenced on Jan. 1, 1884. The meteorological instruments comprise mercurial barometers, a barograph, numerous self-registering and other thermometers by the best makers and Kew verified; besides rain-gauges, ozone tests, rain-band spectroscope, and other appliances used by Mr. Wragge at the Ben Nevis Observatory. He hopes to train an assistant, who will carry on the work during any prolonged absence. The house is to be called the Torrens Observatory, and is admirably situated on Stephens Terrace, Gilberton, two miles from Adelaide.

ON the proposal of M. de Lesseps, the Paris Geographical Society has decided to publish the biographies of all the French travellers of the present century.

THE *Journal of the Society of Arts* for February 1 contains two papers of special interest. One by Mr. J. G. Colmer, the Secretary to the Canadian High Commissioner, tells what the British Association will find in Canada on its visit in August next; the other is a paper of much practical value, by Mr. Thomas Fletcher, on coal-gas as a labour-saving agent in mechanical trades.

WE learn from a communication from Orkney that on January 27 at 3 a.m. the barometer fell to 27·508, and that the tide was unusually high. At Dundee the lowest record was 27·382 at 10.30 p.m. on the 26th, while the velocity of the wind is given at from fifty to sixty-five miles per hour. In Orkney a velocity of eighty-eight miles was recorded by the anemograph.

IT appears from the researches of M. Sokoloff that the water of the Neva at St. Petersburg, at a depth of 9 feet, is very pure when compared with the water supplied to other large cities. The matter in suspension in 1 cubic metre of water (in September and October) does not exceed 5·5 grm., and sometimes it is so small as to be less than 0·02 grm. The mineral matter dissolved varies from 31·0 to 38·1 grm., and the organic matters reach but 18·7 to 22·5 grm. The average for August and September is 20·4 grm. of organic matter and 31·6 of inorganic; for October, 21·7 and 33·9 grm. respectively.

CAPTAIN STUB, Corresponding Member of the Society of Arts at Smyrna, writes to Mr. Hyde Clarke that "the cold wave which was passing over America reached here last Sunday, January 21, and for Smyrna the cold was intense. I am told in exposed positions the thermometer went down to 10° below zero. At the point near the railway station I saw ice one inch thick. On the 24th the weather became milder."

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Dr. Harrison Branthwaite; a Bonnet Monkey (*Macacus sinicus* ♂) from India, presented by Mr. E. F. Shortt; a Quebec Marmot (*Arctomys monax*) from Virginia, U.S.A., presented by Mr. G. S. White; a Long-eared Owl (*Asio otus*) from Germany, presented by Master Owen Dallmeyer; a Water Rail (*Rallus aquaticus*), British, presented by Mr. T. E. Gunn; a West African Python (*Python sebæ*) from West Africa, presented by Capt. J. Grant Elliott; five European Tree Frogs (*Hyla arborea*) from France, presented by Miss E. Brunton; a European Tree Frog (*Hyla arborea*), South European, presented by the Rev. J. Stapledon Webber; a Rhesus Monkey (*Macacus rhesus*) from India, a Common Wolf (*Canis lupus*), European, a Fallow Deer (*Dama vulgaris* ♀), British, two Chattering Lories (*Lorius garrulus*) from Moluccas, two Vieillot's Firebacks (*Euplocamus vieilloti* ♂ ♀) from Malacca, deposited; a Sykes's Monkey (*Cercopithecus albigularis*), a Gray-cheeked Mangabey (*Cercocebus albigena* ♀) from West Africa, two Spotted Hyænas (*Hyæna crocuta* ♂ ♀) from South Africa, a Red-vented Parrot (*Pionus menstruus*) from Brazil, a Golden Eagle (*Aquila chrysaëtos*), a Tawny Eagle (*Aquila nævioides*), a White-tailed Eagle (*Haliaëtus albicilla*), a Cinereous Vulture (*Vultur monachus*), seven Knots (*Tringa canutus*), European, a Temminck's Snapper (*Macroclemmys temmincki*) from North America, purchased.

OUR ASTRONOMICAL COLUMN

THE COMET OF 1664.—"Cette comète de 1664," remarks Pingré, in introducing the description of it given in his "Cométographie," "a singulièrement exercé les presses des Imprimeurs," and that this statement was justified will be evident to any one who may consult Lalande's "Bibliographie," the catalogue of the library in the Observatory of Pulkowa, or the "Repertorium der Cometen-Astronomie," by Dr. Carl of Munich; in the latter will be found references to some eighty works, either treating specially upon this comet, or in which it is noticed in more or less detail. And further, as Mädler observes: "Lubienietsky hat über ihn allein einen ganzen Quartband geschrieben, der freilich für unsere Zwecke sich auf einige Seiten reducirt;" the volume here referred to is the first of the "Theatrum Cometicum."

This comet appears to have been discovered in Spain as early as November 17. Huyghens observed it at Leyden on December 2, while the observations of Hevelius at Dantzic, which have been used exclusively in the determination of the orbit, commenced on December 14, and it was generally observed in France and Italy about the same time. Observations properly so-called do not appear to have been made in this country, and on scanning the long list of publications enumerated by Carl we find, in addition to a notice by J. Ray in the *Philosophical Transactions* for 1707, only two works named as having been printed here: (1) "An Astronomical description of a comet as it appeared in new Ingland, in the year 1664;" and (2) "The blazing star, or a discourse of Comets. In a letter from J. B. to T. C. concerning the late comet." Flamsteed was then an ailing youth, and though given to astronomical exercises he has no reference to the comet in question. Indeed, in his account of his early life we read: "I had now completed eighteen years, when the winter (that of 1664-1665) came on and thrust me again into the chimney, whence the heat and the dryness of the preceding summer had happily once before withdrawn me;" and he thus attended rather to calculation from Street's "Caroline Tables," which he had just procured, than to observations.

The comet was not suffered to remain without notice by Samuel Pepys, and we find several references to it in his "Diary," which it may not be quite without interest to examine. Pepys records the old style dates, but we reduce them to the present reckoning. The first notice of the comet is on December 27, and runs thus: "Mighty talk there is of this comet that is seen a' nights; and the King and Queene did sit up last night to see it, and did it seems. And to-night I thought to have done so too; but it is cloudy, and so no stars appear. But I will endeavour it." On the night of December 26 the comet would rise in London just before eleven o'clock, and would be on the meridian at two o'clock at an altitude of less than nine degrees, in R.A. 126°·4, and declination 30°·0 south, distant from the earth 0·193. The apparent length of the tail (37°) mentioned by Carl, assigns a real length of 43,000,000 miles, if it were in the line of the radius-vector. On December 31 we read: "My Lord Sandwich this day writes me word that he hath seen (at Portsmouth) the comet, and says it is the most extraordinary thing he ever saw." On January 3 Pepys says: "I saw the comet, which is now, whether worn away or no I know not, but appears not with a tail, but only is larger and duller than any other star, and is come to rise betimes, and to make a great arch, and is gone to quite a new place in the heavens than it was before; but I hope in a clearer night something more will be seen." At eight o'clock on the evening of January 3 the comet was in R.A. 47°·5, declination 1°·5 south, distant from the earth 0·276; the moon was at full two days previously, so that the tail might have been in great measure overpowered by her light in the indifferent state of the sky. Pepys has no further reference to the comet till March 11, when the "Diary" says: "To Gresham College, where Mr. Hooke read a second very curious lecture about the late comet; among other things proving very probably that this is the very same comet that appeared before in the year 1618, and that in such a time probably it will appear again, which is a very new opinion; but all will be in print." We do not remember to have met with other reference to this opinion of Hooke's, though probably such must exist; and it is not easy to explain upon what grounds he founded the idea. The comet referred to was the third of 1618, which, to use Pingré's phrase, almost exercised the printing-press as much as that of 1664. It was observed by Harriot at Sion House, Isleworth, or, as it was then called, Thistleworth.

GEOGRAPHICAL NOTES

Our readers may have noticed that Dr. Holub had met with unexpected difficulties at the Cape in the prosecution of his journey into the African interior, the Cape authorities insisting on payment of the full duty on the traveller's scientific equipment. It will be seen from the following communication, which has been sent us for publication, that the difficulty has been happily and promptly settled:—"Downing Street, February 2, 1884.—Sir,—I am directed by the Earl of Derby to acknowledge the receipt of your letter of the 29th ult., relative to the exploring expedition undertaken by Dr. Holub in South Africa; and I am to acquaint you, for the information of Sir Joseph Hooker, that a telegram has been sent to the officer administering the Government of the Cape of Good Hope, requesting that special concessions may be made in respect to the Customs duties, and that support may be afforded to Dr. Holub in the prosecution of his enterprise. A despatch to the same effect will follow by the outgoing mail.—I am, &c. (signed), Robert G. W. Herbert.—The Assistant Director, Royal Gardens, Kew."

In the *Bolletino* of the Italian Geographical Society for January an account is given of a curious manuscript recently presented to the Society by Count Pietro Antonelli. It forms a bulky codex of 125 sheets of parchment, consisting mostly of formulas and magic incantations written in the old Giz (Ethiopic) language with a large admixture of Amharic. Amongst the contents is also the *Aud Neges't*, or Royal Circular, comprising sixteen circles, each of which occupies a whole page of the codex. All are divided into sixteen segments, each containing some text on the various incidents of human existence, which are afterwards expounded in greater detail. Then come thirty chapters, each divided into fifteen lines, every one of which contains some sentence or aphorism. The donor has received the King Humbert gold medal for the scientific work accomplished by him in the Italian settlement of Assab and neighbouring district. The same number of the *Bolletino* contains a description of the interesting collection presented last year to the prehistoric ethnographic museum at Rome by M. van Oordt of Leyden. This collection comprises a beautiful series of amulets, musical instruments, costumes and all kinds of personal ornaments used by the Maronites of the Lebanon, the Druses of Hauran and other Syrian populations. Some have a considerable intrinsic value, while others are noteworthy for their rarity and the elegance of their forms and ornamentation. One of the most remarkable objects is the girdle worn by rich Bedouin and Druse brides, consisting of a broad many-coloured silken sash with a large silver clasp nearly oval at both extremities. It is opened by means of a needle, and embellished with conic filigree buttons and silver chains, from which are suspended little globules, crescents, and other charms.

The *Sydney Morning Herald* of December 27, 1883, says:—An exploring party, under the leadership of Mr. Charles Winnicke, an experienced explorer and bushman, has just made a successful journey through a large portion of unknown country in the interior of Australia. The party was provided with camels and horses, but the latter were never required. Mr. Winnicke made a start from Cawarrie station, on the Warburton River, in latitude 28° S., and traversed the country to the north as far as latitude 27°, effecting a connection with previous explorations near Goyder's Pillars. A most remarkable natural feature in the Tailton Range was discovered by Mr. Winnicke during his Herbert River explorations. Several long stages without water were encountered a few days after the party left Cawarrie station, and a distance of 200 to 300 miles had to be traversed across the highest sand ridges in Australia before water could again be obtained. Many more long stages of between 100 and 200 miles without water were travelled. In many instances the sand ridges, which were from 300 to 400 feet high, and very steep, had to be crossed at right angles. Two large rivers and an extensive range were discovered near the Queensland boundary, and altogether Mr. Winnicke succeeded in mapping about 40,000 square miles of unknown country, which will help to fill in another large blank space on the map of Australia.

Mr. O'Neill, who arrived at Mozambique on February 4, after having traversed 1400 miles of unexplored country, situated between Mozambique and Lake Nyassa, has discovered Lake Amarambu, the existence of which was previously unknown, and which he declares to be the true source of the Pienda (?) River. Mr. O'Neill reports Lake Shirwa to be smaller than has been represented. On his return Mr. O'Neill followed the Likelungo Valley, which he found to be well populated.

Dr. Chavanne will start in a few days on his expedition to the interior of Africa, undertaken for the Belgian "Institut National de Géographie." He will employ the first eight months of his time in drawing up an accurate chart of the Congo; and then penetrate from Leopoldville to the north to explore the hitherto unknown districts lying in that direction and the water-courses. It must depend on circumstances whether he will effect his return along the Nile, by Zanzibar, or by the Congo. The provisional chart of the Congo, which was published a short time since in America, is now sold here.

In vol. xix. of the *Izvestia* of the Russian Geographical Society we find the results obtained by M. Grinevetsky during his journey across Novaya Zemlya in the spring of 1878. The country is a plateau, about 450 feet above the sea-level, with deep valleys in which several lakes are concealed. The rivers cut deeply into the plateau. The south-eastern winds blow freely on the plain, denuding it of its snow covering. Three different parts may be distinguished in the southern island of Novaya Zemlya: the northern part, which is covered by mountains quite unknown, is bounded on the south by the Pukhovaya River. The middle part is covered by five or six parallel chains of hills, the highest summits of which reach 800 feet; they run north-west, close to the western coast, having a wide plateau to the east. The southern part is a plateau not more than 450 feet high, and M. Grinevetsky doubts very much if there are mountains 2000 feet high, as has been stated. One observation of M. Grinevetsky is worthy of notice. It is most probable, he says, that there are two varieties of reindeer in Novaya Zemlya. One of them inhabits the southern island, and the other, which does not mix with the former, inhabits only the northern island; it is said by the hunters to be much like that of Spitzbergen. In fact the Russian hunters have found very often on Spitzbergen a kind of reindeer with cut ears, which, they are persuaded, comes from Novaya Zemlya. In the Report of the Polar Commission in the *Izvestia* of the Russian Geographical Society (1871) reasons were given for believing, along with Baron Shilling, in the existence of an archipelago to the north-west of Novaya Zemlya (the feebleness of the cold sea current in Barents Sea, and the large quantities of mud and gravel seen on the floating ice north-west of Novaya Zemlya). The remark of the hunters was also referred to, and the opinion expressed that, if such an archipelago existed, the Novaya Zemlya reindeer really might cross the sea during favourable years, reach this archipelago, and thence continue their migrations to Spitzbergen. The discovery of Franz Josef Land renders this supposition still more probable, especially if the Franz Josef archipelago extends farther to the east, which extension seems most probable, on account of the feebleness of the polar current that enters Barents Sea, which surely would be much stronger if the space between Novaya Zemlya and the North Pole were occupied entirely by an open sea. The observation of M. Grinevetsky again raises this question: Is it true that the Novaya Zemlya reindeer afford so many distinct affinities with the Spitzbergen reindeer as to be considered as belonging to the same sub-variety? And if so, how explain these affinities without admitting (as the hunters do) that the reindeer in his migrations goes from Novaya Zemlya over to Spitzbergen, availing himself of the archipelagos scattered between the two islands?

In Nos. 9 and 10 of vol. x. of the *Transactions of the Berlin Geographical Society*, is an address on the wild tribes of Madagascar, by Herr J. Audebert, who divides them collectively, both those of Malayan (the Hovas) and those of African descent, according to their mode of life, into three classes: the inhabitants (1) of the coast; (2) of the woods; (3) of the grassy lands and steppe-like wastes of the southern interior. Of all the races the Sakalavi are first in point of number, power, and civilisation. The aborigines, or Malagasy proper, are generally of a dark complexion, though those of direct Arabian descent are very clear-skinned, with hard features, broad, often also high forehead, eyes wide apart, nose flat, lips prominent, but not swollen, mouth broad, with splendid teeth. The long rather woolly hair is worn in innumerable plaits woven, in the case of the women, into crowns, vaccine ears, snail-shells, &c., smeared with tallow and ashes into the hardness of stone, and very malodorous. In the grassy interior cattle-rearing is the principal industry; on the coast fishing and the cultivation of rice. In the woods the people live on roots, tubercles, and honey.—Next follows an interesting though brief account of Dr. Stecker's chequered travels, of nearly three years' duration, through Abyssinia. About the middle of February, 1881, when Dr. Rohlfs left Debra Tabor, Dr. Stecker made his way to the Tana Lake, which he travelled round, sending a detailed map of it, executed on the spot, to the German African Society. At Zabul, the recently-acquired seat of King John, Dr. Stecker drew a plan of the grand and interesting chain of mountains traversing the eastern part of Abyssinia, but both report and map failed to reach the German African Society, whither they were directed. Dr. Stecker was bent on penetrating into Koffa, but on account of war tumults and King John's refusal to give him permission, was obliged to abandon his design. He, however, joined the three kings, King John, the King of Shoa, and the Negus Tekla Haimanot into the Eastern Gala lands of Komboltsha, Antsharo, Tshaffa, Rikke, and Argobba, and was thus enabled to make first acquaintance with a tract of country never before trodden by a European.—Some interesting particulars of travels in South America are taken from a letter of Dr. G. Steinman to Dr. W. Reiss, dated November 5, 1883.—The stones collected by Herr P. Güssfeldt on the north-west slopes of Aconcagua, at a height of from 5500 to 6100 metres have been analysed by Prof. J. Roth of the Academy of Sciences, and the result has established beyond all further doubt the fact that Aconcagua is a volcano.

THE ORIGIN OF THE SCENERY OF THE BRITISH ISLANDS[1]

A TRUE mountain chain is the result of a local plication of the earth's crust, and its external form, in spite of sometimes enormous denudation, bears a close relation to the contours produced by the original uplift. Tried by this standard, hardly any of the heights of Britain deserve the name of mountains. With some notable exceptions in the south of Ireland, they are due not to local but to general upheavals, and their outlines have little or no connection with those due to underground movement, but have been carved out of upheaved areas of unknown form by the various forces of erosion. In the course of their denudation the nature of these component rocks has materially influenced the elaboration of their contours, each well-marked type of rock having its own characteristic variety of mountain forms. The relative antiquity of our mountains must be decided not necessarily by the geological age of their component materials, but by the date of their upheaval or of their exposure by denudation. In many cases they can be shown to be the result of more than one uplift. The Malvern Hills, for example, which from their dignity of outline better deserve the name of mountains than many higher eminences, bear internal evidence of having been upheaved during at least four widely separated geological periods, the earliest movement dating from before the time of the Upper Cambrian, the latest coming down to some epoch later probably than the Jurassic period. The oldest mountain fragments in Britain are those of the Archæan rocks, and of these the largest portions occur in the north-west of Scotland. Most of our mountains, however, belong to upheavals dating from Palæozoic time, though the actual exposure and shaping of them into their present forms must be referred to a far later period. Two leading epochs of movement in Palæozoic time can be recognized. Of these the older, dating from before the Lower Old Red Sandstone and part at least of the Upper Silurian period, was distinguished by the plication of the rocks in a dominant north-east and south-west direction, and the effects of these movements can be traced in the trend of the Lower Silurian ridges and hollows to the present day. In Wales two types of mountain-form exist—the Snowdon type, and that of the Breconshire Beacons. In the former the greater prominence of the high grounds arises primarily from the existence of masses of volcanic rocks, which from their superior durability have been better able to withstand the progress of degradation. In the latter the heights are merely the remaining fragments of a once continuous tableland. The Lake District presents a remarkable radiation of valleys from a central mass of high ground. It might be supposed that these valleys have been determined by some radiating system of fractures in the rocks; but an examination of the area shows them to be singularly independent of geological structure. So entirely do they disregard the strike, alternations, and dislocations of the rocks among which they lie that the conclusion is forced upon us that they have been determined by some cause wholly independent of structure, and before the present visible structure was exposed at or could affect the surface. This could only have happened by the spread of a deep cover of later rocks over the site of the Lake mountains. The former presence of such a cover, which is demanded for the explanation of the valleys, can be inferred from other evidence. The Carboniferous Limestone on the flanks of the Lake District is so thick that it must have spread nearly or entirely over the site of the mountains. But it was overlaid by the Millstone Grit and Coal-measures so that the whole area was probably buried under several thousand feet of Carboniferous strata which stretched continuously across what is now the north of England. At the time of the formation of the anticlinal fold of the Pennine Chain the site of the Lake District appears to have been upraised as a dome-shaped eminence, the summit of which lay over the tract now occupied by the heights from Scafell to Helvellyn. The earliest rain that fell upon this eminence would gather into divergent streams from the central watershed. In the course of ages, after possibly repeated uplifts, these streams have cut down into the underlying core of old Palæozoic rocks, retaining on the whole their original trend. Meanwhile the whole of the overlying mantle of later formations has been stripped from the dome, and is now found only along the borders of the mountains. The older rocks yielding to erosion, each in its own way, have gradually assumed that picturesqueness of detail for which the area is so deservedly famous. The Scottish Highlands likewise received their initial plications during older Palæozoic times their component rocks having been thrown into sharp fold, trending in a general north-east and south-west direction. But there is reason to believe that they were in large measure buried under Old Red Sandstone, and possibly under later accumulations. No positive evidence exists as to the condition of this region during the vast interval between the Old Red Sandstone and the older Secondary rocks. We can hardly believe it to have remained as land during all that time, otherwise, the denudation, vast as it is, would probably have been still greater. Not improbably the region had become stationary at a base-level of erosion beneath the sea; that is, it lay too low to be effectively abraded by breaker-action, and too high to become the site of any important geological formation. The present ridges and valleys of the Highlands are entirely the work of erosion. When they began to be traced the area must have presented the aspect of a wide undulating tableland. Since that early time the valleys have sunk deeper and deeper into the framework of the land, the ridges have grown narrower, and the mountains have arisen, not by upheaval from below, but by the carving away of the rest of the block of which they formed a part. In this evolution, geological structure has played an important part in guiding the erosive tools. The composition of the rock-masses has likewise been effective in determining the individuality of mountain-forms. The mountains of Ireland are distributed in scattered groups round the great central plain, and belong to at least three geological periods. The oldest groups probably took their rise at the time of the older Palæozoic upheaval, those of the north-west being a continuation of the Scottish Highlands, and those f the south-east being a prolongation of those of Wales. Later in date as regards the underground movements that determined their site, are the mountainous ridges of Kerry and Cork. These are local uplifts which, though on a small scale, are by far the best examples in Britain of true mountain structure. The Old Red Sandstone and Carboniferous rocks have there been thrown into broad folds and troughs which run in a general east and west direction. In some cases, as in the Knockmealdown Mountain, the arch is composed entirely of Old Red Sandstone flanked with Carboniferous strata. But in most instances an underlying wedge of Lower Silurian rocks has been driven through the arch. As not only the Carboniferous Limestone, but the rest of the Carboniferous system covered the south of Ireland and participated in this plication, the amount of denudation from these ridges has been enormous. On the Galty range, for example, it can hardly have been less but may have been more than 12,000 feet. The third and latest group of Irish mountains is that of Mourne and Carlingford, which may with some probability be referred to older Tertiary time when the similar granitic and porphyritic masses in Mull and Skye were erupted.

---

[1] Abstract of second lecture given at the Royal Institution, February 5, by Archibald Geikie, F.R.S., Director-General of the Geological Survey. Continued from p. 325.

The tablelands of Britain strictly include the mountains, which are in general only prominences carved out of tablelands. But there are still large areas in which the plateau character is well shown. Of these the most extensive and in many respects the most interesting is the present tableland or plain of Central Ireland. As now exposed, this region lies upon an undulating eroded surface of Carboniferous Limestone. But it was formerly covered by at least 3000 or 4000 feet more of Carboniferous strata, as can be shown by the fragments that remain. The present system of drainage across the centre of Ireland took its origin long before the ancient tableland had been reduced to its present level, and before some of the ridges, now prominent, had been exposed to the light. The Moors and Wolds of Yorkshire present us with a fragment of a tableland composed of nearly horizontal Jurassic and Cretaceous rocks. The Lammermuir Hills and Southern Uplands of Scotland form a broad tableland which has been formed on a deeply eroded surface of Lower Silurian rocks.

THE MONK FISH

NATUREN has recently supplied its readers with some interesting details concerning the so-called "monk-fish" of the Sound, which may be regarded as the genuine forerunner of the sea-serpent of modern times. Its capture and appearance were deemed worthy of record in Arild Hirtfeld's great "History of Denmark," published in 1595, while portraits of the sea-monk embellished the works of various Scandinavian and German natural history writers of the middle of the sixteenth century. Among these, Guillaume Rondelet, in his great folio work, "Libri de Piscibus Marinis," first claimed the special privilege of giving to the world a facsimile of the authentic likeness of the monk. This, we are assured, had been taken from life for, and in the presence of, a nobleman, who had caused one copy to be made for the Emperor Charles V., and another for Margaret, Queen of Navarre, by whom it was presented to the author. Hirtfeld does not profess to have been brought into such close connection with the original, but he and the historians, Krag and Stephanius, agree in reporting that a fish, bearing the semblance of a human head with a monk's shaven crown, and having torn or mutilated limbs indistinctly defined under a scaly covering, was, in the year 1550, captured in the Sound, in a herring-fisher's net, and brought to the King of Denmark, who immediately gave orders that it should be buried deep underground, "to hinder indiscreet talk among the ignorant, whose minds are always perturbed by what is new." The speedy burial of the monster did not allay the excitement caused by its apparition, and Rondelet found, to his extreme annoyance, that his Swiss friend, Gesner, and other philosophers then in Rome, were in possession of other reputed original likenesses of the monk, differing from his own. This circumstance, he admits, inclined him to suspect that the artist had added "this or that according to fancy to make the fish seem more wonderful than it was in reality." He even confesses that some of the portraits have no more resemblance to a human head than might be detected in a frog or a toad; that the extremities look like fins, and that the so-called monk's gown is more like a dark seal's skin than a scaly armour. From these and other corrections, coupled with Gesner's mention of a fish's tail having formed part of the monk's body, Prof. Steenstrup infers that the "monk-fish" was an unusually large specimen of the Loligo or Squid family, whose caudal extremity, bearing probably bruises or other marks on the skin, had acquired in the imagination of the spectators the semblance of a head and neck with torn-off arms, while the arms of the cephalopod had served to represent lacerated extremities. A comparison of the numerous conflicting contemporaneous descriptions of the Danish "sea-monk" and of the later "*Kraken*" of the old Norwegian Bishop Pontoppidan might possibly be not wholly useless in the present day in checking an over-hasty confidence in the truth of every fresh tale of encounters with sea-serpents, as recorded by credulous seafaring men. We may, in the meanwhile, refer all who are interested in sea-monsters to the July number of *Naturen*, in which they will find a faithful representation of Rondelet's monk-fish, while the September number of the same journal gives reproductions of two characteristic Japanese pictures, in one of which a solitary boatman is battling in a stormy sea with a formidable creature, evidently a highly magnified form of octopus, one of whose arms has been severed as it encircled man and boat, while the other arms are represented as striving to draw their prey nearer to the huge head with its protruding eyes. In the second picture, which, if less forcible, is more realistic, we see in the wondering and terrified expression of the assembled men and boys the surprise and alarm excited by the appearance at a fishmonger's stall of two octopus arms, not unlike suspended serpents. The terror of the spectacle has communicated itself to domestic animals—a dog hiding himself, while a cat is taking rapid flight up the roof of the house.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The Examiners for the Radcliffe Travelling Fellowship give notice that the examination will commence on February 20 at 10 a.m. in the University Museum. The Examination for the Burdett-Coutts Geological Scholarship will commence on March 3 at 10 a.m.

Mr. Robert Stockdale, of Giggleswick School, has been elected to a Hastings Exhibition in Natural Science at Queen's College.

CAMBRIDGE.—The following are the words spoken by the Public Orator in presenting Dr. Hans Gadow (formerly of the British Museum), Curator of the Strickland Collection of Birds, for the complete degree of M.A. *honoris causâ* :—

"Dignissime Domine, Domine Procancellarie et tota Academia : Anni proximi sub finem (iuvat recordari) fabulam illam Aristophanis quæ Aves nominatur cum voluptate maxima prope omnes spectavimus. Hodie vero, ad studia nostra severiora redeuntes, nihil auspicatius esse arbitramur, quam annum novum honore in illum collato signare qui omnium avium genera et naturas quasi propriam provinciam sibi sumpsit explorandam. Illum igitur senatoribus nostris hodie merito adscribimus, qui Pomeraniæ maritimæ in parte orientali a gente antiquissima oriundus in celeberrimis Germaniæ Academiis zoologiæ, palæontologiæ, mineralogiæ, studiis operam suam feliciter impendit; qui quarto abhinc anno in Britanniam idcirco est vocatus, ut aves in Museo Britannico conservatas summa cura describeret; qui in nostra denique Academia nuper non modo de vertebratis quæ dicuntur animalibus prælectiones habuit doctissimas, sed etiam thesauris nostris ornithologicis custodiendis cum fructu nostro maximo est præpositus. Inter antiquos quidem avium a volatu cantuque rerum futurarum omina ducebantur; nos meliora edocti hodie in hoc viro Procancellarii novi auspiciis veram avium scientiam laude debita exornamus, ex initio tam felici omnia fausta in futurum augurati. '*Date candida cives Omina, et inceptis dextera cantet avis.*' Vobis præsento virum et de studiis ornithologicis et de Academia nostra optime meritum, HANS GADOW."

Mr. W. F. R. Weldon, B.A., St. John's College, has been appointed Demonstrator of Comparative Anatomy.

Mr. Francis Galton, F.R.S., has been appointed Rede Lecturer for the present year.

Prof. W. J. Sollas, M.A., late Fellow of St. John's College, First Class in the Natural Sciences Tripos, 1873, and Mr. P. H. Carpenter, M.A., Trinity College, First Class in the same Tripos, 1874, have been approved for the degree of Doctor of Science. The able original works in Geology and Zoology by both these gentlemen are familiar to all students.

LONDON.—At King's College, Prof. W. Grylls Adams, F.R.S., will continue the course of lectures on Light, and the Scientific Principles involved in Electric Lighting, during the remainder of the session. A course of practical work in Electrical Testing and Measurement with especial reference to Electrical Engineering will also be carried on under his direction in the Wheatstone Laboratory. The lectures will be given once a week—on Mondays, at 2 p.m.—and the Laboratory will be open on Wednesday and Friday from 1 to 4.

SCIENTIFIC SERIALS

THE monthly parts of the *Journal of Botany* for 1883 contain many useful and interesting papers. Among the more important must be regarded Mr. J. G. Baker's synopsis of the genus *Selaginella*. This is not yet completed, but already extends to nearly 100 species, many of them now described for the first time. This is understood to be an instalment of a complete monograph by Mr. Baker of the Vascular Cryptogams, excluding ferns, a work eagerly demanded by botanists.—The additions to the phanerogamic flora of Great Britain are not yet completed; and the palm of recent discoveries must be awarded to Mr. Arthur Bennett. In this year's record he describes and figures two, one of them, *Potamogeton Griffithii*, new to science, from a lake in Carnarvonshire. The other, *Naias marina*, is a native of the "Broads" of Norfolk. This is rendered more interesting by the discovery, by other botanists, of another species of *Naias*, *N. alagnensis*, also during the present year, in Lancashire. It is not many years since the genus was first found in Britain; and the only species hitherto known, *N. flexilis*, has been gathered only in Scotland and Ireland.—The structure and distribution of the Characeæ are still engaging attention from Messrs. H. and J. Groves and others; and of this cryptogamic order, another species, *Chara Braunii*, has also been added to the flora of Great Britain.—Mr. H. Boswell also describes two new British mosses, *Bryum gemmiparum*, from Breconshire, and *Sphagnum torreyanum*, from Shropshire.—Messrs. R. M. Christy and H. Corder contribute an interesting paper on the cross-fertilisation of *Arum maculatum*.—Numerous other articles and short notices of more local and special interest fill up the number.

THE second part of vol. xiv. of *Pringsheim's Jahrbücher für wissenschaftliche Botanik* contains two important articles on cryptogamic botany:—Dr. A. Fischer, on the occurrence of crystals of gypsum in the Desmidieæ shows that they are of very wide distribution in the family, as well as in other freshwater algæ such as *Spirogyra*, though by no means universally present. He believes it to be simply a product of excretion in the process of metastasis, whether present in the form of crystals or dissolved in the cell-sap. Dr. O. Müller, on the law of cell division in *Melosira arenaria*, offers an important contribution to the life-history of the diatoms. By a most careful series of observations he establishes the law that "the larger daughter-cell of the nth generation divides in the following or $(n + 1)$st generation, while the smaller daughter-cell always divides only in the $(n + 2)$nd generation," by an argument which is too long to go into here. He deduces from this law the reason of the comparatively rare occurrence of the auxospores, by which the original size of the species is restored after the continued degradation which it necessarily undergoes in the process of division.—B. Fritsch contributes also a paper on coloured granular constituents of the cell-contents.

THE second part of vol. iv. of *Engler's Botanische Jahrbücher* for 1883 contains a continuation of its very valuable review of the more important works on systematic and geographical botany which appeared in 1882.—The other papers are:—By T. Wenzig, on the genus *Fraxinus*.—By F. Moewes, on hybrids of *Mentha arvensis* and *M. aquatica*.—By E. Warming, on the order Podostemaceæ.

Archives of the Physical and Natural Sciences, Geneva, December 15, 1883.—Meteorological *résumé* of the year 1882 for Geneva and the Great Saint-Bernard, by M. A. Kammermann, Assistant-Astronomer.—On the ancient lake of the Soleure district (coloured map), by M. Alph. Favre. The existence of this lacustrine basin confirms the conclusion arrived at by other geological studies, that during the early post-Glacial epoch a far greater portion of Switzerland was under water than at present.—Descriptive notice of the meteorological observatory installed on September 1, 1882, at Sentlis, canton of Appenzell, 2467 metres above sea-level.—On the periodical oscillations of the ground, determined by the spirit-level (fifth year, 1882–83), by M. P. L. Plantamour.—On the theory of dynamo-electric machines, by M. R. Clausius. These machines having in their practical development outstripped the theory of their construction, an attempt is made in this elaborate paper to expound a theory more in harmony with the results already obtained than are any of the mathematical formulas hitherto employed to represent them.

Rendiconto of the Sessions of the Accademia delle Scienze di Bologna for the year 1882–83. Nov. 19, 1882.—Memoir on the "null envelopes" of the second class in a given system of points affected by given coefficients, showing how, from the general formula, others may be deduced, rendering more evident the property of the envelopes, and solving some questions connected with the momenta of the second order of said system, by Prof. Ferdinando P. Ruffiani.—On three sicephalous monsters, and more particularly on the seven-month Janus recently born in Bologna, by Prof. Luigi Calori.—Note on the extremities of the motor nerve fibres in the striated muscles of the torpedo (*Torpedo marmorata*) treated with bichloride of gold and cadmium, by Prof. G. V. Ciaccio.—Microscopic researches on the traces of electric sparks incised on glass, by Prof. Elmilio Villari.—On the electric figures of condensers, by the same author.

November 26.—A systematic classification of the genus Puccinia, by Prof. Cocconi and Dr. F. Morini.—On a case of hypertrophic hepatitis, by Prof. C. Taruffi.—Symptomatic and anthropometric studies on the cretinism prevalent in the Valle d'Aosta, Piedmont, by the same author.—Some new researches on the artificial reproduction of the spleen, by Prof. Guido Tizzoni.—On the results of the measures hitherto adopted to improve the soil and climate of malarious districts in Italy, by Dr. Paolo Predieri.—A new contribution to the study of Addison's disease, by Prof. Ferdinando Verardini.

January 14, 1883.—On a fossil cetacean (*Orca cetoniensis*) recently discovered at Cetona in Tuscany, by Prof. G. Capellini.—A study of some reactions of phosphuretted hydrogen gas, by Dr. Alfredo Cavazzi.

January 28.—On a rapid method for determining the lunar motions, by Prof. A. Saporetti.—New researches on the anatomy and pathology of the placenta in mammals, by Prof. G. Escolani.

February 11.—Notes on the history of geodesy in Italy from the earliest times down to the second half of the present century, by Prof. P. Riccardi.—Experimental researches on the hypertrophy and partial regeneration of the liver, by Dr. V. Colucci.—On the relative length of the neck in both sexes, and on the best method of making these anthropometric measurements, by Dr. G. Peli.—On the preventive inoculation of contagious pleuro-pneumonia for cattle by means of intravenous injection of the virus, by Prof. A. Gotti.—Anatomical researches on five bovine monstrosities, by Prof. G. P. Piana.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 10.—"Experimental Researches on the Electric Discharge with the Chloride of Silver Battery." By Warren De La Rue, M.A., D.C.L., Ph.D., F.R.S., and Hugo Müller, Ph.D., F.R.S.

Plasticity and Viscosity of Strata.—During our experiments we have often been struck by the evident plasticity of strata whose form at times becomes modified when they meet with an obstacle or are influenced by other causes, as, for example, the crossing of other strata produced by a separate discharge.

One of our tubes, No. 9, with a residual hydrogen vacuum, has a diaphragm in the centre ¼ of an inch, 0·63 cm., thick, through the centre of which there is a hole ¼ of an inch, 0·63 cm., in diameter. To the end of the tube is attached a potash absorption chamber, the heating and cooling of which causes a change in the number of strata; when the number of strata increases they approach closer and closer to the diaphragm, and occasionally one threads itself through it, as if squeezed through, and its form is gradually changed thereby.

A tube, No. 368, Fig. 1, with a hydrogen residue gives evidence of the viscosity of a stratum.

At right angles is a tube of smaller diameter; in this tube is a stopper having a loop underneath from which is suspended by two silk fibres, *s*, a piece of decarbonised iron, *n n'*. The stopper when greased turns quite smoothly, and by rotating it the needle can be easily placed in any direction with regard to the tube.

In the first place the tube was placed in the magnetic meridian, and the needle of iron wire, *n n'*, in the same direction; tested by means of a very small magnet, both ends were equally attracted and not repelled, showing that the needle had been thoroughly decarbonised; this was done by heating it to redness for many hours in peroxide of iron, prepared by burning its oxalate.

The discharge was in the first instance passed from the ring to the point, so that the needle was in the dark space; no magnetism was developed in the needle, which would have been the case if the discharge had had a spiral motion as we have often observed and described to be sometimes the case. It was indeed with the object of ascertaining this fact that the apparatus had been made.

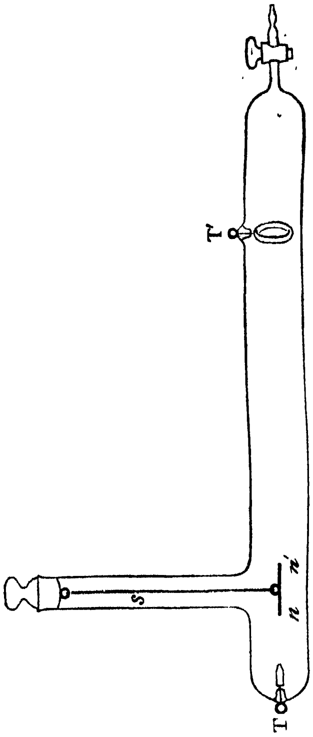

FIG. 1.

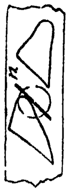

FIG. 3.

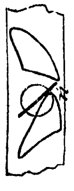

FIG. 2.

The needle was now placed at right angles to the tube, and the point made positive; after a few trials at different exhausts a beautiful tongue-shaped stratification was obtained, and it was then possible by altering the amount of the current to make the apex of a stratum impinge on one or the other end of the needle, Figs. 2 and 3; on whichever end the stratum touched, that end was pushed away by it, showing clearly that the balance of forces which hold together the molecules composing a stratum are sufficient to render it viscous, and unyielding to a small resistance.

Geological Society, January 23.—R. Etheridge, F.R.S., vice-president, in the chair.—George Henry Nelson and John Philip Spencer were elected Fellows of the Society.—The following communications were read:—On the Serpentine and associated rocks of Porthalla Cove, by J. H. Collins, F.G.S.—Outline of the geology of Arabia, by C. M. Doughty. Communicated by Prof. T. G. Bonney, F.R.S. The author described the general outline of the geology of a considerable district of the western part of Arabia, over which he had travelled. It was not in his power to enter into details, especially as regarded the sedimentary rocks, because the circumstances under which his journey was undertaken made it impossible to bring back specimens. There was, however, considerable simplicity in the geological structure of the country. The igneous rocks consisted of granites and basalts, the latter breaking through the former. The sedimentary rocks, which are newer than the granites and, in fact, rest upon them, consist of—(*a*) A yellowish sandstone, with stains of a reddish or greenish colour and veins of ironstone. In this, for example, the rock-tombs, &c., of Petra have been excavated. These substances, in the author's opinion, may be traced as far as Medina, and occur all about Kasîm. They often weather in a singular way; pebbles are scarce in them; fossils he had not seen. (*b*) The limestone contains bands of flint, and appears to be identical with that which occurs in Palestine, and is, he thinks, probably of Cretaceous age. (*c*) Of much later date is a coarse flat gravel which overspreads a considerable tract of country, as, for example, at Mount Seir in Edom, altogether about 250 square miles. The flints are doubtless derived from the limestone, and are often polished by drifting sand. It occurs on plateaux at very considerable elevations above the sea, sometimes forming the highest ground in the neighbourhood; and sections had shown this gravel to be more than 20 feet deep. In it the author had discovered two or three flint weapons of palæolithic type, rude, but very like those of Hoxne or St. Acheul. The granite by its aspect and mode of occurrence recalls that of Sinai. It is cut by dykes of basalt; and now and then the author had observed other intrusive igneous rocks, which he must be content to classify as traps. The dykes of basalt, however, were not the only modes of occurrence of this rock; there were considerable flows of basaltic lavas and occasional small craters. These volcanic districts bear the name of Harra; the principal are the Aneyrid, the Khaybar, and the Kesshub. The last lies between Nejd Arabia and the Mecca country. These masses of lava, &c., are comparatively modern; eruption, indeed, has in one or two localities occurred in historic times, and steam has been seen to issue from certain craters.

Physical Society, January 26.—Prof. Clifton in the chair.—New member, Yung Free, Secretary of the Chinese Legation.—Prof. Clifton announced that Lady Siemens had presented a portion of the late Sir William Siemens's library to the Society.—The meeting, which was at first a special meeting to consider the resolution that it is expedient for the past presidents of the Society to be permanent vice-presidents, having agreed to this resolution, was constituted an ordinary meeting, and Professors Ayrton and Perry described and exhibited their new ammeters and voltmeters, also a non-sparking key. The well-known ammeters and voltmeters of the authors used for electric light work are now constructed so as to dispense with a constant, and give the readings in amperes and volts without calculation. This is effected by constructing the instruments so that there is a falling off in the controlling magnetic field, and a considerable increase in the deflecting magnetic field. The deflections are thus made proportional to the current or E.M.F. measured. The ingenious device of a core or soft iron pole piece adjustable between the poles of the horseshoe magnet is used for this purpose. By means of an ammeter and voltmeter used conjointly, the resistance of part of a circuit, say a lamp or heated wire, can be got by Ohm's law. Professors Ayrton and Perry's non-sparking key is designed to prevent sparking with large currents. It acts by introducing a series of resistance-coils determined experimentally one after the other in circuit, thereby cutting off the spark.—Dr. C. R. Alder Wright, F.R.S., read a paper on the electromotive force set up during interdiffusion, being the result of experiments made by himself and Mr. C. Thompson to determine the effect of varying densities of solutions used in voltaic cells on their E.M.F.'s. The observations were made by constructing the cells of pure materials and opposing them so that the differential E.M.F.'s could be measured by galvanometer or quadrant electrometer, when solutions of different densities were employed. The following general conclusions were reached: (1) In any two fluid cells containing solutions of two metallic salts and plates of the respective metals contained therein, an increase of strength in the solution surrounding the plate acquiring the higher potential in virtue of the normal action of the cell causes an increment in the potential difference between the two plates; and the opposite effect is produced by an increment in the strength of the solution surrounding the other plate. (2) A law of summation holds, expressible thus: the effect of the sum of a series of changes in the strengths of the solutions in a two-fluid cell is equal to the algebraic sum of the effects of each change severally. The author considered this law very fully; and pointed out that "diffusion cells" act at least partly after the fashion of thermo-couples transforming into electric energy a certain amount of sensible heat.

Anthropological Institute, January 22.—Anniversary meeting.—Prof. Flower, F.R.S., president, in the chair.—The following gentlemen were elected officers and Council for the year 1884:—President: Prof. W. H. Flower, F.R.S.; vice-presidents: Hyde Clarke, John Evans, F.R.S., Francis Galton, F.R.S., Lieut.-Col. H. H. Godwin-Austen, F.R.S., Major-General Pitt-Rivers, F.R.S., E. B. Tylor, F.R.S.; director: F. W. Rudler, F.G.S.; treasurer: F. G. H. Price, F.S.A.; Council: J. Beddoe, F.R.S., S. E. B. Bouverie-Pusey, E. W. Brabrook, F.S.A., C. H. E. Carmichael, M.A., W. L. Distant, C. I. Elton, B.A., A. W. Franks, F.R.S., J. G. Garson, M.D., Prof. Huxley, F.R.S., Prof. A. H. Keane, B.A., A. L. Lewis, Sir J. Lubbock, Bart., M.P., R. Biddulph Martin, M.P., Henry Muirhead, M.D., J. E. Price, F.S.A., Lord Arthur Russell, M.P., Prof. G. D. Thane, A. Thomson, F.R.S., Alfred Tylor, F.G.S., M. J. Walhouse, F.R.A.S.—The President delivered an address on the aims and prospects of the study of anthropology, which we gave last week.

Edinburgh

Royal Society, January 21.—Robert Grey, vice-president, in the chair.—Prof. Crum Brown communicated a paper on distant vision, by Dr. Maddox. Dr. Maddox finds that accommodation for a distant object in the case of most persons is naturally connected with a slight convergence of the optic axes, so that the intersection of the optic axes is nearer than the object looked at. At a certain distance, different in different persons, and probably varying in the same person from time to time, the optic axes naturally converge at the distance focused for. When a nearer object is looked at, the point of intersection of the optic axes is beyond the object. In ordinary vision these differences between the distance of convergence and of accommodation are not observed, because the effort for single vision easily overcomes them, and forces the optic axes into the portion corresponding to the accommodation.—Mr. John Aitken read a paper on the dark plane in dusty air, a full report of which was given in our last issue.—Mr. Aitken also read a note on the recent sunsets.

Cambridge

Philosophical Society, January 28.—On the microscopic structure of a boulder from the Cambridge Greensand found near Ashwell, Herts, by Prof. Bonney.—On critical or apparently neutral equilibrium, a note on Mr. Greenhill's paper, *Camb. Phil. Proc.*, 1883, by Mr. J. Larmor.—On the normal vibrations of a thin isotropic shell, bounded by confocal spheroids, by Mr. W. J. Ibbetson.—On the isochromatic curves of polarised light seen in a uniaxial crystal cut at right angles to the optic surface, by Mr. C. Spurge.—Tables of the number of numbers less than n and prime to it, and of the sum of the divisors of n, and the corresponding inverse tables up to $n = 3000$, by Mr. J. W. L. Glaisher.

Paris

Academy of Sciences, January 21.—M. Rolland in the chair.—Reflections on M. P. Bert's last communication regarding his new method of anæsthesis in surgical operations, by M. Gosselin. Although somewhat inconvenient in practice, the author still considers that the innovation presents certain advantages, while supplying a fresh argument to those who recommend moderate and progressive inhalation, rather than a large dose administered all at once. In his reply M. Bert submits that the objections raised to his method on the ground of the cumbrous nature of the apparatus are greatly exaggerated in the case of public hospitals. He further urges that it appears to be the only process in which surgeons are relieved of all personal responsibility in administering anæsthetics.—On the preparation in large quantities of artificial virus (bacilli of splenetic blood) attenuated by rapid heating (continued), by M. A. Chauveau. Here the author explains the conditions essential to the successful performance of this important and difficult operation. The subject is treated at length under the following heads:—(1) on the degree of heat required for the complete attenuation of the artificial virus; (2) on the heating process; (3) on the practical value of this system of prophylactic inoculation.—Extract from a letter by Baron Nordenskjöld on the remarkable optical effects observed during the last two months at sunset and sunrise in Sweden, presented by M. Danbrée. The author suggests that the phenomenon cannot be attributed exclusively to the dust discharged during the recent eruptions in Sunda Strait. Small particles of dust contained in the snow which fell near Stockholm at the end of last December were found on analysis to contain a considerable quantity of carboniferous matter, which burnt in the dry state with a flame, and left a reddish residuum containing oxidised iron, silica, phosphorus, and as much as 0·5 per cent. of cobalt and nickel.—Observations of the Pons-Brooks comet made at the Brunner 6-inch equatorial (0·160m.), Observatory of Lyons (continued, by M. F. Gonnessiat.—On the multipliers of linear differential equations, by M. Halphen.—On the approximate values assumed by an integral polynome when the variable quantity varies within definite limits, by M. Laguerre.—Note on the shading of a sphere, by M. J. Cotillon. The author here attempts a reproduction of the shaded sphere traditionally said to have been constructed at the École Polytechnique on the theoretical indications supplied by Monge.—On the electric conductibility of greatly diluted saline solutions, by M. E. Bouty. M. Berthelot, who insists on the importance of the results obtained by M. Bouty, points out that, according to the new law established by his numerous experiments, the electric resistance of greatly diluted solutions is determined, not by the atomic weight, but by the chemical equivalent of the bodies.—On the repulsion of two consecutive portions of the same electric current, by M. Izarn.—On the development of the nacreous crystals of sulphur, by M. D. Gernez.—Determination of the equivalent of chromium by means of the sesquioxide of its sulphate, by M. H. Baubigny.—Telegraphic despatch regarding the liquefaction of hydrogen addressed to M. Debray by M. Wroblewski. On this communication, which was worded: "Hydrogen cooled by boiling oxygen has been liquefied by expansion," M. Debray offers some remarks, and shows how it entirely confirms the remarkable observations made by M. Cailletet on the expansion of hydrogen.—On the products of reduction of erythrite by formic acid, by M. A. Henninger.—On an aromatic diacetone, by M. E. Louïse.—Quantitative analysis of the moisture of amylaceous substances (starch, fecula, &c.), by M. L. Bondonneau.—On the classification of the plumicole Sarcoptidæ (sub-family of the Analgesinæ), by MM. E. L. Trouessart and P. Mégnin.—On the Cipolino marble of Paclais, Loire-Inférieure, by M. Stan. Meunier. From a careful study of this remarkable calcareous formation the author considers that even more than the blue marble of Antrim it may be regarded as a type of metamorphic rock by contact.—On the nature of the deposits observed in the water of contaminated wells, by M. E. Gautrelet. To the organisms examined under the microscope the author gives the name of *Stercogona tetrastoma*, and for several reasons concludes that they are the true typhic microbe.—On the remarkable atmospheric disturbances produced by the Krakatoa eruption, by M. E. Renou.—On the twilight effects observed on December 27 on the summit of the Puy de Dôme, by M. Alluard.—The recent remarkable sunsets and sunrises compared with those observed in various parts of Europe during the summer of 1831, by M. A. Angot.

January 28.—M. Rolland in the chair.—Spectral study of the group of telluric bands in the brightest regions of the solar spectrum, which were discovered by Brewster and collectively called α by Angström, one illustration, by M. A. Cornu. A protracted study of the bandlets of lines in this mysterious α band has suggested a practical method for distinguishing by simple inspection the lines of telluric from those of solar origin. It has also enabled the author to establish the intimate relation between this group and the A and B Fraunhofer bands, while the origin of the group itself must be referred to absorption by the oxygen of the air.—Remarks on Faraday's electrochemical law in connection with the law discovered by M. Bouty regarding the conductibility of greatly diluted saline solutions, by M. Wurtz.—On the atmospheric disturbances attributed to the Krakatoa eruption, and on the storm of January 26, by M. C. Wolf. The storm was announced the day before by great oscillations of the magnetic curves, especially those of the declinometer. The most remarkable feature attending it was its sudden cessation about one o'clock a.m. when the velocity of the gale fell at once from 38m. to 12m. per second.—On the physical disturbances that have taken place during the last few months, by M. Faye.—On the period of most frequent occurrence of solar spots in recent times, according to the data supplied by M. R. Wolf of Zurich, by M. Faye. The maximum (424) seems to have been reached during the first six months of 1882.—Remarks on the official topographic chart of Algeria, scale 1 : 50,000, the first twelve sheets of which have been presented to the Academy, by M. F. Perrier.—On the employment of titrate mixtures of anæsthetic vapours and air in the administration of chloroform, by M. Richet.—Note on the dissemination, assimilation, and determination of phosphoric acid in arable lands, by M. P. de Gasparin.—On the mean movement of the first satellite of Saturn (Mimas), based on ninety-one observations made at Toulouse since October 24, 1876, by M. B. Baillaud.—Observation of the Pons-Brooks comet made at the Observatory of Meudon (one illustration), by M. E. L. L. de Saint Martin.—Researches on abnormal menstrual discharges, by M. J. Rouvier.—On the barometric disturbances produced by the Krakatoa eruption (second note), by M. E. Renou.—On the barometric disturbances observed on August 27, 1883, at Montsouris, by M. Marié-Davy.—On the causes (1) of the production of atmospheric electricity in general; (2) of electricity in thunderstorms; (3) of electricity of sheet-lightning, by M. G. le Goarant de Tromelin.—On an auroral and crepuscular display of light observed at the island of Réunion, in the Indian Ocean, on September 8, 1883, by M. Pélagaud.

BERLIN

Physiological Society, January 11.—Prof. Kossel discussed the methods which had hitherto been adopted in order to become acquainted with the transformations of nitrogenous substances in the animal body in the course of their passage from the well-known starting point, the albumen, to the likewise well-known final products, urea, uric acid, and creatine. The way which, in the opinion of the speaker, was most likely to lead to good results was to seek in the tissues the chemical combinations which, in accordance with their composition, stood midway between the albumen and its final products. In relation to this point, the analyses of nitrogenous substances occurring in the animal body had already yielded some definite data to work on. The proportion of carbon to nitrogen (C : N) had, namely, been found to be, in the albumen, 100 : 30; in urea, 100 : 233; in creatine, 100 : 66; in hypoxanthine and xanthine, 100 : 93; and in guanine, 100 : 116. It appeared evident, therefore, that the substances creatine, hypoxanthine, xanthine, and guanine were mediate products in the process of the transmutation of the albumen, with the discovery of which in the tissues Prof. Kossel had been busied. The bases hypoxanthine, xanthine, and guanine were not found in an isolated state in the tissues, but compounded with albumen and phosphoric acid into the complicate molecule, nuclein, a subject to which the speaker had devoted searching inquiry. There were different forms of nuclein which varied probably according to the share the bases had in their composition. All of them, however, agreed in having common reactions. Nuclein had already, by its discoverer, been brought into close relationship with the cell-nucleus, and it would be of great consequence if it could be conclusively proved that the cell-nucleus consisted exclusively of nuclein, as in that case the changes of the cell-nucleus occurring under different physiological conditions would be accompanied by chemically demonstrable quantitative changes in this nuclein substance. The quantitative analysis of the nuclein could, namely, be worked out by determining the xanthine or guanine bases. In this case, however, it was necessary to ascertain beforehand that the tissue examined contained no free xanthine or guanine besides the nuclein. A second method for determining the quantitative nuclein was through determining the amount of phosphoric acid in the composition. Phosphoric acid occurred in the body in three different combinations, namely, as inorganic phosphoric salt, in lecithin, and in nuclein. Inorganic phosphoric acid was to be extracted by diluted acids, lecithinic phosphoric acid by hot alcohol. The phosphoric acid then remaining would belong to the nuclein, and could serve for its quantitative determination. Prof. Kossel had now ascertained that the blood of mammalia contained no nuclein, while on the other hand the blood of birds did. The muscles contained little nuclein, the brain somewhat more; still more was found in the liver, and most of all in the spleen. In all these successive cases the nuclein substance kept about equal pace with the presence of cell-nucleus. Nuclein was also, however, to be met with in substances which contained no cell-nucleus; in the yolk, for example, and in the milk. Possibly in this case there might be chemical proof of granules without their having come morphologically to view. In pathological processes, by which cell-nucleus becomes excessively developed in tissues which otherwise contained no cell-nucleus, as was the case in leucæmia or sarcomatous tumours in the muscles, Prof. Kossel had invariably found an increase of nuclein in corresponding quantities.—Dr. W. Wolff explained some microscopical preparations which he had set up in the demonstrating hall. In one of these preparations was seen a stage in the development of the nerves in the tail of the larva of a frog. These nerves consisted of primitive fibres ramifying as far as the finest fibrelets. At a farther stage cells were seen attaching themselves to these at the thicker parts. Next appeared the nerve-sheath, and finally the marrow. Other preparations demonstrated the growth of the bones of frogs which took place only at the periosteum and at the ends of the diaphyses. By treatment with chromic acid and with two different aniline colours, Dr. Wolff had stained the cartilages a beautiful blue, and the osseous tissue red, and was therefore able readily to follow the development of the latter.

MR. RUSKIN'S BOGIES

PROFESSOR RUSKIN'S utterances are perhaps to be taken least seriously when he is himself most serious, and probably he was never more in earnest than in his jeremiad on modern clouds, delivered at the London Institution on the 4th and 11th inst. Probably none of the readers of NATURE have been terrified by the storm cloud of the nineteenth century, but should it be otherwise we hasten at once to their relief. Twenty years before the date fixed by Mr. Ruskin for the first appearance of his portentous "plague-cloud," the writer of the present article commenced a series of observations on the forms and structures of clouds, followed a few years later by such daily charts of wind and weather as could be constructed from the data, somewhat meagre, that were then accessible. As might be expected, cyclone and anticyclone were then as they are now. The dimensions and densities of the cloud layers have not altered, neither has our moral degeneracy nor the increased smoke of our manufacturing towns developed any new form of cloud. Neither (until the phenomenal sunrises and sunsets of the last three months) has Nature, in painting the clouds, employed upon her palette any fresh tints, whatever artists may have done. Further, we have not observed, nor met with any one, except Mr. Ruskin, who has observed, that the wind during the last thirteen years has adopted a "hissing" instead of a "wailing" tone, or that the pressure anemometer indicates that the motion of the air has become more tremulous than heretofore.

Admiration ought ungrudgingly to be bestowed on one who has done good service as an art critic and as a contributor to English literature. The sympathy, moreover, which, denied to those who are in advance of their age, is naturally accorded to the archaic type of mind, is enhanced by the attractiveness of a personality whose idealism is as lofty as that of Mr. Ruskin. But we maintain that there is a further sentiment which contributed to the applause which Mr. Ruskin's audiences bestowed upon him. Speaking generally, "broadly and comfortably," as he would say, Mr. Ruskin is not a representative man, yet he represents a certain spirit of Philistinism (for it merits this name), which is far from being unpopular, and which shows itself in opposition to scientific culture. He is the spokesman of that mental attitude which misinterprets the province of science and affects to misunderstand the plainest utterances of the physicist. "The first business," he says, "of scientific men is to tell you things that happen, as, that if you warm water it will boil." "The second and far more important business is to tell you what you had best do under the circumstances —put the kettle on in time for tea." "But if beyond this safe and beneficial business they ever try and explain anything to you, you may be confident of one of two things—either that they know nothing (to speak of) about it, or that they have only seen one side of it, and not only have not seen, but usually have no mind to see, the other. When, for instance, Prof. Tyndall explains the twisted beds of the Jungfrau to you by intimating that the Matterhorn is growing flat, or the clouds on the lee side of the Matterhorn by the winds rubbing against the windward side of it, you may be pretty sure the scientific people do not know much (to speak of) yet either about the rock beds or the cloud beds. And even if the explanation, so to call it, be sound on one side, windward or lee, you may, as I said, be nearly certain it will not do on the other. Take the very top and centre of scientific interpretation by the greatest of its masters. Newton explained to you—or at least was supposed to have explained—why an apple fell [*sic*], but he never thought of explaining the exactly correlative but infinitely more difficult question how the apple got up there." One would have supposed that even the lecturer must be aware that modern science is at least as much occupied with the last as with the first of these problems. Mr. Ruskin has not yet done with Prof. Tyndall;—in other words, he can nowhere suppress his dislike of scientific thought. "When I try to find anything firm to depend on, I am stopped by the quite frightful inaccuracy of the scientific people's terms, which is the consequence of their always trying to write Latin-English, and so losing the grace of the one and the sense of the other." "I am stopped dead because the scientific people use undulation and vibration as synonyms. 'When,' said Prof. Tyndall, 'we are told that the atoms of the sun vibrate at different rates, and produce waves of different sizes, your experience of water waves will enable you to form a tolerably clear notion of what is meant.' 'Tolerably clear,' your toleration must be considerable then. Do you suppose a water wave is like a harp string? Vibration is the movement of the body in a state of tension, undulation that of a body absolutely lax. In vibration not an atom of the body changes its place in relation to another; in undulation not an atom of the body remains in the same place with regard to another. In vibration every particle of the body ignores gravitation or defies it; in undulation every particle of the body is slavishly submitted to it." And more of the same sort. We should not weary the reader with these quotations were it not too true that much of the poetry which Mr. Ruskin adores, and much of the art of which he is the apostle—not a little in short of the poetry and art of our day—are full of this anti-scientific Philistinism, whose ideal is ever in harsh contrast to the real, and which from its antagonism to the facts of Nature is the great producer of bogies. One has only to go through any picture exhibition to see plenty of those clouds which Mr. Ruskin persuades himself occur in Nature, which, "irrespective of all supervening colours from the sun," are intrinsically "white, brown, grey, or black"; "argent or sable, baptised in white, or hooded in blackness."

We recommend those who sympathise with Mr. Ruskin to study some of those little books which are beginning to be the delight of our children. Such readers may never attain the scientific spirit, yet they may possibly catch a few chords of that great song in which there is complete harmony between the Universe of Nature and that of poetic and artistic sentiment, whose faint beginnings will alone be heard in this plague-stricken century.

Against cloud-classification the stars in their courses have hitherto fought, and Mr. Ruskin in his continues the battle. Grievous are the wounds which he inflicts

Let us see how he heals them. "Every cloud is primarily definable—'visible vapour of water, floating at a certain height in the air.'" It is thus distinguished from that "form of watery vapour" which "exists just as widely and generally at the bottom of the air as the clouds do on what for convenience' sake we may call the top of it." Mr. Ruskin hopelessly confuses vapour with water-dust, and this confusion leads him into some amusing difficulties. He asks whether it is "with cloud vapour as with most other things, that are seen when they are there, and not seen when they are not there, or has cloud vapour so much of the ghost in it that it can be visible or invisible as it likes, and might, perhaps, be all unpleasantly and malignantly there just as much when they did not see it as when they did?" To this he answers "comfortably and generally" that "on the whole a cloud is where we see it, and not where we do not see it," and that we must not allow the scientific people to tell us that rain is everywhere, but palpable in one place, impalpable in another. He presently returns to his point. He has defined a floating or sky cloud, and defined the falling or earth cloud (which by the way had been altogether excluded by his first definition from his category of clouds). "But there is a sort of thing between the two which needs another sort of definition, namely, mist." The definition of this intermediate substance, however, Mr. Ruskin does not supply, being content with asking what difference there is between clear and muddy vapour. This division of clouds has at least the merit of brevity, although it is subsequently complicated by a further division into "two sorts of clouds, one either stationary or slow in motion, reflecting unresolved light, the other fast-flying and transmitting resolved light. [Really, clouds at a distance and clouds overhead.] As regards the difference in the nature of these, Mr. Ruskin merely "hints to us his suspicion that the prismatic cloud is of finely comminuted water or ice, instead of aqueous vapour";—it is difficult to understand what he supposes the former kind of cloud to be composed of.

During the forty years previous to 1871, according to the certificate of Mr. Ruskin, the clouds, thus divided and cross-divided, appear to have behaved themselves in a peaceable and orderly manner. Even the "thunder-cumulus" (English-Latin, by the way) did "its mighty work in its own hour and in its own dominions, not snatching from you for an instant or defiling with a stain the abiding blue of the transcendent sky, or the fretted silver of its passionless clouds." We may remark that these "good, old-fashioned, healthy storms" frequently had rather extensive dominions: *e.g.* on August 13, 1857, one of these storms was simultaneously felt over many thousand square miles, and extended from the Land's End to John o' Groat's, besides covering a very extensive district on the north-western parts of the European continent. The deportment of the great bogy meteor, "storm-cloud or more accurately plague-cloud," of the nineteenth century is exceedingly different. From one part of Mr. Ruskin's description of this phenomenon we imagined that he might allude to the sheet of stratus commonly occurring in winter anti-cyclones, a sheet which occasionally covers upwards of 60,000 square miles, with scarcely a rift in its surface, the greatest vertical thickness of the cloud being only 300 or 400 feet. But this illusion was soon dispelled. For we find that "in the plague-wind the sun is choked out of the whole of heaven all day long by a cloud which might be a thousand miles square and five miles deep." One would scarcely have expected so dense a cloud mass merely to turn the sun red, but Mr. Ruskin is angry with it for not doing so: "That thin, scraggy, filthy, mangey, miserable cloud, for all the depth of it, could not turn the sun red as a good business-like fog did with a hundred feet or so of itself." Further, it is accompanied by a terrible wind by which "every breath of air is polluted half round the world" [*sic*]. Mr. Ruskin omitted to mention the effects of this plague-wind on agricultural or vital statistics. "It is a wind of darkness," also "a malignant wind." Further, "it always blows tremulously, making the leaves of the trees shudder as if they were all aspens but with a peculiar fitfulness which gives them an expression of anger as well as of fear and distress." Further, "it pollutes as well as intensifies the violence of all natural and necessary storms." Here again some explanation is sorely needed, since we should much like to know whether during the plague-wind barometric gradients become steeper, or whether the force of the wind in relation to the gradient is greater than usual.

Enough for the present of such bogies; although we fear that we have by no means done with them until our literary men will master the simplest elementary primers. But not enough of Mr. Ruskin, whom we could ill spare. His English is often delicious; always in his most dyspeptic diatribes amusing. And we can all appreciate his concluding advice that we should "bring back our own cheerfulness and our own honesty; and cease from the troubling of our own passions," and (not least we think of all) "the insolence of our own lips." A good recipe: add a dash of humility and of respect for the opinions of wiser men;—and all may yet be well, even though our return to the paths of rectitude should fail to dissolve the "mangey" clouds, and quench the fevered wind of a storm-harried and woe-worn era.

W. CLEMENT LEY

Ethic. By Benedict de Spinoza. Translated from the Latin by William Hale White. (London: Trübner and Co., 1883.)

IF proof were requisite that the standard of value in philosophy is different from that which obtains in the estimation of scientific research, it would only be necessary to point to the case of Spinoza. There is probably no thinker of the nature of whose work there obtain conceptions more hopelessly irreconcilable; there is certainly none about whose position there is more general unanimity. To refer to the more recent of his English critics, Prof. Caird and Mr. Frederick Pollock are at one in assigning to Spinoza most important functions in the development of philosophical inquiry. Yet there is scarcely a single point in his system as to which their respective interpretations are not mutually exclusive. But as regards the broad feature which makes Spinozism deeply interesting to students of science in the strict sense there can be no doubt. The application of the method of geometry to philosophical problems finds its counterpart in the prevailing, and apparently by no means diminishing, disposition to bring certain questions of metaphysics within the scope of scientific inquiry. That any one should have rejected the current method of metaphysics in favour of a geometrical investigation into the nature of God and existence, cannot be otherwise than significant to persons who seek to determine the psychological problem of the nature of consciousness by physiological means. Hence it is that there are some students who think that, if any philosophy were possible, it were that of Spinoza, and others who say that in the work of Mr. Spencer and Prof. Clifford they find the inheritance which Spinoza left behind him.

Mr. Hale White has done his difficult work well. The translation is executed with great care, and the style of the original has been reproduced with some success. That English readers of Spinoza have entertained very loose notions of his real teaching has been due in no small measure to the very inaccurate translation which has hitherto passed current. The present volume should do much to improve the popular conception of Spinoza's system.

At the risk of repetition of what has already been insisted on in these columns, it is right to contrast the position of the naturalists who accept Spinoza's application of scientific methods to metaphysical questions, with the procedure of Kant and those who are currently described as Neo-Kantians. It is the more desirable to revert to this topic because, although there is much complaint that the Neo-Kantians do little (if anything) more than repeat Kant's criticism of the naturalist (or, as he would have described it, dogmatic) doctrine, there is but little evidence that this criticism has been considered, much less met. People go on reasoning upon the old lines about the relation of mind to body and of God to the world as if Kant (to borrow a phrase from another branch of learning) had never obtained a rule calling upon them to show cause why there should not be a new trial of all such questions. It cannot be sufficiently borne in mind that at the present time there are only two courses open in this reference to conscientious thinkers. Either they must abstain altogether from the discussion of an increasing number of problems which are suggested by scientific inquiry, or they must be at the pains, however irksome, to master the nature of the sceptical doubts which Kant brought to bear upon the possibility of these problems. And it may be added that to single them out for elimination is not so easy a task as might be supposed. Probably the real reason why the study of Spinoza's ethics is attended with so much difficulty is that the extraordinary instinct which guides men of the highest genius in inquiries in new and unknown regions raised doubts in his mind which the investigations of Kant subsequently exhibited as the consequences of a more profoundly sceptical point of view. That difficulties arise when men reflect upon the nature of God was for Spinoza, as for Kant, due to the impossibility of reasoning on such matters as if they were ordinary facts of experience. In Spinozism the geometrical method culminated in the abrupt cessation of thought of this kind, just as in Hume empiricism ended in the paralysis of speculation. Had Spinoza pressed his distinction between different kinds of knowledge further, his system must have become in a greater or less degree sceptical in its tendencies—sceptical in the sense in which Kant was sceptical as a preliminary to reconstruction, or in which, to take the case of a very recent scientific writer, the late Prof. Clifford was a sceptic when he completed his analysis of experience with his theory of ejects. The difference between the three cases is that Kant clearly saw the origin and nature of the difficulties raised by himself, and made the inquiry the preliminary to a radically different discussion of the issues raised in philosophy and science alike. It were well if the fact were less left out of account that the rule obtained by Kant for a new trial of these issues has never yet been discharged.

R. B. HALDANE

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

The Krakatoa Eruption

THE Council of the Royal Society has appointed a Committee for the purpose of collecting the various accounts of the volcanic eruption at Krakatoa, and attendant phenomena in such form as shall best provide for their preservation and promote their usefulness.

The Committee invite the communication of authenticated facts respecting the fall of pumice and of dust, the position and extent of floating pumice, the date of exceptional quantities of pumice reaching various shores, observations of unusual disturbances of barometric pressure and of sea-level, the presence of sulphurous vapours, the distances at which the explosions were heard, and exceptional effects of light and colour in the atmosphere.

The Committee will be glad to receive also copies of published papers, articles, and letters bearing upon the subject.

Correspondents are requested to be very particular in giving the date, exact time (stating whether Greenwich or local), and position whence all recorded facts were observed. The greatest practicable precision in all these respects is essential.

All communications are to be addressed to

G. J. SYMONS,
Chairman Krakatoa Committee
Royal Society, Burlington House, W., February 12

The Remarkable Sunsets

THE following facts in reference to the unusual sunsets, as witnessed in the United States, will I hope be of sufficient value to your readers to justify an insertion in the pages of NATURE.

The place from which I write is 1063 feet above sea-level, 40° 48′ 47″ N. lat. and 81° 53′ 37″ W. long. from Greenwich. The main features of the exhibition here have been the crimson glow—the first and after-glow, with other accompanying colours, closely corresponding with those in England and Europe. Hence I need not occupy your pages with a special description.

I have on record seven cases, nearly all the weather would permit one to see. These occurred on November 27, December 9, 10, 25, and 28, and on January 13 and 17.

The first and second glow have extended in two or three instances, though faintly, to the zenith, and the first has occasionally been reflected on the eastern sky. On December 28, the most brilliant exhibition in the series, an arch was formed in the east, the colours red and yellowish green, very soft, and much blended. The crimson glow on the sky flooded the western sides of buildings with an unearthly light, and cast faint shadows across the snow. The appearance of the after-glow, when the sun had reached a certain angle in its decline, favours the view that it is a reflection of the first. If this be true, it is not necessary to admit so great an elevation of the reflecting matter above the earth, and thus removes a serious difficulty in explaining the glow by known causes.

In no case here has the sun during the day or at setting appeared green. On December 28 and January 13 Venus has appeared a beautiful green through the complementary crimson. This fact became important only when it was discovered that the green remained after the crimson had disappeared. The light of the planet was struggling through some medium invisible to the eye, but which arrested the other colours.

Another important point. The glow has been seen without the slightest trace of cirrus clouds behind it. Three times faint ribbon-like stripes of cirri appeared in the first glow, but in the second the gorgeous crimson has generally been projected against the clear blue sky.

The writer has seen no notice of observations on the appearance of the sun and sky during the day, and especially the afternoon, before the brilliant sunsets.

The peculiar appearance of the atmosphere in the vicinity of the sun attracted his attention on the day the first remarkable sun glow occurred. The sky was perfectly clear except around the sun, which was embedded in a soft haze that extended out some 6° or 8° on every side. Yet a distant boundary could not be assigned to the haze, so gradually did it shade into the blue of the sky. The sun was obscured so that the eye could look at it for a moment and outline its disk. Covering the sun with the hand the haze adjacent glowed like a furnace, the light diminishing rapidly as the eye swept outwards.

Two or three remarks, naturally spring from this appearance. 1. The haze was not an ordinary cirrus cloud. It had no distinct bounding surfaces; it was invisible everywhere except near the sun. 2. There was, of course, no more of the matter forming the haze around the sun than elsewhere. 3. It was capable of reflecting intensely the light that fell upon it at a large incident angle, nearly 90°. 4. The reflection of light in a high degree by any substance at a large incidence would indicate a liquid. But the clearness of the sky showed the absence of condensed vapour. And yet there was something in the air around the sun—and no more there than anywhere else—which was then, some three hours farther east, flinging its gorgeous crimson over earth and sky, and which, three hours later, would drape the earth and sky of the observer in the same beautiful colours. And what was that something? That is doubtless the great question, and I can only echo, What was it? If the answer be "Vapour of water in some peculiar state," then it is wondrous strange that water, subject as it always has been to almost every conceivable change in the air, should rarely if ever before have assumed this peculiar state! Besides, the prevalence of this phenomenon around the globe, manifesting the same characteristics everywhere, requires some marked and probably unusual cause.

As to the volcanic theory, it has some good points. It gives an unusual explanation for an unusual occurrence.

It might be expected that a convulsion which would ingulf islands and mountains, and send the throbbings of ocean around the globe, would leave some tokens of its presence on the more sensitive air.

The difficulty of accounting for the suspension of solid particles for months in air of extreme rarity may be avoided by admitting the effects to be due mainly to gases ejected in the eruptions. Most of these being condensible by extreme cold would occupy definite strata and not rise to an extreme height.

The sinking of Krakatoa and the admission of sea water to the awful and fiery gulfs below, would, it seems, set free immense quantities of chlorine from the salt water. As this gas is readily absorbed by pure water it may have condensed around its molecules the vapour of the air, and thus become capable of reflecting the light in a higher degree.

Of course these are suppositions, consistent as far as we know with law; and they may stand among other probabilities till clearer light confirms or rejects them.

In a communication to NATURE, December 13, p. 149, Prof. C. Piazzi Smyth advances the idea that one of the conditions of the red sunsets was the *dryness* of the *lower atmosphere*. The hygrometric condition of the air here on the days the crimson sunsets were seen, is given in the following table, taken from the monthly reports of the writer to the U.S. Signal Office. The two columns give the mean temperature of the dry and wet bulb thermometers (F.) for three observations each day, at 7.32 a.m., 2.32 and 9.32 p.m.

Dates		Dry bulb	Wet bulb
November	27	29	26·8
December	5	40	38
,,	9	36·6	32
,,	10	36	33
,,	25	29·5	26
,,	28	23·6	22·2
January	13	37	33
,,	17	23·2	21·2

A mere inspection of the table shows that the dew point was high, and the percentage of possible moisture in the air quite large. Whether this weird and beautiful play of colours around the dying day is due to watery vapour in the air time will show; here it has certainly not been due to any *deficiency* in the vapour of the lower strata. O. N. STODDARD

Wooster, State of Ohio, United States, January 18

Unconscious Bias in Walking

THE following little experiment seems to show that if the majority of people are, as Mr. Darwin argues, left-legged, they would circle to the left in a mist, as Mr. Larden says they do. I would call myself normal, my left leg being the stronger. That is to say, like the majority, I jump from the left, rest my weight standing on the left (a glance at a photograph album shows this to be normal) and generally cross my right over my left whilst sitting. Having put myself in a dark empty room, I could not satisfy myself as to which way I circled, there not being space enough, but when I artificially lamed myself by putting a few tin tacks in my slipper, I circled strongly in the direction of the sound foot. From what had been said in NATURE on the subject at the time, I expected the for-the-time-being longer and stronger limb to circle round the other. The fact seems to be that there is a bias towards the stronger, most-leant-upon limb, irrespective of length. It is worth noting that, if the object causing pain be placed under the inside of, say, the right foot only, the experimenter will lean on the outside of that foot and circle to the right.

In the matter of left-leggedness I have requested several right-handed people to feign lameness. Every one of them has limped with the right foot; and, on being asked to do so, has found difficulty in imagining the left lame, and acting as if it were. May it not be because the right leg is somewhat weaker that canes are carried in the right hand?

But although left-leggedness *quâ* strength seems normal, the reverse seems to hold good *quâ* skill: one pushes a door to with the right, feels his way down a dark stair with the right, kicks a football with the right. A friend of mine, a skilful athlete, particularly known as a jumper, at first expressed astonishment that there should be any doubt as to the left leg being the stronger. On reflection he added: "I'm not sure, however; figures in skating are easier on the right." This nine figure-skaters out of ten will assent to. It is to be expected, if my theory is correct. The right leg is more easily controlled, guided, and kept in position—in a word, the more skilful limb; and at the same time the left being the better kicker, the impulse is better given.

It seems to me that mounting a horse from the near side is not a mere fashion (except for the left-handed minority). The stronger leg is put in the stirrup and gives the lift, whilst the more skilful leg is thrown over the animal's back.

It would be interesting to know which foot it is, if any in particular, which Indian servants use for prehensile purposes; also whether the higher quadrumana are right or left hind-handed.

I have noticed that persons walking in the street dwell longer on the one foot than on the other, and I remember once arguing that in-toed persons with a rolling gait were the only people who were not lame. I have been trying to observe this seriously for some days, and believe it to be so, but as the mind naturally invents a beginning and an end for a continuous motion it may be imagination. W. G. SIMPSON

The Ear a Barometer

THE phenomenon described by my friend Mr. Boys, on p. 333, is pathological, and not physiological. He is clearly suffering from slight obstruction of the Eustachian tube, a canal which leads from the inner side of the tympanic cavity into the posterior fauces. Its natural relief is, as he very accurately describes, by the act of swallowing, which temporarily distends the tube. He can test its perviousness by holding his nose with his fingers and forcing air into the nasal cavity. Physicians are in the habit of placing an ordinary stethoscope over the ear, causing the patient to go through the act of deglutition, and listening for the "click" of escaping air. Mr. Boys will see, as a physicist, that, if the access of air on either side of the tympanum were free, increase or decrease of atmospheric pressure would make no difference.

14, Dean's Yard, February 10 W. H. Stone

With regard to the letter of Mr. C. V. Boys in Nature of February 7 (p. 333), I should like to make a remark or two on the matter, in which I have had practical experience. I am in the habit of running between Rugby and London daily, and pass through six different tunnels on the route. The Leighton tunnel is divided into three parts, the down fast line being single, and the space between the rails and the walls of the tunnel very small. On entering this, if in the first three coaches next to the engine, a sudden expansion of the tympanum is felt. I have been led to account for this phenomenon as follows: The engine acting as a piston forces the air before it through the tunnel, and so causes a partial vacuum, which extends to the first three or four coaches. After that the air has had time to rush in and fill the empty space, and this explanation is rendered almost certain by the fact that at the end of the train of twelve or fourteen coaches no aural effects are observable, thus demonstrating that the sudden propulsion of the air through the tunnel is compensated for before the middle of the train has entered. In Kilsby tunnel nothing has been noticed by myself. I account for the pressure alteration in the above manner, the engine and the tunnel-mouth closely fitting, and so are fairly comparable to a piston within a cylinder. The effects decrease from the engine to the end of the train, and are practically unobservable in the last few coaches.

Rugby, February 9 George Rayleigh Vicars

Diffusion of Scientific Memoirs

Allow me a few final words on this curious case. I spoke of the *Trans. C. P. S.*, 1849-54, in which Stokes' papers were "buried," as "almost inaccessible." This expression was challenged by the ex-Secretary of the Society, and I replied that the question could be decided by statistics alone. I indicated what statistics were required, and waited some weeks for them. The present Secretary then gave me the less essential part of the desired information, and I proceeded to make the best I could of it. Now I am told that I misunderstood his object, and that he practically admits what his predecessor challenged.

I also stated that my copy of the *Proc.* was very imperfect, and that I had not received any *Trans.* I was then told that "publications" were given only on application. If so, I replied, I should have had all, or none. To this there is no answer. P. G. Tait

Coll. Edin., February 9

Wind Sand Ripples

Some time ago, whilst reading an account in Nature of very ingenious and interesting experiments by Prof. G. H. Darwin on sand ripples, my memory was recalled to some very beautiful sand ripples caused by the action of wind, seen by another person and myself on the west coast of Ireland, near Bundoran. The locality was a sand ridge twenty or thirty feet above high-water mark, and beyond the influence of either sea or river action; the ripples extended over a space of twenty yards or more. At the time there was a fresh breeze, with frequent squalls, blowing across this ridge. This ripples moved before the wind at the rate of about a foot in three or four minutes, but faster during the squalls, retaining all the time (I watched them an hour or more) perfect uniformity of shape and size. The distances were roughly measured by sticking up in the sand bits of wood at, as nearly as could be guessed, one foot apart, in a line with the direction of the wind. The ripples were about three inches from summit to summit, and the depth of trough three quarters of an inch.

The time was carefully noted with a watch. The forward movement of the ripples was evidently caused by the sand being drifted from their weather sides, and deposited on their lee, and thus there was a progressive movement to leeward, more or less rapid according to the increase or diminution of the wind force.

Animal Intelligence

The following anecdote, received the other day from Russia, may possibly interest your readers:—"The following was narrated to me by Mohl's brother, on whose estate it took place. The carcass of a cow was laid out in the woods to attract the wolves, and a spring-trap was set. Next morning the forester found there the track of a bear instead of a wolf on the snow; the trap was thrown to some distance. Evidently the bear had put his paw in the trap and had managed to jerk it off. The next night the forester hid himself within shot of the carcass to watch for the bear. The bear came, but first pulled down a stack of firewood cut into seven-foot lengths, selected a piece to his mind, and, taking it up in his arms, walked on his hind legs to the carcass. He then beat about in the snow all round the carcass with the log of wood before he began his meal. The forester put a ball in his head, which I almost regret, as such a sensible brute deserved to live." J. M. Hayward

Sidmouth, February 9

Circular Rainbow seen from a Hill-top

Climbing, several summers ago, with three friends among the Coolin Hills in Skye, I was fortunate enough to witness phenomena similar to those described by Mr. Fleming in last week's Nature (p. 310). Our shadows were apparently thrown against the precipitous side of a deep corry, distant 200 feet or perhaps more. They vanished and reappeared as thin mists passed through the corry, the sun shining continuously. We could not see each other's shadows unless close. The distance apart at which they became visible I do not clearly remember, but know it was approximately as one of my friends, Mr. W. A. Brown, writes:—"So long as we kept a few yards apart each could only see his own shadow, but when two were within arms' length a double shadow was visible to each, and on getting still nearer the shadows merged into each other." My estimate of the angle subtended by the diameter of the rainbow is 15°, that of my friend 10°. He adds, however, "I may be very far out in this." J. M. White

Spring Grove, Dundee, February 5

Referring to Mr. Fleming's letter in Nature of January 31 (p. 310), I would state that many years ago, before Pontresina, in the Grisons, was so resorted to as it is now, I walked up the Piz Languard early one fine morning with an old smuggler and chamois hunter—the terms are synonymous on the frontier—named Colani. On the summit of the peak is a ledge of rock, on which I lay down for twenty minutes' sleep. I had been asleep but a few minutes when Colani woke me, and, with excuses and an expression of fright on his face, begged me to come with him to see something which he had never seen in his life before. We moved to the western edge of the peak. Below us were some thin clouds of mist curling about like vapour from a large cauldron. On these clouds appeared a circular rainbow and within it, as though in a gilded frame, were two figures—in fact, the shadows of ourselves.

"There are two of them now," cried Colani, and it was not until I told him to take off his hat and wave it, as I did mine, and he saw the action repeated by the figures, that he began to feel assured they were not "Geists." It was not the "Arch St. Martin," a Romansch name for a rainbow, which had frightened him, though it was the first time he had seen a circular one, but the appearance of the dark solitary figure had awakened his conscience, for some of his smuggling adventures had not been without bloodshed. The details of the phenomenon were the same as those described by Mr. Fleming, with the exception, perhaps, that the figures were more vivid and the whole spectacle of longer duration, owing to an unclouded sun.

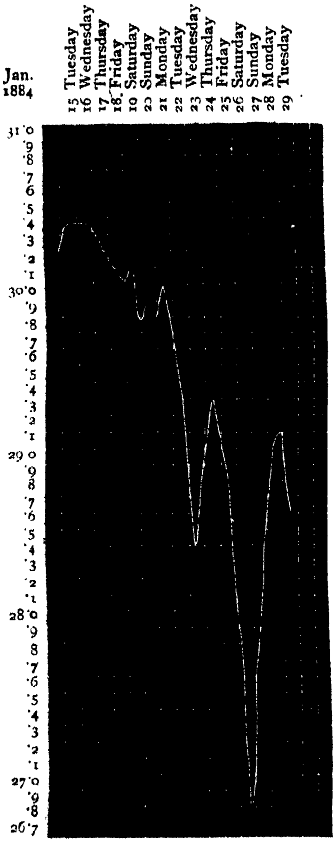
A similar appearance has lately been seen on the Tonjabe Range in Nevada, by Mr. R. A. Marr, of the Coast and Geodetic Survey. I subjoin his description of it, taken from a recent number of the *Mail*. T. R. Maynard

The Black Forest, February 7

"Suddenly, as I stood looking over the vast expanse beneath me, I saw myself confronted by a monster figure of a man standing in mid air before me, upon the top of a clearly-defined mountain peak, which had but the thin air of the valley below for a resting place. The figure was only a short distance from me. Around it were two circles of rainbow light and colour, the outer one faintly defined as compared with the inner one, which was bright and clear and distinctly iridescent. Around the head of the figure was a beautiful halo of light, and from the figure itself shot rays of colour normal to the body. The sight startled me more than I can now tell. I threw up my hands in astonishment, and perhaps some little fear, and at this moment the spectre seemed to move towards me. In a few moments I got over my fright, and then, after the figure had faded away, I recognised the fact that I had enjoyed one of the most wonderful phenomena of nature. Since then we have seen it once or twice from Jeff Davis Peak, but it never created such an impression upon me as it did that evening when I was doing service as a heliotroper all alone on the top of Arc Dome."

The Storm of January 26

DURING this storm there was a remarkable depression of the barometer, it falling to 26·9, as shown in the accompanying chart. The lowest depression last year was 28·2 on Nov. 25. Lurgybrack lies in lat. 54° 56′ N., and long. 7° 42′ W. It is 225 feet above the Ordnance datum level. A nearly similar depression was observed at Letterkenny, 140 feet above the Ordnance datum level. The wind veered round from the north-west by north and east to the south, and from the latter by west to north. The storm was succeeded by a fall of snow, which has now melted away.



G. HENRY KINAHAN

Lurgybrack, Letterkenny, Ireland, January 29

EARTHQUAKE DISTURBANCES OF THE TIDES ON THE COASTS OF INDIA

FOR some years past tidal stations have been established at various points on the coasts of India, from Kurrachee round *viâ* Cape Comorin and Adam's Straits to Calcutta, and on to Rangoon and Moulmein; also beyond these points, eastwards at Port Blair in the Andaman Islands, and westwards at Aden; but not anywhere in the Island of Ceylon, which happens—unfortunately for the interests of science—to be outside the administration of the Government of India. At each of the tidal stations an observatory has been established, containing a self-registering tide-gauge, and all requisite meteorological instruments, with a clerk in charge who tends the instruments, sets the driving clocks to true time—usually received telegraphically from Madras—and sends in daily reports to the supervising officer. That officer exercises a general superintendence over all the tidal stations, inspects them periodically, collates and analyses the observations, and deduces from them the values of the "tidal constants" for each port or point of observation; these constants enable future tides to be predicted, and tide tables to be prepared for the guidance of mariners; they are also otherwise valuable, in that they have thrown light on the question of the earth's rigidity, and on various other matters of scientific interest.

The operations have been carried on in connection with the Great Trigonometrical branch of the Survey of India. Major A. W. Baird, R.E., has been the supervising officer from their commencement in 1873 up to the present time, with the exception of an interval of a little more than a year, when he was on furlough in Europe, and Capt. J. Hill, R.E., first, and afterwards Major M. W. Rogers, R.E., officiated for him.

At certain of the Indian stations the registrations have twice indicated that the normal tides had been greatly disturbed by supertidal waves: first, on the occasion of the earthquake in the Bay of Bengal on December 31, 1881; and secondly, during the volcanic eruptions in the Island of Krakatoa, between Sumatra and Java, which occurred on August 27 and 28 last. The first disturbances do not appear as yet to have attracted much attention out of India; a full account of them is given in the General Report on the Operations of the Survey of India for 1881-82, and also in the *Proceedings of the Asiatic Society of Bengal* for March 1883. The second are now famous all the world over, not merely because of the havoc they are known to have produced on the spot and at the time, but also because of the effects they are believed to have produced on the condition of the atmosphere long afterwards and in far distant quarters of the globe. A report on the tidal disturbances at Indian stations which were caused by the eruptions at Krakatoa has been drawn up by Major Baird, and sent to me for communication to the Royal Society, and an abstract of it was read at the meeting of the Society on January 31.

I now propose to indicate certain points of similarity and others of dissimilarity between the recorded effects of the disturbing forces on the two occasions; for fuller details the reports themselves must be referred to.

The usual effect of an earthquake or volcanic eruption occurring at an island or under the bed of the sea is the transmission in all directions of an "earth-wave" and a "sea-wave"; the former travels with much greater rapidity than the latter, and may reach points which the latter does not reach; or it may die away and cease at points far short of those attained by the latter; which of the two will travel the greater distance depends generally on the structure and homogeneity of the strata through which the earth-wave is transmitted, and on the depth of water and configuration of the bottom over which the sea-wave passes.

On the occasion of the earthquake of December 31, 1881, the "centre of impulse" was situated under the bed of the ocean in the western portion of the Bay of Bengal; the shock of the earth-wave was very violent in the Andaman and Nicobar Islands, and along the entire length of the Madras coast up to Calcutta, and also far inland; it was followed by a succession of sea-waves which the tidal diagrams show to have arrived after the earth-wave, at an interval ranging from half an hour at Port Blair (in the Andamans), the nearest station, to six hours at Dublat (in Sangor Island at the mouth of the River Hooghly), the furthest station at which such waves were certainly registered. At Rangoon, Moulmein, and various points in the Mergui Archipelago, the earth-wave was distinctly perceptible, though its shock was here much less violent; but no trace of a sea-wave has been met with at any of the tidal stations in this quarter; the belt of islands and shoals which extends from Cape Negrais to the Island of Sumatra, practically dividing the Bay of Bengal into two portions, must have formed a barrier to the sea-waves, for though great and numerous at Port Blair, they died away in the deep sea beyond, and in no case reached the eastern coast line.

The position of the earthquake in the Bay of Bengal was necessarily not a matter of observation as at Krakatoa; but it has been inferred by Major Rogers from the following facts. The moment at which the shock of the earth-wave was felt happens to have been recorded with considerable accuracy at three places, two on the west coast of the Bay, viz. the Madras Astronomical Observatory and the tidal station at False Point; the third on the east coast, Kisseraing, a principal station of the Great Trigonometrical Survey, where Major Rogers was actually at the moment observing a distant station in the field of the telescope of his theodolite. He reports that "he saw the earthquake before feeling it," for he first became sensible of its occurrence by noticing the object which he was observing appear to rise and fall in the telescope; he immediately examined the spirit-levels of his instrument, found they were violently agitated, and made a note of the time. Subsequently he ascertained that the shock he felt and those recorded at Madras and False Point must have occurred almost simultaneously. due allowance being made for the differences of longitude, Therefore, assuming the earth-wave to have travelled from the centre of impulse with the same velocity in all directions, the centre would be near that of the triangle joining the three points of observation, but probably a little to the south, towards the line joining Port Blair and Negapatam, the stations at which the tidal disturbances were the greatest.

Having thus ascertained the probable position of the centre of impulse, Major Rogers proceeded to ascertain the probable time of the earthquake. Here again he was favoured by his facts. It so happened that his assistant, Mr. Rendell, had just completed an inspection of the tidal station at False Point, and was at work on a line of levels a few miles away, when he felt a violent shock of earthquake; he noted the time; the clerk at the station also felt the earthquake, and noted that the observatory was much shaken; afterwards it was found that at the time recorded by Mr. Rendell the pencil of the tide-gauge had been vibrating very sensibly on the diagram; the vibration must have been caused either by the shaking of the observatory, or by a forced sea-wave such as is sometimes produced momentarily in shallow waters by a passing earth-wave. The great sea-wave which was transmitted from the centre of impulse arrived 3 hours 18 minutes afterwards. Now there can be no question that the vibration mark on the diagram correctly registers the moment at which the earth-wave reached False Point; Major Rogers therefore conjectures, with much probability, that a similar very prominent vibration mark on the Port Blair diagram registers the moment of the arrival of the earth-wave at Port Blair; thirteen minutes after the time thus registered Major Rogers felt the earthquake at Kisseraing, and as the distance between the two points is 400 miles it may be inferred that the earth-wave travelled with a velocity of about 1800 miles an hour. With this velocity, the distance of the assumed centre of impulse from either of the three surrounding stations, and the time of the occurrence of the earth-wave at either station, Major Rogers calculates the time of the original disturbance when both the earth-wave and the sea wave were initiated. Comparing this time with that of the arrival of the sea-wave at his stations, he obtains the following velocities for the sea-wave: to Port Blair 360 miles an hour, to Madras and Negapatam 240, to False Point 180, and to Dublat 120. The average depth of the sea is known to diminish in every instance of diminished velocity.

The sea-wave here specifically referred to was the first and generally the greatest of the supertidal waves; its amplitude from trough to crest was a maximum, 36 inches, at Negapatam, and 30 inches at Port Blair; it was always positive, the crest preceding the trough and raising the sea-level. The latter point is to be specially noticed because the first result of the great eruption at Krakatoa was the reverse of this, namely, a negative wave or general lowering of the sea-level at the stations of observation, as will be shown more fully further on. Secondary sea-waves followed the first, disturbing the normal tides for some hours; their greatest duration was twenty-five hours at Port Blair, the nearest tidal station to the centre of impulse. A single earth-wave of a few seconds' duration is all that appears to have been perceived at the tidal stations; possibly, therefore, the whole of the tidal disturbances were due to a single earthquake.

Proceeding now to the eruptions at Krakatoa, we find that while there is no uncertainty as regards their locality, and there is evidence of one great eruption far exceeding all the others in violence, there is as yet no certain information of their number nor of the times at which any of them, even the greatest, occurred. No earth-waves appear to have reached India; but sea-waves of more or less magnitude were transmitted to all the tidal stations on both coasts of the peninsula, and not alone to those on the east coast, as on the former occasion; they were also transmitted far beyond, to Aden, the Mauritius, and the south-east coast of Africa, as shown in Major Baird's report. Lately it has been announced that traces of the sea-waves have been discovered at French tidal stations on both coasts of the Atlantic.

The principal facts set forth by Major Baird are the following:—

1. Distinct evidence of tidal disturbance was met with at twelve of the seventeen Indian tidal stations, including all which were fairly placed to receive the force of the impulse from Krakatoa; but, as in the previous instance, no disturbance was perceived at the stations on the east coast of the Bay of Bengal.

2. The first result of the great eruption at Krakatoa was a negative supertidal wave, or general fall of the sea-level, at Major Baird's stations and also at the Mauritius.

3. This negative wave was succeeded by a great positive wave, at an interval ranging from seventy-five minutes at Negapatam, the station nearest Krakatoa, to twenty-four minutes at Aden, the most distant station.

4. Supertidal waves of greater or less magnitude were registered at the Indian stations some hours before the negative wave of the great eruption, showing that there must have been antecedent minor eruptions. They appear at Aden about three hours before the negative wave, and eighteen hours before at Negapatam, showing that the explosions were at first comparatively feeble, affecting only the nearer stations; but afterwards they increased in intensity and became sensible even at Aden, a distance of over 4000 miles.

5. Waves of amplitudes ranging from a maximum of 22 inches at Negapatam to a maximum of 9 inches at Aden were registered at all the more favourably situated stations. The first was the positive wave immediately succeeding the primary negative wave, and it was generally of a greater amplitude than any other wave, but in a

few instances it was succeeded by greater waves. The succeeding waves maintained considerable amplitudes—not less than half the maxima values—for about twelve hours, appearing at intervals of one or two hours apart at all the more prominent stations. They were succeeded by wavelets gradually diminishing in size, but continuing for some time, being traceable on the diagrams for August 29 and 30, the second and third days after the great eruption. It is noticeable that they ceased first at Port Blair and Negapatam, the two nearest stations, and last at Aden, the farthest station.

6. Loud reports, resembling the firing of distant guns, were heard at Port Blair on August 26 and 27, and being supposed to be signals from a vessel in distress a steamer was sent out in search of the vessel; similar reports were heard on the 26th in Ceylon.

These facts show that the great eruption at Krakatoa was preceded by minor eruptions sufficiently powerful to produce effects which were sensible at a distance of upwards of 4000 miles; also that it was probably followed by minor eruptions, to the influence of which the long-protracted continuance of tidal disturbance is due.

The time at which the great eruption occurred is still not known with any precision. Major Baird has endeavoured to calculate it from the following data: he was informed by Her Majesty's Consul in Java that the first great (positive) wave reached Batavia at 12h. 10m. local time on the afternoon of August 27; as the distance from Krakatoa by sea is 105 miles, and the average depth of the sea about 186 feet, he infers from the table of the velocity of free tide waves passing over seas of different depths, in Sir George Airy's article on "Tides and Waves" in the *Encyclopedia Metropolitana*, that the wave must have taken about two hours to reach Batavia, and therefore that it must have started at 10.5 a.m. Krakatoa time, allowing five minutes for the difference of longitude. Another estimate has been recently furnished by General Strachey in a paper—read before the Royal Society—on the "Barometrical Disturbances which passed over Europe between August 27 and 31"; General Strachey connects these disturbances with the great eruption at Krakatoa, and infers, from the recorded evidence of the times of transit of the barometric waves over the European observatories, that the initial barometric rise occurred at 9h. 24m. Krakatoa time on the morning of August 27. Now we have seen that the first effect of the great eruption on the ocean was the production of a negative wave which preceded the great positive wave by an interval of seventy-five minutes at Negapatam, and twenty-four minutes at Aden; if then we assume that the interval was somewhat more than seventy-five minutes at Krakatoa itself—as is to be inferred from the fact that wherever registered it increases as the distance from the centre of impulse diminishes—General Strachey's and Major Baird's determinations will be seen to corroborate each other very closely; indeed, considering the absolute independence of the two methods of deduction, the facts of observation being in one instance derived from the atmosphere, in the other from the ocean, the coincidence between the results is very striking.

Major Baird has calculated the velocities with which the great positive wave travelled from Krakatoa to the more important of his own stations, and also to Port Louis in the Mauritius, and Port Elizabeth in South Africa.[1] Starting with the assumption that the wave left Krakatoa at 10·5 a.m., August 27, local time, he finds that it attained its maximum value, 467 statute miles per hour, in transit to both Port Louis and Port Elizabeth. Considerable interest attaches to this determination, in that it is identical with Sir George Airy's tabulated value of the velocity of a free tide-wave passing over an ocean 15,000 feet deep, which is supposed to be the average depth of the ocean in this direction; moreover, the fact that the same velocity is obtained for both the ports, and that the nearer of the two is only 3400 miles from Krakatoa, while the other port is 5450 miles distant, indicates that there is probably no material error in Major Baird's adopted time of starting. The velocity of the wave in all other directions is less, viz. to Galle 397 miles, to Negapatam 355 miles, and to Aden 371 miles. The velocities are necessarily computed on the assumption of a uniform rate of progress from the origin to the point reached; but each of the slower waves must have coincided with the wave which impinged on Ports Louis and Elizabeth for a considerable distance in the early portion of its course, and it must then have travelled with the same high velocity; afterwards, on passing over shallower seas, the velocity must have much diminished, and very possibly it may have fallen to the smaller velocity values which Major Rogers has calculated for the sea-waves in the Bay of Bengal, on the occurrence of the earthquake of December 31, 1881.

The Admiralty chart of the Eastern Archipelago shows that Krakatoa is situated at the focus of what may be regarded as a parabolic figure, formed by the contiguous portions of the coasts of Java and Sumatra; the axis of the figure is directed towards the Indian Ocean. Thus the waves generated by an eruption at Krakatoa would be mostly propelled towards that ocean, both directly and by reflection from the coasts; but near the apex of the parabola there is an opening, the Straits of Sunda, through which a great wave passed, carrying widespread destruction for some distance beyond along the contiguous coasts. This wave may have impinged with great force on the south-west corner of the Island of Borneo, which is on the prolongation of a straight line drawn from Krakatoa through the Straits. But it did not reach Singapore, where a tide-gauge is established, and which is within a third of the distance of the nearest Indian station from Krakatoa; the Master-Attendant at Singapore reports that the gauge shows "no difference whatever in the tide." This is obviously due to the fact that the wave which passed through the Straits of Sunda had but a shallow sea to advance over towards Singapore, and its course must have been greatly impeded by numerous islands and shoals and the narrow straits and passages between them. For similar reasons, and because the axis of the parabola in which Krakatoa is situated is pointed towards the Indian Ocean, it is probable that the effects of the eruptions were not conveyed to anything like so great a distance along the numerous groups of islands to the east and into the Pacific Ocean.

J. T. WALKER

THE INDIAN SURVEY[1]

THIS is the fifth report of the amalgamated Department of Surveys under the Government of India. It is divided into two parts with an appendix. Part I. gives a summary of the operations of the great trigonometrical, the topographical, and revenue survey parties; also of the geographical, geodetic, and tidal, and levelling operations. Part II. describes the operations at the Head-Quarters Offices, viz. the Surveyor-General's Office, the Revenue Survey Office, the Lithographic Office, the Photographic Office, and the Mathematical Instrument Department, all in Calcutta; and of the Trigonometrical Survey Office in Dehra Dun. Index charts, coloured maps, and sketches showing the present state of this very important department accompany this report; to which is prefixed, as frontispiece, a "Specimen of *Heliogravure* by Major Waterhouse's Process," which invites the special attention of photographers and engravers. An appendix, separately paged, of 120 pages, completes the volume, and consists of extracts from the narrative report of the executive officers in charge of the survey parties and operations.

---

[1] For these ports he employs the data published in NATURE, vol. xxviii. p. 626.

[1] "General Report on the Operations of the Survey of India during the year 1881-82." Prepared under the superintendence of Lieut.-General J. T. Walker, C.B., R.E., F.R.S., &c., Surveyor-General of India. (Calcutta, 1883)

This report is distinguished from previous ones by announcing the completion of the great triangulation on the lines originally marked out in 1830 by Col. Everest, which affords the Surveyor-General, in his introductory statement, an opportunity of giving a brief but interesting history of this great undertaking from its commencement in the year 1800, in Southern India, by Major Lambton, on the recommendation of the Hon. Col. Wellesley, afterwards the Duke of Wellington. The object of this so-called "Mathematical and Geographical Survey" was then stated to be "to determine the exact positions of all the great objects best calculated to become permanent geographical marks to be hereafter guides for facilitating a general survey of the peninsula," and further, that in the interests of general science it would have to be executed with the utmost possible precision, and be supplemented by astronomical determinations of position, with a view to the requirements of geodesy.

The operations between the years 1800 and 1825 may be briefly described as consisting of a network of triangulation over Southern India, and through the middle of which a principal chain of triangles was carried in a meridional direction from Cape Comorin up to Sironj in Central India. This chain forms that which is now known as Lambton and Everest's Great Arc. Col. Lambton died in 1823, and was succeeded by Col. Everest, who, two years afterwards, proceeded to Europe, spending four years in supervising the construction of new instruments—great theodolites, astronomical circles, standards of length, and compensation bars for base-line measurements, for employment in extending and revising the Great Arc, the importance of which was recognised by all men of science in Europe.

Returning to India in 1830, Col. Everest recommended the abandonment of the network system of triangulation and the substitution instead of what he called the "gridiron" system, consisting of meridional chains of triangles tied together at their upper and lower extremities by longitudinal chains. The meridional chains were to be constructed at intervals of about one degree apart, while longitudinal chains would follow the parallels of Calcutta, Bombay, and Madras, and thus run at intervals of from five to six degrees apart. The external chains of the gridiron would of course follow the British frontier lines and the coast lines, and all grounded on ten base lines measured with the Colby apparatus of compensation bars and microscopes. This programme of operations was approved by the Government of India and Court of Directors, and has furnished the guiding lines on which the principal triangulation has been executed during the period of almost exactly fifty years which has since elapsed. For geodetic purposes, the amount of principal triangulation is now ample. Outside the limits of India proper, the recently completed chain of principal triangles, called the eastern frontier series, is a valuable contribution to geodesy and geography.

Thus the great work of the principal triangulation of India is now an accomplished fact. Commenced in 1800, under the auspices of the Madras Government, it was carried on, almost alone, by Major Lambton, until 1818, when the Marquis of Hastings, then Governor-General, placed it under the control of the supreme Government, and Capt. Everest was appointed assistant to Major Lambton. In 1832 additional officers were appointed, and by the year 1840, when the northern section of the Great Arc was completed, the *personnel* sufficed for the equipment of six triangulation survey parties, which number has been uniformly maintained from that time onwards until gradually diminished on the completion of the successive chains of triangles. The operations have been uniformly and consistently supported by successive Governments of India with equal liberality and constancy, and to whom it must be a source of much satisfaction to know that this great work of permanent peaceful usefulness will assuredly take the highest rank as a work of scientific labour and skill.

It is stated that there are 3472 principal stations. On the plains they are constructed in the form of towers, rising from 20 to 40 and even 60 feet above the ground, and usually about 16 feet square at base, with an isolated central pillar for the instruments to rest on. On hills and mounds and other eminences the central pillar, always of masonry, is raised 2 to 4 feet above the ground level, and is surrounded with a platform of earth and stones. Mark-stones, engraved with circle and central dot to define precisely the station point of observation, are inserted at the surface and at the base of the pillar. The stations, scattered over 338 British districts and native states, are placed under the protection of local officials, each of whom is required to send annual reports of the condition of the stations within his district. Repairs are effected when necessary, and if so maintained by future generations of officials, the duration of the stations should be coeval with the hills and plains on which they stand, and be of lasting utility.

The field operations of measurements of base-lines and angles of the principal triangulation being completed, the simultaneous reduction of the vast number of such facts, acquired over all India, by many individuals and during a period of many years, to a harmonious whole, was obviously impossible. Thus it became necessary to divide the triangulation of India proper into five sections; and even then the simultaneous reduction of the numerous facts of observation collected together in each group was a work of enormous labour, necessitating, as stated by the most eminent living authority (Col. Clarke, C.B., *Geodesy*, p. 257), "the most elaborate calculations that have ever been undertaken for the reduction of triangulation by the method of least squares." The final results of the first section are given in vols. ii., iii., and iv. of the "Account of the Operations of the Great Trigonometrical Survey of India," published in 1879 (vol. i. is devoted to base-lines, and vol. v. to pendulum operations); those of the second section in vol. vi., published in 1880, and those of the third in vols. vii. and viii. will be shortly published. The simultaneous reduction of the fourth section is now completed. The final reduction of the last section has not yet commenced, nor has the recently completed eastern frontier series.

The requirements of geodesy necessitate astronomical observations for the determination of latitude and azimuth and electro-telegraphic observations for the determination of differences of longitude at several stations of the principal triangulation. These have already been completed to a considerable extent; and further operations of this nature are in progress by two small astronomical parties attached to the geodetic branch of the department, and by whom all the operations subservient to geodetic science should be completed in the course of a few years. An extensive series of pendulum observations for investigations of gravity and the figure of the earth, taken chiefly at stations of the principal triangulation, has been completed and connected with the groups of corresponding observations in other parts of the globe. Long lines of spirit levels have been, and are still being carried on in connection with the principal triangulation, from the sea to the base-lines in the interior, and from sea to sea across the peninsula; they rest on determinations of the mean sea level, which have been and are being made at tidal stations on the coasts, and which promise to furnish most important data by means of which our knowledge of the constitution of the earth's mass may be extended.

Reference can only be here made to the report for most interesting information as to the progress of the thirteen topographical parties, the two *Mouzawar*, or village survey parties, and the six cadastral or field survey parties, whose duties now include, as an experiment, the reecording of particulars about each field; thus reducing the cost of preparing the "Record of Rights" for the Board of Revenue. The geographical reconnaissance and trans-Himalayan explorations are replete with curious information to every student of nature, and of the habits and customs of the frontier hill tribes and peoples. The perusal of this report increases, if possible, our good opinion of the skill and devotion to duty of the several officers, and of the marked ability of the administration of this department by General Walker, and which it is most pleasing to find so handsomely acknowledged by the Government of India.

ZOOLOGY AND BOTANY OF ALASKA[1]

THE United States Revenue cutter *Corwin* went on a cruise in 1881 to Alaska and the Arctic Ocean. The main object of the voyage was to search the various accessible portions of the Arctic coasts for traces of the *Jeannette* and two missing whaling vessels which were lost the same season that the *Jeannette* entered the ice. Leaving St. Michael's on June 21, Behring's Sea was crossed to St. Lawrence Island and Plover Bay on the Siberian coast; then the *Corwin* went along this coast through the Straits and north-west to the vicinity of Nordenskjöld's winter quarters, where a sledge party, which had been left there earlier in the season to search the coast in that district, was taken on board; it then returned to St. Lawrence Island and St. Michael's. After a short delay it again proceeded to the Arctic, touching at all the islands in Behring's Straits, visiting in succession the entire Alaskan coast line from Behring's Straits to Point Barrow, including Kotzebue Sound, and on the Siberian shore from the Straits to North Cape. It also cruised along the edge of the ice pack, visiting Herald and Wrangel Islands—almost unknown masses of land—and, returning homewards, some time was spent at Ounalaska in the Aleutian Islands fitting for the voyage to San Francisco, which was reached in October.

As one of the results of this cruise, we have a series of notes and memoranda, medical and anthropological, botanical and ornithological, published by order of the House of Representatives at Washington.

The medical and anthropological notes of Alaska are by Dr. Irving C. Rosse. The health of the ship's crew was fairly good throughout the voyage, very careful precautionary measures being observed: for the usual habit of deluging the decks above and below every morning with water, a system of scraping and dry scrubbing was substituted with excellent results, and the decks were only wetted once or twice a month on fine days. Good water was procured nearly everywhere in the Arctic, and it is noted as of unusual excellence at Cape Thompson and at Herald and Wrangel Islands. The weather was mostly wild, with snow and hail; in the latter part of June at St. Michael's the sun was found almost overpowering, although the thermometer registered but 60°. Dr. Rosse gives a sketch of the diseases peculiar to the aboriginal population, especially of an epidemic of pneumonia which prevailed at Ounalaska. He declares "that there is an absolute consensus of opinion both among the executive and medical officers of late Arctic expeditions in regard to the judicious use of alcoholic beverages," and that though himself of abstemious habits, yet the facts observed "warrant him in testifying to the undeniable good effects of whisky when served out to the crew after unusual fatigue and exposure." On reaching St. Lawrence Bay, Siberia, a native speaking a little English was at his own request taken on board; the bustle and stir brought on a state of sleeplessness, and his state of mind was not improved on seeing the collection of skulls on board, nor by the chaff of the forecastle men, who tried to persuade him he was to be brought to San Francisco as an anatomical curiosity. As a result he stabbed himself dangerously in the left chest, and then leaped overboard; a boat being alongside, he was promptly rescued. The knife was found to have entered several inches, and blood and air were escaping from the wound. The symptoms were such that, writes Dr. Rosse, "the patient ought to have promptly perished, notwithstanding the treatment," but in a few days the patient was landed at Plover Bay, where he recovered sufficiently to start on foot for his home over a rugged mountain way 150 miles distant. "Wounds seem to heal uncommonly well in the Arctic, a fact doubtless owing to the highly ozonised condition of the atmosphere, and the absence of disease germs and organic dust."

Dr. Rosse's anthropological notes on the natives met with are of some importance, though his conclusions based on these may not always be acceptable. Referring to the prevalence of tattooing among the Esquimaux women, he gives a figure of strange design seen on the cheeks of a woman of St. Lawrence Island. Some drawings of crania are given, but we have failed to find any detailed account of them.

The botanical notes on Alaska are by John Muir. There is no line of perpetual snow on any portion of the Arctic regions known to explorers. Every summer the snow disappears not only from the low sandy shores and boggy tundras, but also from the mountain tops; for nearly three-fourths of the year the plants lie buried under it, but they awake up in June and July to a vigorous growth, and on the drier banks and hills about Kotzebue Sound, Cape Lisbourne, and elsewhere, many species show but little climatic repression, growing during the long summer's day tall enough to wave in the wind, and to unfold a rich profusion of flowers. A list of the species found at the following localities is given—St. Michael's, Golovin Bay, Kotzebue Sound, and Cape Thompson, where a new species of Erigeron was found (*E. muirii*, Gray). On Herald Island sixteen species of flowering plants were gathered. At Wrangel Island, from an area of about half a square mile, twenty-seven species of flowering plants were collected; they all occurred in separate tufts, leaving the ground between them bare and raw as that of a newly ploughed field. Some portions of the coast, however, farther south, presented a greenish hue, as seen from the ship, at a distance of eight or ten miles, owing no doubt to vegetation growing under less unfavourable conditions than at the point the *Corwin* touched at.

The birds of Behring's Sea and the Arctic Ocean are described by Mr. E. W. Nelson; many of the breeding quarters of North American birds are given, and details are also added of some of the rarer forms met with. A fine adult male Siberian Wagtail (*Motacilla ocularis*, Swinhoe) was taken at Plover Bay the last day of June; it was in perfect breeding plumage. A specimen of *Lanius cristatus* was picked up dead on Wrangel Island. Strictly an Asiatic bird, it must have reached this distant spot during some storm, and died of starvation or exposure. A fine adult female, in breeding plumage, of *Eurinorhynchus pygmæus*, was taken at Plover Bay, and several others were seen. A specimen of *Rhodostethia rosea* in immature plumage was obtained at St. Michael's, and reference is made to three fine specimens secured by Mr. Newcomb during the drift of the *Jeannette*, which are now in the Smithsonian collection, one of which still retains its extremely rich peach-blossom pink so characteristic of this the most beautiful of the gulls.

---

[1] "Cruise of the Revenue Steamer *Corwin* in Alaska and the North-West Arctic Ocean in 1881. Notes and Memoranda, Medical and Anthropological, Botanical and Ornithological." (Washington: Government Printing Office, [illegible])

A list of the fishes known to occur in the Arctic Ocean, north of Behring's Straits, by Tarleton H. Bean, is appended. The list is based exclusively upon specimens in the United States National Museum, and is acknowledged to be incomplete; it only contains twenty-one species, eight others being added as "properly belonging to the fauna." No details beyond the localities where found are given.

SOUND-MILLS

AFTER the notable researches of Crookes on radiation, which culminated in the discovery of the radiometer, or light-mill, it was a natural transition of thought which suggested to several minds almost simultaneously the possibility of devising an apparatus which should rotate under the influence of sound-waves as does the radiometer under the influence of the rays of light and heat. Such instruments were indeed devised independently about six years ago by Lord Rayleigh, by Prof. Alfred M. Mayer of Hoboken, by Mr. Edison, the well-known inventor, by Prof. Mach of Prague, by Dr. A. Haberditzel of Vienna, and by Prof. V. Dvorák of the University of Agram (in Croatia). These researches, though of great scientific interest, have been somewhat overlooked in the rush of scientific inventions during the intervening years. During the course of the past year, however, Dr. Dvorák has given to the world, in the pages of the *Zeitschrift der Instrumentenkunde* (vol. iii. Heft 4), a detailed account of his experiments, together with figures of various pieces of apparatus hitherto undescribed. We propose to give a *résumé* of the principal points of Dvorák's researches.

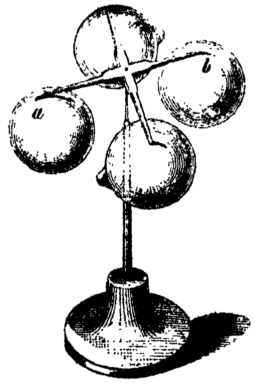


FIG. 1.

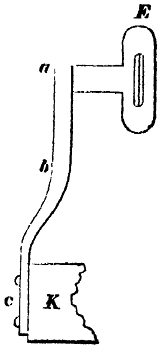

FIG. 2.

Four kinds of sound-mills are described by Dvorák, two of them depending on the repulsion of resonant-boxes or cases, and two others on different principles.

The first of these instruments is depicted in Fig. 1, and consists of a light wooden cross, balanced on a needle point, carrying four light resonators made of glass. These resonators are hollow balls of 4·4 cms. diameter, with an opening of 0·4 cm. at one side. They respond to the note g' ($=392$ vibrations). When the note g' is forcibly sounded by an appropriate tuning-fork, the air in each of the resonators vibrates in response, and the apparatus begins to rotate. As a resonator will respond when placed in any position with respect to the source of sound, it is clear that one single resonator properly balanced should rotate; and this is found to be the case, though, naturally, the action is more certain with four resonators than with one.

Before proceeding to the other forms of sound-mill devised by Dvorák, it may be well to explain briefly the cause of the phenomenon, and to describe Dvorák's particular method of exciting the appropriate sound Dvorák has pointed out, as indeed has been done elsewhere both by Lord Rayleigh and by Prof. A. M. Mayer, that, when sounds of great intensity are produced, the calculations which are usually only carried to the first order of approximation cease to be adequate, because now the amplitude of motion of the particles in the sound-wave is not infinitely small as compared with the lengths of the sound-waves themselves. Mathematical analysis shows that under these circumstances the mean of the pressures in the condensed part and in the rarefied part of the sound-wave is no longer equal to the undisturbed atmospheric pressure, but is always greater. Consequently at all nodal points in the vibrations of the air in tubes or resonant-boxes the pressure of the air is greater than elsewhere; and therefore any resonator closed at one side and open at the other is urged along bodily by the slight internal excess of pressure on the closed end. The apparatus, Fig. 1, therefore rotates by reaction, in the same way as Hero's primitive steam-engine rotated, though the reaction is due to a different cause.

To produce vibrations of sufficient intensity Dr. Dvorák employs heavy tuning-forks mounted on resonant-cases, and excited electrically. For this purpose he places between the prongs of the fork an electromagnet constructed on the following plan. Two plates of iron separated by a sheet of paper are used as a core. They are cut of such a breadth as to lie between the prongs without touching them. This core is overwound with insulated copper wire, as shown at E, Fig. 2, and the electromagnet is then mounted by a bent piece of wood, *abc*, upon the sounding-box, K, of the fork. The wires are connected in a circuit with a battery, and with the electromagnet of a self-exciting tuning-fork of the same note. Dr. Dvorák is extremely particular about the arrangements of the resonant-boxes of his tuning-forks. They must not touch the table, the arm *a b c* being clipped at about the point *b* in a firm support. Moreover the resonant-boxes themselves require to be specially tuned, for all are not equally good. Dr. Dvorák points out that, beside the tone of the fork, and the tone of the air column in the cavity of the box, there is also a tone proper to the wood of the box itself, which in most of the forks used in acoustic researches is too base, the wooden walls being too thin. To hear this tone the prongs of the fork should be damped by sticking a cork between them, and the cavity should be filled with cotton-wool, while the wooden box is gently struck with the knuckle or with a cork hammer. It is important that the wood-tone should be tuned up to coincidence with the tone of the fork and with that of the air in the cavity. Dr. Dvorák himself used the box depicted further on in Fig. 6, in which drawing F is the socket into which the stem of the fork

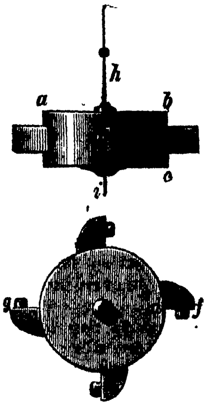

FIG. 3.

was screwed. The wood was tuned by planing it away at the top and bottom, while the air cavity was tuned by enlarging the circular opening in front. In the later researches the box stood on four feet made of india-rubber tubing. The note of the fork so mounted was very strong. At 40 cms. distance it would set the sound-mill in motion.

Dvorák's second apparatus, a "rotating resonator," consists of a short cylindrical box, constructed of stiff glazed paper, having four projections, shown in plan and elevation in Fig. 3, each of which bears at its side a short open tube of paper. It is, in fact, a resonator with four openings, arranged so that it can be hung upon a silk fibre. A fine needle projects also below to steady the motion during its rotation, which occurs whenever the apparatus is brought near to the sounding-fork. For the note g' the dimensions were: diameter, 7 cms.; height, 3·6 cms.; diameter of openings, 0·6 cm.

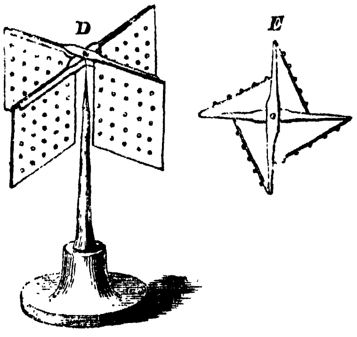

FIG. 4

The third apparatus is the "sound-radiometer" described by Dvorák before the Imperial Viennese Academy in 1881. Its cause of action is less readily explained, though its construction is even more simple. Its form is shown in Fig. 4, D; there being, as before, a light cross of wood, pivoted by a glass cap upon a vertical needle. To the four arms of the cross are cemented four pieces of fine white card, about 0·08 cm. thick, perforated with holes which are depressed conically at one side, and raised at the other. These holes may be made by punching the card upon a lead block with a steel perforating-punch of the form shown in Fig. 5, A, the dimensions of which are: *a b* = 0·38 cm.; *c d* = 0·2 cm. The holes should be from 0·6 to 0·65 cm. apart from one another. When a card so perforated is held in front of the opening of the resonant-box of the tuning-fork it is repelled if the smaller ends of the conical holes are toward the box; or is attracted if the wider openings are toward the box. A better, but less simple, way of perforating the cards is by the use of the conical steel punch shown in Fig. 5, B, and the matrix, Fig. 5, C. The angle of the cone is 55°, and the narrow projecting nose of steel is 0·2 cm. The card should be damped, laid on the matrix C, and the hole pierced by two or three blows upon the die. Dr. Dvorák prefers this plan: it throws up a high burr or edge behind the conical hole, and such perforations are more effective. The cards may be varnished, and are then mounted upon the cross. The rotations are more rapid if the cards are set on obliquely in the fashion shown in Fig. 4, E, the burred sides being outwards. Cards with twenty-five perforations so mounted rotate briskly when the "mill" is set in front of the resonant-box.

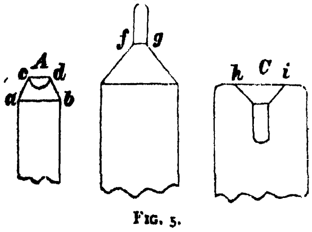

FIG. 5.

The fourth apparatus of Dvorák is called by him an "acoustic anemometer." It is shown in Fig. 6. This is merely a little "mill" of simple construction, the vanes being small pieces of stiff paper or card slightly curved. The sounding-box previously described is placed a little way from it, and between them is held an ordinary Helmholtz's resonator, with its wide mouth, *b*, turned toward the box, and its narrow opening, *a*, toward the mill. From what has been previously said it will be understood that the internal increase of pressure in the resonator at *a* has the effect of driving a jet of air gently against the sails of the mill, which consequently rotates. Dr. Dvorák also suggests that this two-aperture resonator may be replaced by one having but one aperture, as shown at R, with its open side, *l*, turned towards the mill. This resonator is formed of a glass ball cut away at one side and cemented to a glass plate having a small hole at the centre. It may be remarked that when the air ejected from the mouth of this resonator is examined by the method of mixing smoke with it, and then viewing it through slits cut in a rotating disk, the currents are seen to consist of a series of vortex-rings.

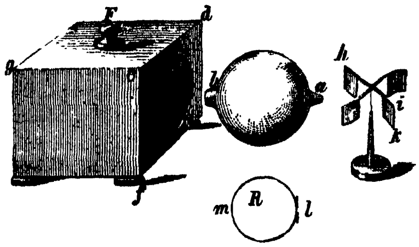

FIG. 6.

A second kind of "acoustic anemometer" may be made by taking a card pierced with 100 conical holes, as previously described, and placing this between the resonant-box and the "mill." The latter rotates in the wind which passes through the conical holes.

Space does not admit of a comparison being drawn between these instruments and those of Mayer, Mach, and others, which are very closely akin in their design and mode of action, interesting though such a comparison might be. Nor can we here compare the action of these instruments with the "phonomotor" with which Mr. Edison literally accomplished the feat of talking a hole through a deal board. But this remarkable machine was a purely mechanical toy, which converted the vibrations of the voice, by means of a very finely-cut ratchet-wheel, into a motion of rotation round an axis.

SILVANUS P. THOMPSON

NOTES

IN the last week British science has sustained a great loss in the death of Mr. Thomas Chenery, the editor of the *Times*. During his all too short reign the leading journal of Europe has been in strict harmony with the real progress of humanity, instead of being merely a chronicle of "politics" and "society," and day by day it has been wonderful to watch with what continuous well-balanced vigour and skill the general public has been made interested in the victories achieved in the domains of science, literature, and art, as only a daily journal can interest it.

Never before in the history of daily journalism in any country did science receive the recognition which Mr. Chenery accorded to it. Mr. Chenery was not only a great scholar, but the nearest approximation to an admirable Crichton that we have known, and in this we find the secret of his skill as an editor. So many-sided was he that whether teaching Arabic at Oxford as Lord Almoner's Professor; taking his part in the revision of the Old Testament; acting as Special Correspondent in the trenches in the Crimea; at his post as Editor of the *Times* or in private life, he won the admiration of all who knew him by his deep knowledge and splendid modesty. He was a perfect friend, and gained the respect and love of all who came into contact with him.

Dr. John Hutton Balfour, Emeritus Professor of Medicine and Botany in the University of Edinburgh, Regius Keeper of the Royal Botanic Garden, and Queen's Botanist for Scotland, died on Monday at Inverleith House, Edinburgh. He was born in 1808. Dr. Balfour was the father of Prof. Bayley Balfour, whose appointment to the vacant Chair of Botany at Oxford we announce to-day. We hope to say more about the late Prof. Balfour next week.

The death is announced of the distinguished American geographer, Prof. Arnold Henry Guyot. He was born at Neuchâtel, Switzerland, on September 28, 1807. He studied at Neuchâtel, Stuttgart, and Carlsruhe, and at the last-named place formed a close friendship with Agassiz, with whom he studied natural science. In a tour through Switzerland in 1838 he first discovered the laminated structure of the ice in glaciers, and showed that the motion of the glacier is due to the displacement of its molecules. Agassiz, Forbes, and others afterwards confirmed these discoveries. For seven successive summers Guyot now investigated the distribution of erratic boulders, tracing them on both sides of the Central Alps, in Switzerland and Italy, over a surface 300 miles long and 200 miles wide, and delineating eleven different regions of rocks. Their vertical limits and the laws of their descent were determined by means of more than 3000 barometrical observations; and the characteristic species of rock of each basin were tracked step by step to their source. In the United States he was employed by the Massachusetts Board of Education to deliver lectures in the normal schools of the State, and before the teachers' institutes, and by the Smithsonian Institution to organise a system of meteorological observations. In 1855 Guyot was appointed Professor of Physical Geography in the College of New Jersey at Princeton, which post he retained till his death. He was awarded a medal for his researches at the Vienna International Exhibition of 1873.

The Royal Society has appointed a committee, consisting of Sir F. Evans, Prof. Judd, Mr. Lockyer, Mr. R. H. Scott, General Strachey, and Mr. G. J. Symons, with power to add to their number, to collect the various accounts of the volcanic eruption at Krakatoa, and attendant phenomena, in such form as shall best provide for their preservation and promote their usefulness; and a sum of 25*l.* has been placed at their disposal for this purpose. In connection with this we direct attention to the letter of Mr. Symons in our Correspondence Columns.

The following note has been sent us from the Meteorological Office:—"We have received notice of the establishment of a system of storm and weather warnings on the Spanish coast. The warnings are based upon observations received from stations reporting daily by telegraph to the Marine Observatory at San Fernando, which is superintended by Capt. C. Pujazon of the Spanish Navy. This institution also issues a daily weather report and chart."

The "Johns Hopkins University Circulars" have become an important medium for communicating briefly the results of research in all departments in connection with the many-sided institution which issues them. Doubtless they are to be found at the leading scientific centres in this country, and are always well worth looking into. The number for January contains a brief report of the meetings in connection with the departure of Prof. Sylvester from America; how highly he was appreciated there is evident from the following:—On the afternoon of December 20 the academic staff of the University met in Hopkins Hall, by invitation of the President, and after a brief review by Dr. Story of the mathematical lectures here given from 1876 to 1883, and a like review by Dr. Craig of the contributions printed in the *American Journal of Mathematics*, Prof. Gildersleeve read the following paper, which, on motion of Prof. Rowland, was adopted by the meeting as an expression of their respect and good will. "The teachers of the Johns Hopkins University, in bidding farewell to their illustrious colleague, Prof. Sylvester, desire to give united expression to their appreciation of the eminent services he has rendered the University from the beginning of its actual work. To the new foundation he brought the assured renown of one of the great mathematical names of our day, and by his presence alone made Baltimore a great centre of mathematical research. To the work of his own department he brought an energy and a devotion that have quickened and informed mathematical study not only in America, but all over the world; to the workers of the University, whether within his own field or without, the example of reverent love of truth and of knowledge for its own sake, the example of a life consecrated to the highest intellectual aims. To the presence, the work, the example of such a master as Prof. Sylvester, the teachers of the Johns Hopkins University all owe, each in his own measure, guidance, help, inspiration; and in grateful recognition of all that he has done for them, and through them for the University, they wish for him a long and happy continuance of his work in his native land; for themselves the power of transmitting to others that reverence for the ideal which he has done so much to make the dominant characteristic of this University."

An ascent of Ben Nevis was made on Monday by Mr. C. D. Cunningham, a member of the Alpine Club, accompanied by M. Emile Rey, a Swiss guide, and John Cameron, the well-known guide at Fort William. There were about six inches of snow on the ground from the commencement of the new road to the Red Burn. Here considerable difficulty was experienced in crossing the Burn and arriving on the top of the opposite bank, owing to the great quantity of snow which had drifted into the watercourse. From the well to the summit the ground, covered with deep snow, was hard frozen, making the task comparatively easy. Mr. Omond and his companions at the Observatory appeared in good health and spirits, and entertained the party in the most hospitable manner. The ascent occupied three hours thirty-five minutes, and the descent two hours.

The estimates submitted to the Dominion Parliament include (says a Reuter's telegram from Ottawa) the sum of 25,000 dollars for the expenses connected with the meeting of the British Association at Montreal this year.

The German Cholera Commission has sent a fifth report from Calcutta, dated January 5. Dr. Koch seems to have really discovered special cholera bacilli. The Commission was further occupied with the investigation into the causes of the great decrease in cholera mortality in Calcutta, where the percentage of deaths per thousand has diminished from ten to three. This diminution is attributed to the improvement of the water supply.

The Nautical Meteorological Office of Sweden maintains at present nineteen stations at which meteorological observations are made on a large scale, twenty stations for measuring the fall of rain and snow, and sixteen hydrographical observatories. Weather journals were last year received from eleven men-of-war and fifteen merchantmen. The Meteorological Office in London having requested that of Sweden to forward as complete journals as possible of the meteorological phenomena of the North Atlantic Ocean between August 1, 1882, and September 1, 1883, the Office has made a careful abstract of these journals for this purpose.

The consistory of the Upsala University has voted a sum of about 200*l*. for the purchase of objects of natural history for the University collected by the *savants* of the *Vanadis* Expedition round the world, now taking place.

On January 14 a "green" moon was observed at Kalmar in Sweden. At about 5 p.m., just after the sun had set, leaving an intense purple glow on the sky—more intense than the late sun-glows—the moon came out of a layer of heavy clouds in the east. A few seconds after—the disk being then perfectly clear—a light haze gathered around it, partly veiling it, which immediately changed the bright silver colour to an emerald green. The phenomenon lasted for three minutes, when the disk again by degrees assumed its former brightness. A similar phenomenon was observed near Stockholm on January 17 at about 8 o'clock in the morning. It lasted about three minutes.

The Council of the Royal Meteorological Society have arranged to hold, at 25, Great George Street, S.W., by permission of the President and Council of the Institution of Civil Engineers, on the evening of March 19 next, an Exhibition of Thermometers. The Committee will also be glad to show any new meteorological apparatus invented or first constructed since last March; as well as photographs and drawings possessing meteorological interest.

A special meeting of the Committee of the Sunday Society was held on Monday afternoon, February 4, at 9, Conduit Street, W., Prof. W. H. Corfield, M.D., in the chair. The Honorary Secretary submitted a Report on the recent voting as to the future political action of the Society, from which it appeared that 391 had voted in favour of making the Sunday opening of museums a test question at elections of Members of Parliament, and that 470 voted against this proposal; 853 voted in favour of making the question the subject of an annual motion in the House of Commons, and only 11 voted against this proposal. Resolutions were subsequently passed pledging the Society to action in accordance with these results.

Like its better known namesake in the metropolis, the Royal Institution, Liverpool, has done much to popularise scientific knowledge during the present century. So far back as 1820 it first gave a permanent home to a scientific society in Liverpool, by admitting the Literary and Philosophical Society to share its roof, for the purpose, say the Minutes, "of extending the knowledge of arts and sciences." Since then the number of societies with scientific aims has steadily grown in Liverpool, and the number of members composing them to some extent increased as steadily. The accommodation of the Institution is found to be limited, and the idea of devoting the whole of the available space for the purpose of meetings is beginning to take definite shape, and was supported by Mr. Morton, F.G.S., in his presidential address last week. A very large part of the building is occupied by the museum, which was formerly the most important in Liverpool; for many years not less than 30,000 persons visited it on free days annually; this number was maintained up to 1868-69, when it all at once fell off; last year the number was only 4489, of whom only 1019 visited the natural history collections. This diminution of interest was coincident with the opening of the Free Public Museum. In 1817 the Institution disposed of the mammalia, reptiles, fishes, crustacea, polyzoa, and corals in the museum, and it is thought desirable that the remaining collections of interest and *local character* should be absorbed into the Corporation Museum. The Institution has schools which are in an exceedingly prosperous condition, and its library has a large collection of standard works in natural science.

In a letter on the remarkable sunsets from Mr. S. E. Bishop, dated Honolulu, January 15, the writer mentions the important fact that the reddish haze was seen 4000 miles west of Panama on September 3 from the barque *Southard-Hurlburt*.

The Worshipful Company of Clothworkers has been pleased to grant a donation of 21*l*. to the National Health Society, 44, Berners Street.

A proposition has been presented to the Municipal Council of Paris to give the name of Darwin to a new street about to be opened.

The Hotel Dieu, Paris, having Gramme machines and steam-engine, the Administration of the Assistance Publique has decided to introduce experimentally the use of Edison incandescent lights in the halls inhabited by patients. The Hotel Dieu is the largest and the leading French hospital.

The French Minister of Public Instruction will organise in Paris an exhibition of the objects which have been collected at Cape Horn by the *Romanche*. The collection is composed of 170 cases of valuable specimens of mineralogy, geology, and zoology, as well as living plants which will be acclimatised as far as possible in French forests.

The International Association of Electricians, of which we have announced the creation in Paris, will hold its monthly sittings at the rooms of the Society of Geography. The first took place at the beginning of this month. The first part of the *Transactions* of the Association has reached us.

A new popular scientific paper has been published in Paris entitled *Le Mouvement Scientifique*.

The Aristotelian Society for the Systematic Study of Philosophy will meet henceforth in the rooms of the Royal Asiatic Society, 22, Albemarle Street, W.

Shortly before sunset on Tuesday evening when the whole of the population of Notaresco, in the Abruzzo, had retired within doors on account of the intense cold, a shock of earthquake was felt, of such severity that the people rushed headlong into the streets and remained there until after midnight. The shock was also felt at Atri, Guilianova, Avellino, and Citta Sant' Angelo. A violent earthquake also occurred on the 10th inst. in the district of Birvari, Province of Bitlis, Turkey. A large number of houses and other buildings were thrown down.

Mount Etna has, since Saturday, entered into an eruptive stage by throwing out ashes from the topmost crater. Strong earthquake shocks in the districts around the mountain preceded the outbreak.

An unusually bright meteor was seen in Western Germany on January 28, about 7.30 p.m. At Barmen its motion seemed to be from east to west, while at Neuwied south to north was the direction. Its brilliancy is generally compared to that of the full moon.

At the last meeting of the Berlin Anthropological Society, Prof. Nehring reported on the discovery of a cave near the village of Holzen (Brunswick), which is of special interest, inasmuch as there is strong evidence of cannibalism among the ancient cave men of that place, the first time that such evidence is forthcoming concerning the prehistoric inhabitants of what is now Germany. In Belgium and Spain similar evidence had been found, but had been dismissed as doubtful. The bone-remains of the Holzen cave are not completely calcined; at the same time there is proof that the bones were opened to get at the marrow. But the strongest evidence of cannibalism was furnished by the arrangement in which the bones were found. Besides these bones and bone implements, roughly worked bronzes were found. At a lower level numerous lemming bones were found, which, with regard to the age of the cavern, seems to point to the Glacial epoch. In the debate following Prof. Nehring's report, Prof. Virchow raised some doubts regarding the cannibalism of the cave dwellers.

A MEETING of delegates of Natural History Societies in the east of Scotland (including the counties of Fife, Perth, Forfar, Kincardine, and Aberdeen) was held in the lecture-room of the Perthshire Natural History Museum, Perth, on Nebruary 9, to consider the question of federation alluded to in NATURE. The following societies were represented:—Aberdeen Natural History Society, Alford Field Club and Scientific Society, Arbroath Horticultural and Natural History Association, Dundee Naturalists' Society, Dundee Naturalists' Field Club, Kirkcaldy Naturalists' Society, Largo Field Naturalists' Society, Montrose Natural History and Antiquarian Society, and the Perthshire Society of Natural Science—being all but four of the Societies in the above-mentioned counties. Two of these four societies considered that their objects did not quite entitle them to join the proposed federation, at least for the present; and from the other two no response had been received. After deliberation it was resolved to federate the societies under the title of "The East of Scotland Union of Naturalists' Societies." The objects of the Union are the promotion of good and systematic work by the various societies in it, and of friendly intercourse amongst their members; its affairs are to be conducted by a council of representative members, two being elected by each society. The president is to be a man of scientific eminence, connected with the district; and it is to hold an annual general meeting at the headquarters of the various societies in rotation, and other meetings in such places in the district as may be agreed on. The Union starts with a membership of about 1300. It was determined that the first general meeting should be held in Dundee on June 6 and 7 next. Dr. Buchanan White, F.L.S., was elected President, and Mr. F. W. Young, F.R.S.E., Hon. Secretary of the Dundee Naturalists' Society, was appointed Secretary.

WE learn from *Science* that Mr. Joseph Wharton of Philadelphia writes to the *Public Ledger* of that city (January 22) that he has found volcanic glassy dust in fresh, clean snow of recent fall. The snow, melted under cover in the porcelain vessel it was gathered in, showed at first no sediment; but after a time, and aided by a gentle rotatory movement which brought all to the deepest point, a slight deposit appeared. By pouring off most of the water, and evaporating the remainder, a little dry dust was obtained, which, even to the naked eye, showed, in the sunlight, tiny vitreous reflections. The dust weighed by estimate a hundredth of a grain, and showed under the microscope the characteristics of volcanic glass. It was partly irregular, flat, and blobby fragments, and partly filaments more or less contorted, which were sometimes attached together in little wisps, and were mostly sprinkled with minute glass particles. Under a knife-edge the filaments broke easily and cleanly. The irregular fragments were of various sizes and shapes, mostly transparent, but, even when examined by strong transmitted light, showing no trace of crystalline structure. Their diameter was about that of single filaments of silk. No crystalline particle of pyroxine, or black crumb of augite, such as observers have found elsewhere in similar dust, was present; nor did a strong magnet stir any particles of magnetic oxide of iron, though they also have been found in other volcanic dust. It may fairly be assumed that those heavier minerals, if at first mingled with the volcanic glass, had been already deposited during the long voyage through more than ten thousand miles of space and more than four months of time, while the tenuity of the intrinsically lighter glass threads (the Pele's hair of Mauna Loa) enabled them to float farther from the point of eruption.

"THE International Conference for fixing upon a universal prime meridian and a universal system of time has," *Science* states, "at length been called by the State Department to meet in Washington, Oct. 1. Diplomatic proceedings are always expected to go on with a certain dignified leisure; but the arrangements for the meeting of this conference have been delayed far beyond anything customary even in diplomacy. The act authorising the conference became a law in August, 1882. As there was some doubt whether there would be a sufficiently general response to the invitation to insure the success of the conference, a preliminary circular requesting the views of the various governments interested, and an expression of their willingness to enter the conference, was issued from the State Department toward the end of 1882. The responses were in some cases favourable, and in others negative or undecided. A desire was felt by the Europeans to have a preliminary discussion of the subject at the International Geodetic Conference at Rome in October, 1883. The feeling at this conference having shown that there would be little difficulty in the universal adoption of the Greenwich meridian, the final step of calling the conference was taken. Why so late a date was chosen we are not informed."

THE Magdeburg Wetter Verein has been transformed into a branch of the general German Meteorological Society, which is under the direction of Dr. Neumayer of Hamburg.

THE valuable ethnological collection made by Herr Zembsch at Apia, for many years German Consul-General at that place, has been purchased by the Ethnological Museum at Berlin. It consists of over 500 specimens.

THE additions to the Zoological Society's Gardens during the past week include a Chacma Baboon (*Cynocephalus porcarius* ♀) from South Africa, presented by Col. Gildea; a Macaque Monkey (*Macacus cynomolgus* ♂) a Black Kite (*Milvus migrans*) from India, presented by Mr. John M. Hagerman; a Common Hedgehog (*Erinaceus europæus*), British, presented by Mr. Archibald Aitchinson; a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mr. J. Wilson; a Vulpine Phalanger (*Phalangista vulpina*) from Australia, presented by Capt. F. R. Slater; two Common Jackdaws (*Pica rustica*), British, presented by Master Harrott; a Chanting Hawk (*Melierax musicus*) from South Africa, a Partridge Bronze-winged Pigeon (*Geophaps scripta*) from New South Wales, purchased.

OUR ASTRONOMICAL COLUMN

PONS' COMET.—It appears that this comet was sufficiently conspicuous to attract the attention of unscientific passengers on board one of our mail steamships in approaching Rio de Janeiro from the south on January 20, while it was an object of popular interest in Southern Italy towards the end of that month, according to the Naples correspondent of the *Times*. Observers in the other hemisphere may be able to follow it for several months longer; in the last week in June the theoretical intensity of light will be equal to that at the date of its discovery by Mr. Brooks.

This comet approaches the orbit of Venus within 0·076; that of Jupiter within 1·98; and that of Uranus within 1·17. The ascending node falls at a distance of 15·46. During the revolution 1812–1884, the calculations of MM. Schulhof and Bossert show that the approximate effect of planetary attraction upon the periodic time, at the instant of perihelion passage in the former year, has been as follows:—

	Days
Comet accelerated by action of Jupiter	446·49
,, ,, ,, Saturn	13·96
Comet retarded by action of Uranus	13·48
,, ,, ,, Neptune	1·48

Hence the period of revolution in 1812 has been shortened by perturbation to the extent of 445·49 days. The orbital velocity of the comet at perihelion is 29·2 miles in a second, at aphelion it is 3550 feet in the same time.

THE GLASGOW CATALOGUE OF STARS.—Prof. Grant has just issued the important catalogue of stars which has been for some time in active preparation at the Observatory of Glasgow, and towards the publication of which the Royal Society has largely contributed from the Government Grant Fund. Its appearance is too recent to allow of a description of the contents in the present column.

THE VARIABLE STAR U GEMINORUM.—Mr. G. Knott, writing from Cuckfield on the 4th inst., sends observations of a recent maximum of this star; his estimates are:—

	h.	m.				h.	m.		
Jan. 24,	8	10	...	13·3 m.	Jan. 28,	8	15	...	9·95 m.
26,	9	50	...	9·6	30,	9	0	...	11·4
27,	8	53	...	9·7	Feb. 2,	7	20	...	13·9

Clouds prevented observation on January 25, but it is quite possible that the maximum may have been attained on that day, since in 1877 the star increased from 13·2 m. to 9·8 m. between February 20, 8h. 10m., and February 21, 10h. 30m. The last previous maximum observed by Mr. Knott fell on January 30, 1883, the date also assigned by the observations of M. Safarik (*Astron. Nach.* No. 2505).

The period which best represented the observations in the years immediately following the discovery of the star's variability by Mr. Hind (in December 1855) was 97 days, but there has been subsequently great irregularity, and according to Mr. Knott it has fluctuated between 71 and 126 days, though the values on the whole cluster about a mean of from 90 to 100 days; the limits of variation being about 14½ and 9¼ of Argelander's scale. These inferences are drawn from thirty-four maxima, observed partly by Mr. Knott and partly by Mr. Baxendell (see the *Observatory*, April, 1882).

THE LATE J. F. JULIUS SCHMIDT.—Practical astronomy has sustained a serious loss in the sudden death of the well-known Prof Julius Schmidt, who has been for many years Director of the Observatory at Athens. According to a Reuter's telegram his funeral, which took place on the 8th inst., was of a public character, the King and Queen of Greece being present at the Observatory during the delivery of the funeral oration. A notice of Prof. Schmidt's long-continued astronomical labours must be deferred to another week.

THE ROYAL SOCIETY OF EDINBURGH

AT the meeting of this Society on the 4th inst., the President, Lord Moncreiff, delivered an address on "The Past Hundred Years' History of the Society." Regarding this long interval, Lord Moncreiff said: "From the watch-tower of the Royal Society I can trace within the century a revolution more wonderful and more extensive than monarchs, or empires, or republics can display. Since this Society held its first meeting, how great to the community has been the fruit gathered from those branches of knowledge which it was incorporated to prosecute! During that interval, what has science not done for human comfort and happiness? What interest so great, what dwelling so humble, as not to have felt its beneficent influence? Since the invention of the art of printing, no such advance in material comfort, prosperity, and intelligence has ever been made within a similar period as this century has witnessed. Its triumphs have not been confined to the more abstruse fields of thought and study, but have come straight to the world of every-day life. One homely illustration meets me on the threshold of the opening night, and homely things go deep into the foundations of human life. I picture to myself our founders wending their way to the College Library, through close and wynd, in mid-winter 1783, while flickering oil lamps made the darkness visible without, and a detestable tallow candle made the student miserable within doors. Those who cannot recollect the universal reign of tallow candles and their sufferers, cannot appreciate how much the sum of human enjoyment has been enhanced, and the tranquillity of human temper increased, by the transmutation—partial, we must admit—of darkness into light. There has been, I believe, no more potent agent in humanising the denizens of our large cities than the flood of light which chemical science has in our day poured into their recesses. Prophets tell us that, before the end of the century which we now begin, gaslight will probably have followed the tallow candle into the same unlamented obscurity; but, even should this be so, history will carry to its credit the vast amount of public utility, and the many hours of useful employment or comfort in the factory, the study, or the sick-room, which this simple application of chemical science gained in its day for the nineteenth century. But the dispersion of material darkness is but a slender illustration of the triumphs of scientific discovery. Time and space are no longer the tyrants they were in 1783. I rather think that when our founders first met they could hardly hope to hear by post from London under ten days, as Palmer's mail-coaches had not begun to run until 1789. It would be an interesting inquiry, if my limits permitted, to trace the moral and social effects of the change from the days when a London letter took even three days to reach Edinburgh, and cost 13½d.—the pre-Macadamite days, when twenty miles a day was a fair posting rate on any roads but the main thoroughfares. Lord Cockburn lamented over the prospect of London being within fifteen hours of Edinburgh, as endangering the characteristics of our social community. His sagacity was not altogether at fault, but even that time has been reduced by a third, and I rather think we and the world are all the better for the change. But although larger victories were in store for the century, they came slowly. Both Boulton and James Watt were original members of the Royal Society, but it was more than thirty years before steam navigation became general, and more than fifty before the first passenger railway train ran in Scotland. No doubt, in 1791, Erasmus Darwin, in his 'Botanic Garden,' a poem too little read, had exclaimed in the well-known lines:—

> 'Soon shall thy arm, unconquered steam, afar,
> Drag the slow barge, and urge the flying car.'

Godwin, too, looked forward with confidence to the ultimate victories of steam. Now, the locomotive carries mankind to all ends of the earth; their sanguine suggestions have been all but realised. There has been during this interval a still more powerful magician at work. To this audience I need not dwell on the triumphs of the future ruler of the world of science—electricity. But one illustration I may be permitted. Franklin was one of the first of the non-resident members elected by the Royal Society of Edinburgh. How little he thought when, many years before, he drew the electric spark from the cloud, that, before 100 years had sped, his experiment, but slightly modified, might convey a message from a meeting of the Society in Edinburgh to one of its fellows in New York, and bring back an answer before the meeting separated. In slightly alluding to this scientific revolution, my object has been partly to illustrate the surroundings of 1783, and also to remind my hearers that, of all the changes the century has seen, far the most important and the deepest have been the work of science. Increased facilities for inter-communication carry with them a complete change in the economical and social condition of the communities they affect. New wants, new customs, new ambitions, new possibilities, follow in their train by the operation of inevitable laws. By this talisman we have seen, perhaps sometimes without due appreciation, many a social problem solved which had before seemed hopeless; and although in the process of transition some period of adaptation may be necessary, and some temporary hardships endured, the result in all cases must be beneficent, and is, at all events, beyond the power of lawgivers to control or to resist.

"The Edinburgh Royal Society sprung partly out of the example of the Royal Society of London. But its immediate antecedent was the Philosophical Society, which had been founded nearly fifty years before by the celebrated McLaurin, and contained many distinguished names. Lord Kames became its president, and raised it to considerable distinction, both in science and literature, although that vigorous and versatile thinker and writer did not live to witness the commencement of the new institution. Dr. Robertson's plan was to absorb this Society and all its members in a new institute, on the model of the Berlin Academy of Sciences, for the prosecution both of physical science and of literature. The charter, however, was not obtained without some controversy, for, even as Romulus and Remus quarrelled over the boundaries of unbuilt Rome, so did the Philosophical and the Antiquaries squabble over the charter of the Royal Society. The Antiquaries wanted a charter of their own; Dr. Robertson thought Scotland not wide enough for two such institutions; the feud ran high, and great was the "dust," as Prof. Dalzel calls it, which was raised by Lord Buchan on the occasion. Some notice of this dispute will be found from the Antiquaries' side of the question in the recent life of Henry Erskine; and it is also alluded to in Mr. Cosmo Innes' work, where a letter is quoted from the energetic Professor of Greek couched in terms more forcible than philosophical. But it is certainly time to bury such feuds when they come to be a hundred years old. I find, from the minutes of the first meeting, that the Society was of opinion that the College Library was an inconvenient place for their usual meetings, and a committee was appointed to find one more suitable, apparently without success, for they continued to be held in the Library for twenty-three years, when the Society migrated to the Physicians' Hall in George Street in 1807. They afterwards purchased No. 40, George Street, in which the meetings were held until they obtained their present rooms in the Royal Institution. At a subsequent meeting, held on August 4, 1783, it was resolved that the Society should divide into two classes, which should meet and deliberate separately, to be called the Physical Class and the Literary Class, with separate office-bearers.

"The first president was Henry, Duke of Buccleuch, who had rendered great assistance in obtaining the charter. The vice-presidents were the Right Hon. Henry Dundas and Sir Thomas Miller, the Lord Justice-Clerk. I forbear to go over the names of what may be called the original members of the Society. I include in that term all who were elected within the first ten years. All the members of the Philosophical were assumed without ballot; the rest, to the number of more than 100, were elected by ballot, and a general invitation was made to the Lords of Session to join. These were the ordinary resident members. There was also a list of non-resident members, which comprised nearly as many. Of the ordinary resident members there is hardly a name which is not known—I might say conspicuous—in the annals of Scotland at that time. Twelve of the Lords of Session accepted the invitation, including the Lord President, the Lord Justice Clerk, and the Lord Chief Baron of the day; upwards of twenty professors, with Principal Robertson at their head; twenty-two members of the bar, including Sir Hay Campbell, the Lord Advocate, and of these at least fourteen rose afterwards to the bench. The medical contingent included Munro, Cullen, Gregory, and Home; and the non-resident list contained the names of the Duke of Buccleuch, the Earl of Morton, the Earl of Bute, the Earl of Selkirk, Lord Daer, James Steuart Mackenzie, the Lord Privy Seal, Sir George Clerk Maxwell of Penicuik, Sir James Hall of Dunglass, and many other familiar names. But I select from the list those of the members on whom fell the burden of the real work; and I venture to say that no city in Europe could have brought together a more distinguished circle. They were—Hay Cambell, Henry Dundas, Joseph Black, James Hutton, John Playfair, Adam Smith, William Robertson, Dugald Stewart, Adam Ferguson, Alexander Monro (*secundus*), James Gregory, Henry Mackenzie, Allan Maconochie, and William Miller of Glenlee. I ought to add to these Sir James Hall of Dunglass, and Sir George Clerk Maxwell of Penicuik, the last of whom died the first year. Some of these names are European; all are celebrated; and these were men who, for the most part, did not merely contribute the lustre of their names to the infant Association, but lent the practical vigour of their great intellectual power to aid in the first steps of its progress. And very soon the impress thus stamped on the Society began to establish its reputation in the world, and it took no undistinguished place among the learned societies of Europe. I find the names of Goethe and Buffon among the original foreign members; and although the events of the next twenty years interrupted our relations with the Continent, by the time the Society had completed the half-century there was scarcely a distinguished *savant* in Europe who had not joined, or been invited into, our ranks.

"In the Physical Class were four men who rose to great positions in the scientific world, and to whom the Society was greatly indebted for their general reputation, and for the vigour and efficiency with which their proceedings commenced. They were James Hutton, Joseph Black, John Playfair, and Dugald Stewart. Hutton and Black were then in the zenith of their fame, and have left a strong impress on the first years of our Society. I am desirous, in this review of the Society's early days, to revert with gratitude and respect to the memory of one whose labours on behalf of the Society were invaluable. Hutton was an observer and a thinker of remarkable originality and power. Black, again, was a Frenchman by birth, although his parents were British, and he was nearly related both to Adam Smith and to Adam Ferguson. He came to Scotland when he was about twelve years old, and, long before the institution of the Royal Society, had risen to the front rank of European chemists—his discoveries on pneumatic chemistry and latent heat having laid the foundation of much that is valuable in subsequent investigations, and opened a course of inquiry pursued with great ability in our own *Transactions* by Leslie, and Brewster, and Forbes." Lord Moncreiff having glanced at some peculiarities of the social meetings of those days between Black, Adam Smith, Hutton, and others, proceeded to speak of Playfair and Dugald Stewart, who by themselves could have raised to distinction any circle to which they belonged. "Both of them were men of great versatility, and, within the walls of the Royal Society, capable of filling a foremost place whether in the fields of abstract science or in those of literature or mental philosophy. Dugald Stewart's contributions to the *Transactions* are not so numerous as those of Playfair; but no man had more influence in moulding the tone and cast of thought prevalent among the cultivated class of his countrymen than that most popular and most eloquent instructor of youth. But no one can study these volumes of the *Transactions*, as I have done, without feeling that, for the first two decades of the existence of the Royal Society, Playfair was the soul and life of the institution. His versatility and power have impressed me exceedingly, high as was the estimate I had previously formed of him. Profound and transparently clear, whatever might be the topic, he bears about with him a far-reaching vigour which never flags. Whether it be the origin and investigation of porisms, or the astronomy of the Brahmins, or their trigonometrical calculations, or meteorological tables, or a double rainbow, nothing seems too great or too small for him.

"There are many curious and interesting by-paths, both of science and of literature, traversed in these earlier volumes. In 1787 Mr. George Wallace read a paper, which he did not incline to have printed in the *Transactions*, which I regret, for it related to a subject the interest of which has not ceased by the lapse of nearly a century. Its title was, 'On the Causes of the Disagreeableness and Coldness of the East Wind.' In the first volume of the *Transactions* a very singular problem was presented to the Society, through Mr. Adam Smith, along with other learned bodies in Europe, by a Hungarian nobleman, Count Windischgratz, and a prize was offered by him of 1000 ducats for the best solution of it, and 500 ducats for an approximation to a solution. It was a bold effort of philanthropy, for its object was the abolition of lawyers for the future. The problem was addressed to the learned of all nations. It was couched in Latin, but was in substance this:—'To find formulæ by which any person might bind himself, or transfer any property to another, from any motive, or under any conditions, the formulæ to be such as should fit every possible case, and be as free from doubt and as little liable to controversy as the terms used in mathematics.' I suppose that the prospect here held out of dispensing for the future with the least popular of the learned professions inclined the Society to entertain it favourably, for they proceeded to invite solutions of the problem, and three were received by them. In 1788 we find it recorded in the minutes that Mr. Commissioner Smith (for so the author of the 'Wealth of Nations' was designated) reported the opinion of the Committee that none of the three dissertations amounted to a solution, or an approximation to a solution, of that problem; but that one of these, with a certain motto, although neither a solution nor an approximation to a solution, was a work of great merit; and Mr. Fraser-Tytler was instructed to inform Count Windischgratz of their opinion. Whether this meritorious dissertation obtained the 500 ducats or not, we are not informed, but as lawyers continue to flourish, and legal terminology to produce disputes as prolifically as ever, it seems clear that the author had not earned them.

"Now that we have an Observatory on Ben Nevis, our successors at the end of the next century will know accurately the conditions of the climate under which the hundred years have been spent. There are, however, some details scattered over these volumes which are sufficiently interesting, although whether they show any material alteration in our seasons may be doubtful. The only cheering fact which they disclose is that the first set of returns is decidedly the most discouraging, and certainly does not support the idea that the mean temperature in the olden time was higher than it is now. There are two sets of returns printed in the first volume of the *Transactions*—one kept at Branxholm from 1773 to 1783, communicated by the Duke of Buccleuch, who was the first president of the Society; and the second by Mr. Macgowan, kept at Hawkhill, near Edinburgh, from 1770 to 1776. In the first, the mean temperature of the ten years is 44°; in the second, 45°—not a very genial retrospect. Things must have been somewhat discouraging for the farmers in 1782, for a paper is noticed in the second volume of the *Transactions*, by Dr. Roebuck, of Sheffield, who was the manager of the Carron Iron Works, recommending farmers not to cut their corn green in October, although there was ice three-quarters of an inch thick at Borrowstounness, because corn would fill at a temperature of 43°. Things looked brighter from 1794 to 1799, for which years we have results furnished by Playfair. For the first three years—1794, 1795, and 1796—the mean temperature was 48°; and that although 1795 was one of the most severe winters on record, the thermometer having stood frequently several degrees below zero, and a continuous frost having lasted for 53 days. The mean temperature in 1794, however, was 50°. The account of the great frost of 1795, which is given in the *Transactions*, is well worth referring to. In the next three years the mean temperature was 48°, that of 1798 being 49°·28. Of this year (1798) Playfair says that the climate of this part of the island hardly admits of a finer season. No tables were furnished to the Society, in continuation of those of Prof. Playfair, until 1830, when fortunately Dr. Barnes of Carlisle communicated to the Society a series of meteorological tables kept at Carlisle for the first twenty-four years of the century. The results seem mainly to concur with those of Prof. Playfair—the mean temperature for the twenty-four years being 47°·4547, being 3° higher than the average of the ten years from 1773 to 1783 at Branxholm, and 2° higher than the mean temperature of the seven years from 1770 to 1776 at Hawkhill. The highest temperature I have noted in these returns is that of May 1807, when the thermometer stood at 85° at Carlisle, and the next, that on the 5th of August, 1770, when the thermometer at Hawkhill was at 81°. The two years of the century in which the mean temperature was the highest were 1811 and 1822, in both of which years it was 49°.

"Of the purely scientific part of the Royal Society's work for the first fifteen years of its labours, while Hutton and Black and Playfair and Stewart were in full vigour, it is not too much to say it was brilliant—full of interest, full of power, and full of enthusiasm. The first great founders of course gradually waned, and all such associations are necessarily subjected to alterations of the tide, but as the tale goes on the mathematical papers begin to bear the names of John Leslie and William Wallace. We encounter Walter Scott in 1800, in 1808 the name of David Brewster, and in 1811 that of Sir Thomas Macdougall Brisbane, whose names adorned and whose labours were in the future the prop and stay of the Society. Of Scott I need not speak; but of the services rendered by Brewster it is impossible to express myself too strongly. He, too, like Playfair, had a mind of rare versatility. He could observe, as well as draw from his own resources. He could reason as well as describe. He could build a framework of sound deduction from the most unpromising hypothesis, and work out with unflagging spirit the thread of demonstration, however slender. He was the most prolific contributor of his day; nor do I think that any one but himself in these times could have kept the fire lighted by Hutton and Playfair burning so brilliantly. For it is not to be disguised that in the heat of the Continental struggle an air of languor creeps over the proceedings. The joyous enthusiasm of 1783 refuses to be invoked, and is elicited in vain. Nor is it wonderful. When the Gauls were so nearly at our gates, the safety of our own commonwealth was comparatively our only care. But when 1815 had arrived, and men's minds, set free from the long anxiety, had again tranquillity to cultivate the arts of peace, the energy of the rebound was great, and the history of British science has been one continued triumph ever since. By the exertions of Brewster and Brisbane, and many other associates, our Society again began to flourish, both leading and following the course of discovery as the stream flowed on. Both of these men continued to be the pride and ornament of the Society long after the expiration of the half-century which I have assigned to myself as my limit, for Thomas Brisbane succeeded Sir Walter Scott as president in 1832, and survived until 1860. Long before that a new generation had surrounded the veteran philosophers, and their destiny has been to recount and carry forward discoveries of which even Brewster and Brisbane hardly dreamt.

"Enough for the present of this retrospect, and the slender tribute I have attempted to pay to the memory and labours of a masculine and powerful generation. That we have built on their discoveries and learnt even by their errors is quite true; for the history of the second half of the century exhibits science far in advance of 1783, and even of 1833. In 1783 geology was in its infancy; palæontology was all but unknown. Cuvier was only then commencing his pursuits in comparative anatomy, which were to end in reproducing the forms of extinct life. The Glacial epoch had not then been elucidated by the research and genius of Forbes and Agassiz, and the dynamic theory of heat was still unproclaimed. The wonders of the photographic art were unknown even in 1833, for Talbot and Daguerre did not come on the scene for several years afterwards. In 1833 the apostle and disciples of evolution had not broken ground on that vast field of inquiry. Spectrum analysis and the marvellous results which it has already furnished and those which it promises have in our day only heralded the advent of a new science. But however far in advance of the founders of the Royal Society the current philosopher may be, there was a robustness and characteristic individuality about the great men of that generation which we may not hope to see replaced. We may assume—indeed, we hope—that the close of the next century will find the progress of knowledge as far advanced beyond its present limits as we think that the science of to-day is beyond the point reached a century ago. We may be assured that before that time arrives many surmises, still in the region of hypothesis, will have become certainties, and that many supposed certainties will have turned out fallacies. Many errors will have been corrected, many dogmas discredited, many theories confirmed or refuted, at the bar of ascertained fact, as those of 1783 have been. Yet even then will our successors, I trust, as we do now, stand reverently before the memory of our founders. Happy is the institution which can show such a muster-roll, and happy the country which can boast such sons. I take leave of my theme with the fervent hope and firm conviction that in the century which we now inaugurate the Royal Society will continue with success the noble task to which by its charter it is devoted, of investigating the hidden treasures of nature and appropriating them to the benefit and happiness of mankind."

INSTINCT

I. *Is there a Science of Comparative Psychology?*

"IN the family of the sciences Comparative Psychology may claim nearest kinship with Comparative Anatomy; for just as the latter aims at a scientific comparison of the bodily structures of organisms, so the former aims at a similar comparison of their mental structures." These words form the opening sentence of Mr. G. J. Romanes' Introduction to his recently published volume on "Mental Evolution in Animals," and in a footnote he is careful to remind us that the phrase "mental structures" is used in a metaphorical sense. Let us consider how far a comparison of the mental structures of animals, even in a metaphorical sense, is possible.

Our knowledge of mind is either direct or inferential: direct on the part of each individual so far as his own individual mind is concerned; inferential so far as the minds of others are concerned. For it is a law of our being that mind cannot come into direct contact with mind. This fact—that the mental processes of our neighbours can never come within the sphere of our objective knowledge—has long been recognised (see *ex. gra.* Berkeley, "Princ. Hum. Know.," §§ 27 and 145; Kant as quoted in F. Pollock's "Spinoza," p. 177); and the late Prof. Clifford (see "Lectures and Essays," vol. ii. p. 72) coined the exceedingly convenient term *ejective* as descriptive of that class of phenomena which belong neither to the subjective nor to the objective category. My neighbour's mind is not and never can be an object; it is an eject, an image of my own mind thrown out from myself. Into every human being that I meet I breathe this subtle breath; and that man becomes for me a living soul.

Our knowledge of mind is therefore partly subjective, partly ejective. Now it is perfectly obvious that, were I an isolated unit, shut off from all communication with my fellows, no science of psychology would be possible for me. I might by the analysis of my own mental processes arrive at certain conclusions with regard to my own states of consciousness; I might reach some sort of knowledge of the working of my own mind. But this would not be a science of mind. A science of mind only becomes possible when I am able to compare my own conclusions with those which my neighbours have reached in a similar manner. By means of language human beings can communicate to each other the results which each has obtained; and each human being is able *to submit these results to the test of subjective verification*. For human beings therefore a *science* of psychology is possible just in so far as the results obtained indirectly are capable of direct *verification*.

One of the most remarkable results of modern scientific investigation is the establishment of a more or less definite parallelism between the phenomena of ejective psychology (thus capable of subjective verification) and certain objective phenomena of physiology—a parallelism of psychosis and neurosis. But these phenomena of physiology are not restricted to the human subject; and we therefore have grounds for believing that running parallel to the neuroses of animals there are certain psychoses. And it would seem at first sight possible that corresponding to a science of comparative neurosis we might have a science of comparative psychosis. We must remember, however, that it is only on the lower mental levels, so to speak, that we know anything approaching to definiteness with regard to the parallelism of neurosis and psychosis. All, therefore, that, as scientific investigators, we seem to have any grounds for inferring is that accompanying the neuroses of animals there are in all probability some kind of psychoses. We may speculate as to the character of these psychoses—and in the case of the higher mammalia our speculations are probably by no means worthless—but we cannot construct a comparative *science* of these psychoses because the results we obtain ejectively are incapable of direct verification. As a speculation modern constructive psychology has its value—like other speculations it may give direction to our scientific investigations—but let us not forget that the invaluable process of verification is, from the nature of the case, impossible.

To sum up. All our knowledge of minds other than our own is ejective; but in the case of human psychology the results reached ejectively may be verified subjectively. Animal minds are also ejective; they are more or less distorted images of our own minds. But such is the extraordinary complexity of the human mind—a complexity largely due to the use of language—that we may well suppose that any conception we can form of animal consciousness is exceedingly far from being a true conception. The results of comparative psychology—the science which has for its object the comparative study of these distorted images of our own mental processes—are incapable of verification. These are the facts which have to be taken into consideration when we seek an answer to the question "Is there a science of comparative psychology?" Notwithstanding that it has won for itself a more or less recognised place among the sciences, I venture to submit that our answer to this question should be an emphatic negative.

It must be noted, however, that I here mean by psychology the science which deals with subject and eject. If we include under psychology the science which deals with the "perpetual adjustments of special inner actions to special outer actions which accompanies increasing evolution of the nervous system," or that to which Mr. Herbert Spencer gives the name *objective* psychology ("Prin. Psychol.," vol. i. p. 142), our answer will of course be different. Objective psychology, or the comparative physiology of the nervous system *plus* a comparative study of the corresponding adjustive actions, has every right to be termed a science because the results obtained admit of verification. And it is a science in which Ferrier, Hitzig, Romanes, and others have done good work.

2. *The Place of Consciousness*

There would seem to be four hypotheses with regard to the place of consciousness in the animal world.

1. That according to which consciousness is a motive power (Free Will).

2. That according to which consciousness is altogether absent (Automatism).

3. That according to which consciousness is a product (Conscious Automatism).

4. That according to which consciousness is a guide (Determinism).

1. *Free Will.*—By free will I here mean the power of initiating actions by the mere volition of the self-conscious *Ego*. The exercise of free will involves an interference *ab extrâ* with the normal working of the nervous system.

This is not the place for a discussion of free will and determinism. That battle must be fought out within the domain of human psychology. From its bearing on the question of animal consciousness, however, I may be permitted to say a few words on the subject.

The answer which the ordinary believer in free will gives to the determinist is contained in three words—*I can choose*—and he thinks that there is an end of the matter. But the real point at issue lies deeper down, and is involved in the question—*What am I?* Let us hear the answer which the determinist gives to this question. I am, he replies, the sum of my states of consciousness at any moment. Apart from the stream of my mental states I, as a self-conscious individual, have no existence. This stream of conscious states or psychoses I believe to be the subjective aspect of a stream of nervous states or neuroses. And this stream is rigidly subject to law. But if these states of mind—under which head must be included states of definite consciousness, states of sub-consciousness, and states of submerged consciousness—if these states of mind, I say, constitute *me*, then, since these states of mind determine those which follow, these following states, and the actions which accompany them, are determined by me. But at the same time they are part of an orderly sequence subject to law. The moment I identify myself with my states of mind I begin to see clearly that free will in the common-sense acceptation of the term—that is, a sense of individual choice—is perfectly compatible with the doctrine of determinism—that my mind is completely subject to law. The sense of choice I undoubtedly possess is due to the temporary equilibrium of motives, and the eventual prevalence of one set of motives over another set of motives. The freedom which every man is conscious of possessing is freedom to act in accordance with his own character.

"Freedom," says Kant, "is such a property of the will as enables living agents to originate events independently of foreign determining causes." This at first sight seems utterly opposed to determinism. And yet it contains a central core of truth which every determinist will accept. No determinist can deny that every human being carries about with him a special something, peculiar to himself, which is a most important factor—constituted as we are, the most important factor—in determining his choice in any act of volition. This special something we call, ejectively, his character, and, objectively, his organisation. Men are not like inorganic clouds at the mercy of external forces, but contain the springs of action in themselves. The brain is not merely a mass of inert matter; but a mass of matter cunningly organised, in which is locked up a vast store of potential energy. The organism is, moreover, a *variable* piece of mechanism. Hence at different times it reacts differently under the influence of the same stimulus. And this difference of reaction helps to fix the idea that the will is absolutely free. On a certain occasion we acted in a certain way. We see on reflection that our action was not the best. On a similar occasion afterwards we act differently. And we then imagine that we could have acted differently in the first instance. But it is clear that the two cases are not alike. Reflection has altered one of the determinants of action, the character. The character having changed, the action is different. Such a definition as Kant's—the essential truth of which I take to be that a man's actions are the outcome of his character—is as valuable to the determinist as to any one else. At the same time "it is inconceivable," as Chaldai Creskas said long ago (*circa* 1410), "that two men, being themselves of like temper and character, and having before them like objects of choice in like circumstances, should choose differently" (quoted from F. Pollock's "Spinoza," p. 96).

Determinism simply comes to this—that both on the objective side and on the subjective side our actions are determined by law. On the one hand a perfect knowledge of the organism *plus* a perfect knowledge of any stimulus and the surrounding conditions would enable us to say how the organism would act under that stimulus. On the other hand a perfect knowledge of the character *plus* a perfect knowledge of any motive and the circumstances of the case would enable us to say what feelings would result (the actions being the objective side of the feelings). If by free will it is meant that our actions are the outcome of the play of a motive-stimulus on our character-organisation, then free will and determinism are at one.

But this is not what is meant by those who maintain the doctrine of free will. What is meant by them is this—that presiding alike over our thoughts and actions, initiating, guiding, and inhibiting, there is a certain "masterful entity," the self-conscious *Ego*. This *Ego*, though in no wise connected with our bodily organisation, has nevertheless the power of interfering with the action of that organisation. And it is absolutely free, utterly unfettered by law. This doctrine I reject: not because I am in a position to disprove it, but because I see no reason for accepting it. And rejecting this doctrine in the sphere of the human mind, I feel bound to reject it in the sphere of animal intelligence. But I am not blind to the fact that many of my neighbours do not reject it in the sphere of the human mind. To them two courses are open: either to extend it into the sphere of animal intelligence, or not so to extend it. If they do so extend it, they thereby render the study of animal intelligence incapable of scientific treatment, even from the objective standpoint, by the introduction of a factor not subject to law. If they do not so extend it, they must accept one of the three views next to be considered.

2. *Automatism.*—Very little space need be devoted to a doctrine that very few believe. Those who accept the doctrine of the parallelism (or identity) of neurosis and psychosis and add to this a belief in evolution are logically bound to accept the corollary that the neuroses of animals are accompanied by some kind of psychoses which more or less dimly foreshadow our own psychoses. Those, however, who reject the hypothesis of evolution, or at least deny its application to the mind of man, and who believe in the doctrine of free will as restricted to the human being, will, not improbably, accept the doctrine of automatism in animals. In any case it is a theory upon which the study of organic processes, reflex, instinctive, and intelligent (or selective), admits of scientific treatment. It is indeed "objective psychology" *plus* the dogmatic assertion that consciousness is absent.

3. *Conscious Automatism.*—"Materialism," says Mr. Romanes, "is logically bound to argue in this way: We cannot conceive of a conscious idea, or mental change, as in any way affecting the course of a cerebral reflex, or material change; while, on the other hand, our knowledge of the conservation of energy teaches us as an axiom that the cerebral changes must determine each other in their sequence as in a continuous series. Nowhere can we suppose the physical process to be interrupted or diverted by the psychical process; and therefore we must conclude that thought and volition really play no part in determining action. Thoughts and feelings are but indices which show in the mirror of the mind certain changes that are proceeding in the matter of the brain, and are as inefficient in influencing those changes as the shadow of a cloud is powerless to direct the movements of that of which it is the shadow. . . . This is opposed to common sense, because we all feel it is practically impossible to believe that the world would now have been exactly what it is even if consciousness, thought, and volition had never appeared upon the scene—that railway trains would have been running filled with mindless passengers, or that telephones would have been invented by brains that could not think to speak to ears that could not hear" (*Nineteenth Century*, December, 1882, p. 879). How far the materialist—the logical results of whose doctrine are apt to be forced on him from all sides—is ready to accept this particular logical result I leave it for him to say. It is at any rate a possible view, and, like that of unconscious automatism, is one upon which a scientific treatment of organic processes is admissible.

4 *Determinism*—This view has already been incidentally given under the heading of the directly opposed doctrine of free will. It is the doctrine of the parallelism (or identity) of neuroses and psychoses, which, both in their subjective and objective aspects, are rigidly law-bound. Determinism may be treated either from the philosophical or from the scientific standpoint. From the point of view of the man of science we may say that consciousness is a *guide* to action and has been a guide in evolution; that during the process of evolution there gradually emerged something distantly related to what we know in ourselves as consciousness, which at a very early stage of evolution became, so to speak, polarised into pleasurable and painful; that those actions which were associated with pleasurable feelings were more frequently performed than those associated with painful feelings; that those organisms in which there was an association between right action and pleasurable feelings would stand a better chance of survival than those in which the association was between wrong actions and pleasurable feelings; and that finally those organisms in which conscious adjustments of all orders were more perfectly developed would be the winners in life's race. Some such deductions as these would seem to be admissible on the hypothesis of evolution. With such questions as How have psychoses become associated with neuroses? or Why have psychoses been associated with neuroses? or How can psychosis exercise a guiding influence on neurosis?—with such questions as these the man of science, as such, has nothing to do. These are questions for the philosopher, and this is, therefore, not the place to discuss them. Suffice it to say that we must either accept some such view as that advocated by Clifford in his masterly essay "On the Nature of Things in Themselves" ("Lectures and Essays," vol. ii. p. 71) or be content to confess our ignorance.

Upon this view of the place of consciousness in the animal kingdom, the study of organic processes, reflex, instinctive, and intelligent (or selective), admits of scientific treatment. A science of "objective psychology" is possible for us; and a science of ejective psychology is also possible, but not for us.

3. *The Lapse of Consciousness*

One of the most surely established inductions of psychology is this: that the more frequently an action is performed the more perfectly automatic does it become—the more does it tend to pass into stereotyped reflex action. Actions which are at first performed with that definite consciousness implied in the term close attention can, after frequent repetition, be performed almost, if not altogether, without even indefinite consciousness. It would seem that after the definite establishment of the nerve connections necessary for the performance of certain actions or sets of actions the guiding influence of consciousness might be withdrawn.

This principle is too well known to require illustration here. I shall therefore content myself with drawing attention to one or two of its corollaries.

1. Since the same action or set of actions may be performed with full consciousness—a consciousness of the end in view, and of the means necessary to that end—with indefinite consciousness, or with a vanishing amount of consciousness, it is impossible for me to say what amount of consciousness, if any, an action performed by my neighbour involves. Again and again we see our neighbours perform most complicated actions—such as winding up their watches—with so little consciousness as to leave no trace upon the memory. Abernethy quotes a case of a lawyer writing out an important opinion in his sleep. Still more impossible is it for me to say what amount of consciousness, if any, an action performed by one of my dumb companions involves. Decapitated frogs—in which we have some grounds for believing that consciousness is absent—perform a number of seemingly purposive actions.

2. Since those actions which are frequently and persistently performed by the individual have a tendency to pass into the automatic and unconscious stage, it would seem highly probable that those actions which have been performed not only by the individual but by a long line of ancestors whose organisation he inherits are, or very soon become, completely, or in a very high degree, automatic and unconscious. Who can say what amount of consciousness, if any, is involved in the actions of newly-born piglings or newly-hatched chicks?

3. It would therefore seem difficult or impossible to disprove the hypothesis that all truly instinctive actions—in so far as they are not modified (as they so often are modified) by a little dose of reason—are automatic and unconscious. I do not mean to maintain that hypothesis. But I say that, having regard to the known phenomenon of the lapse of consciousness, I do not see how that hypothesis could be disproved.

4. *The Psychological Definition of Instinct*

"Instinct," says Mr. Romanes in his recently published "Mental Evolution in Animals" (p. 159), repeating the definition given in "Animal Intelligence" (p. 17), "Instinct is reflex action into which there is imported the element of consciousness. The term is therefore a generic one, comprising all those faculties of mind which are concerned in conscious and adaptive action, antecedent to individual experience, without necessary knowledge of the relation between means employed and ends attained, but similarly performed under similar and frequently recurring circumstances by all individuals of the same species."

To such a psychological definition of instinct there seem to me to be two grave objections. First, there is the general objection, indicated in the first section, arising out of the ejective nature of our knowledge of animal consciousness. Secondly, there is the special objection raised under the head of "The Lapse of Consciousness." These objections have not escaped Mr. Romanes' notice, but I think he underestimates them. "No doubt," he says ("Ment. Evol.," p. 160), "it is often difficult, or even impossible, to decide whether or not a given action implies the presence of the mind-element—*i.e.* conscious as distinguished from unconscious adaptation; but this is altogether a separate matter, and has nothing to do with the question of defining instinct in a manner which shall be formally exclusive, on the one hand of reflex action, and on the other of reason." But I venture to think that the difficulties of application are from the very nature of the case insuperable, and that the definition is therefore, whatever its logical value, practically of little service.

Again, on p. 17 of his recent volume, Mr. Romanes tells us that "the only test [of the conscious choice element] we have is to ask whether the adjustments displayed are invariably the same under the same circumstances of stimulation. The only distinction between adjustive movements due to reflex action, and adjustive movements accompanied by mental perception, consists in the former depending on inherited mechanisms within the nervous system being so constructed as to effect *particular* adjustive movements in response to *particular* stimulations, while the latter are independent of any such inherited adjustment of special mechanisms to the exigencies of special circumstances." And a little further on (p. 18) he says, "It is enough to point to the variable and incalculable character of mental adjustments as distinguished from the constant and foreseeable character of reflex adjustments." All which may be very true. But it seems to cut away the ground from under his definition of instinct. For surely what he says here of reflex actions is also true of instinctive actions. Surely instinctive actions "depend on inherited mechanisms within the nervous system being so constructed as to effect *particular* adjustive movements in response to *particular* stimulations." Surely we may also point to the "constant and foreseeable character of *instinctive* adjustments."

But though an instinctive action may involve no consciousness in the individual, it may have involved consciousness, during the process of its evolution, in the ancestors of the individual. In this way, perhaps, we may admit consciousness into our definition of instinct. But if we hark back to ancestors in one case, we may fairly do so in another. And since the secondary instincts of the individual involved intelligence in his ancestors, we must import not only consciousness but intelligence into our definition of instinct. If we admit lapsed consciousness, why not admit lapsed intelligence? Our definition will then become: Instinct is reflex action into which is imported (ancestrally) the elements of consciousness and intelligence. In which case instinct and reason run together.

It seems to me, therefore, that the psychological definition of instinct lacks that definiteness of application which is not merely desirable but essential. If I might be permitted to paraphrase Mr. Romanes I would say, "I am persuaded that if we are to have any approach to definiteness in the terms which we employ—not to say to clearness in our ideas concerning the things of which we speak—it is" *not* "desirable to restrict the word instinct to mental as distinguished from non-mental activity." And this just because it is so "difficult, or even impossible, to decide whether or not" instinctive actions "imply the presence of the mind-element—*i.e.* conscious as distinguished from unconscious adaptation."

5.—*A Physiological Definition of Instinct*

"Instinctive actions are actions which, owing to their frequent repetition, become so habitual in the course of generations that all the individuals of the same species automatically perform the same actions under the stimulus supplied by the same appropriate circumstances." This physiological definition of instinct, which is incidentally given by Mr. Romanes ("Animal Intelligence," pp. 16–17), is, if I mistake not, of more practical and scientific value than the psychological definition which immediately follows, and which introduces "the element of consciousness" and "faculties of mind."

Were it impossible to define instinct in such a manner as to be formally exclusive, on the one hand, of reflex action, and, on the other, of intelligent (or selective) action, without having recourse to the associated phenomena of consciousness, then it might be advisable to introduce consciousness into our definitions for the sake of giving them a logical status. And Mr. Herbert Spencer seems to see this difficulty when he defines *or describes* instinct as compound reflex action. But, though reflex action shades into instinctive action, and instinctive action (as seen in the phenomena described by Mr. Romanes, under the heading "The Plasticity of Instinct") into intelligent action, still some such definitions as the following would seem sufficiently to answer to the demand for formal exclusiveness:—

1. *Reflex Actions* are actions taking place in, or performed by, an individual in virtue of his possession of a general type of nervous organisation.

2. *Instinctive Actions* are actions performed by the individual in virtue of his possession of a special type of nervous organisation, that is, a type of organisation common to his species.

3. *Intelligent (or Selective) Actions* are actions performed by an individual in virtue of his possession of an individual nervous organisation, that is, an organisation special to himself.

If we call the foundation type of nervous organisation (in the mammalia, for example) *a*, the special modification of that type (in all dogs, for example) *b*, and the individual modification developed in some individual (say Dr. Huggins's "Kepler") *c*; then reflex actions are the outcome of *a*, instinctive actions the outcome of $a+b$, and selective or intelligent actions the outcome of $a+b+c$.

That there are difficulties in the application of these definitions to special cases I readily admit, but I venture to submit that they are by no means of so grave a nature as those involved in the psychological definitions advocated by Mr. Romanes.

I need not say here that such definitions do not by any means imply the absence of consciousness, since I have devoted a special section to *The Place of Consciousness* with the special object of showing that the doctrine of determinism, which I accept, maintains the parallelism or identity of psychosis and neurosis.

6.—*The Origin and Development of Instincts*

This article has already exceeded the length to which it was intended to run. On this head, therefore, I must be brief. The problem of the origin and development of instincts comes to this—How has it come about that certain nervous structures, and the actions which are their external and obvious manifestations, are developed in all the members of a certain species? It is clear that such a development of certain structures and their corresponding actions in all the individuals of a particular species must answer to a widely felt need. The actions answer to circumstances of frequent occurrence in the life-history of the species, just as intelligent actions "answer to circumstances of comparatively rare occurrence in the life-history of the species" ("An. In.," p. 17). The question is—How far is the equilibration direct, *i.e.* by adaptation, and how far is it indirect, *i.e.* by natural selection? To discuss this question would require a separate article. I content myself with giving two quotations, the former from Mr. Darwin, the latter from Mr. Spencer. "I believe that most instincts are the accumulated result, through natural selection, of slight and profitable modifications of other instincts, which modifications I look at as due to the same causes which produce variations in corporeal structures. . . . . But in the case of the many instincts which, as I believe, have not at all originated in hereditary habit, I do not doubt that they have been strengthened and perfected by habit; just in the same manner as we may select corporeal structures conducing to fleetness of pace, but likewise improve this quality by training in each generation" (quoted "Ment. Ev. in Ans.," p. 264). So far Mr. Darwin. Mr. Spencer says: "The equilibration of organisms that are comparatively passive is necessarily effected indirectly by the action of incident forces on the species as a whole. But along with the gradual evolution of organisms having some activity, there grows up a kind of equilibration that is relatively direct. In proportion as the activity increases, direct equilibration plays a more important part. Until, when the nervo-muscular apparatus becomes greatly developed, and the power of varying the actions to fit the varying requirements becomes considerable, the share taken by direct equilibration rises into co-ordinate importance" ("Princ. Biol.," vol. p. 468). It seems to me that we have here substantial agreement as to the part played by indirect equilibration in laying the foundation, and the part played by direct equilibration in perfecting the superstructure. (I venture to think that Mr. Romanes somewhat mistakes Mr. Spencer's position with regard to the "very subordinate importance of natural selection as an evolving source of instinct," and with regard to the question of "lapsed intelligence.")

7. *Conclusion*

One or two words in conclusion by way of summary.

1. While fully admitting the great interest that attaches to the study of the inferred mental faculties of the higher brutes, I believe that, from the ejective nature of the animal mind and the

necessary absence of verification, no science of comparative psychology, except such as is restricted to "objective psychology," is possible.

2. Of the four views of the place of consciousness in the animal world only one—that of *free will*—renders the study of the actions of animals incapable of scientific treatment. Of the other three I believe *determinism* to be the most satisfactory. According to this view both neuroses and psychoses are subject to law. But from our necessarily ejective knowledge of psychoses, we are forced to confine our attention (from the scientific point of view) to the objective phenomena of neurosis, especially as manifested in conduct. Of the psychoses we can know nothing with certainty; of the neuroses we may learn a little; of conduct we may learn much.

3. From the principle of the lapse of consciousness certain corollaries may be drawn—(*a*) that it is difficult or impossible to say what amount of consciousness, if any, an action performed by my neighbour involves; (*b*) that it would seem probable that the lapse of consciousness in the individual is paralleled by a lapse of consciousness in the species; and (*c*) that the hypothesis that instinctive actions are unconscious is incapable of disproof.

4. On the general grounds given in 1, and on the special grounds given in 3, I see grave difficulties in accepting the psychological theory of instinct—that instinct is reflex action into which is imported the element of consciousness.

5. In accordance with the principle thus advocated a physiological definition of instinct must be sought. Some such definition as this may be proposed: *Instinctive actions* are actions performed by the individual in virtue of his possession of a special type of nervous organisation, that is, a type of organisation common to his species.

6. The question of the origin and development of instincts thus becomes a question as to how this special type of structure has been evolved. It takes its place as part of the general question of the evolution of structures—the actions being the external manifestations of internal structures. To the question as to the relative importance of direct and indirect equilibration I could give no definite answer within the limits of this article, and therefore gave quotations from Darwin and Herbert Spencer.

C. LLOYD MORGAN

A NEW OBSERVATORY FOR PARIS

THE last number of the *Comptes Rendus* of the Paris Academy of Sciences contains a memoir by Admiral Mouchez, urging the necessity of removing to a separate establishment beyond the city the chief departments of the Paris Observatory. When the building was originally erected by Perrault about a mile to the south of the Luxembourg, the city scarcely reached beyond that point. But since then it has spread in every direction, completely surrounding the Observatory with lofty edifices, and charging the atmosphere with all sorts of gases, smoke, and other impurities. These altered conditions are all the more injurious that, thanks to the progress of astronomical studies, the power and accuracy of the instruments have to be continually increased, while a clear and still atmosphere is more than ever needed for taking observations. The vicinity of the Catacombs and of busy streets has also rendered the ground less firm than formerly.

In 1854, and again in 1868, these adverse conditions were brought before the Government, and discussed in the Academy. After a careful study of the situation, the Commission appointed by the Academy to inquire into the matter unanimously reported in 1869 in favour of a branch establishment outside of Paris; but this suggestion, although fully approved of by the Academy, was for various reasons allowed to fall into abeyance.

Since then the evils complained of have been aggravated, in spite of all the improvements introduced for the purpose of modifying them. Hence it becomes more than ever indispensable to carry out the project forthwith, if the Observatory wishes to maintain its efficiency and keep pace with similar establishments abroad. The most serious obstacles to its legitimate development are the disturbed and clouded state of the atmosphere in the centre of a large city, the constant vibrations of the ground, and the impossibility of accommodating the astronomers in the building, as is done in all foreign observatories. Hence arises an insurmountable obstacle to the proper organisation of the night service, while extreme difficulty is felt in improving the existing plant and obtaining other much needed instruments, for which no suitable position can be found.

Merely to erect the long-contemplated tower and cupola of the great telescope there would be required a Government grant of from 20,000*l.* to 24,000*l.*, besides at least an equal sum to prevent the erection of lofty houses in front of the new grounds and to purchase the instruments still needed. But even were such grants obtained, the Observatory would continue to labour under the serious inconveniences above described. Without, however, imposing such a burden on the State, the difficulty might be met, and the old historical edifice of Louis XIV. preserved, by erecting in one of the public domains a new and magnificent observatory furnished with all the improvements and appliances of modern science. In order to effect this, it would suffice to alienate about 22,000 square metres of gardens and open spaces surrounding the present Observatory, and serving only to isolate it from the neighbouring houses. Sold at the moderate estimate of from 4*l.* to 6*l.* per metre, a sum of nearly 120,000*l.* might be raised, which would be more than sufficient for the purpose.

After sacrificing enough land for the construction of two new streets in continuation of the Avenue du Luxembourg, and isolating the Observatory on all sides, it would still retain the northern court and a garden on the south 70 to 80 metres long by 50 broad. The building would thus also retain the exact appearance that it presented when originally constructed by Perrault. Here might be preserved the Archives, the Bureau des Calculs, the Museum, and three or four instruments still capable of rendering some service if placed at the disposition of the Faculty of Sciences for the instruction of students.

All the plans of some such project as is here proposed have already been prepared with the greatest care by the able architect, M. Deharme. They include accommodation for thirty astronomers and assistants with their families, all the instrumental and service rooms, the halls, and an underground gallery, a structure 300 metres high for the study of the atmosphere, gas works, a covered gallery connecting all the instruments with the apartments of the astronomers; lastly, the great cupola for the 16m. telescope, at a total cost of 98,350*l.* Including the price of the new instruments, fittings, and inclosing wall, this sum would be raised to 108,000*l.*, which might be obtained by the proposed sale of lands.

The Council has unanimously adopted this project, demanding that it be referred to the Academy and to the Bureau of Longitudes, which bodies had already pronounced favourably on some such scheme in 1854 and 1868. Thus no serious objections seem to stand in the way of a project by which alone the present adverse conditions may be removed, and France endowed with the most complete and finest observatory of modern times.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The Sherardian Botanical Chair at Oxford has at length been filled up by the election of Mr. Bayley Balfour, Professor of Botany at Glasgow. Mr. Balfour has had a distinguished career. Passing his student life at Edinburgh, he finally graduated as a Doctor of Medicine, receiving the University Gold Medal for his thesis, having previously carried off first class honours as Doctor of Science in Botany. Two years were spent in acquiring a practical knowledge of the methods of morphological and physiological research in the botanical laboratories of France and Germany under Profs. De Bary and Sachs. We next find him assisting his father, the Regius Professor of Medicine and Botany in the University of Edinburgh, in conducting his classes alike in the lecture-room, in the laboratory, in the herbarium, and in practical field work. For four years he was assistant to the Regius Professor of Natural History in the University of Edinburgh, and for six years he lectured on botany to the students of the Royal Veterinary College, until finally he was appointed Crown Professor of Botany in the University of Glasgow. Of good scientific work done there is an ample record. A valuable paper published in the *Philosophical Transactions* gives the result of his labours at Rodriguez, where he was sent by the Royal Society in 1874 as botanist and zoologist to the Transit of Venus Expedition. In 1880 we find him making a scientific exploration of the Island of Socotra, the results of which have been published in various periodicals, the final report on the botany of the island being now in course of publication by the Royal Society of Edinburgh. Prof. Balfour's wide experience in field, labotatory, and herbarium, will make him a valuable addition to the Natural

Science Staff of Professors in Oxford. As Magdalen College has under its new statutes added a Fellowship to the endowments of the Chair, we may congratulate the College on gaining another addition to its already long list of distinguished Natural Science Professors who are members of the Society. Profs. Westwood, Burdon Sanderson, Odling, Lawson, Balfour, Daubeny, Phillips, Brodie (now dead), were all members of the College.

On May 6 an examination will be held at New College to elect an Exhibitioner in Natural Science. The Exhibition will be given for proficiency in Chemistry and Biology.

At Magdalen College an open Demyship will be offered for Natural Science in June next.

The University College (London) School "Old Boys" annual dinner will be held this year at the Holborn Restaurant, on Tuesday, February 19, at 7 p.m.; George Buchanan, M.D., F.R.S., in the chair.

The Central Institution of the City and Guilds of London Institute in Exhibition Road is now approaching completion, and the Executive Committee are proceeding to appoint, in the first instance, four professors to the chairs of Chemistry, of Engineering, of Physics, and of Mechanics and Mathematics respectively. The salary attached to each professorship will be 1000*l.* per annum, with a prospect of increase depending upon the number of students in attendance. It is expected that the appointments will be made during the next few weeks. The Council of the Institute, at the request of the Duke of Buckingham and Chandos, have consented to lend, during the summer months, and pending the preparation of the fittings, a portion of the Central Institution to the Commissioners of the International Health Exhibition for the display of appliances for scientific and technical instruction and of the work done in technical schools here and abroad.

SCIENTIFIC SERIALS

The *Journal of Physiology*, vol. iv. Nos. 4 and 5, December, 1883, contains:—An account of the discussion which took place in the Physiological Section of the International Medical Congress held in London, 1881, on the localisation of function in the cortex cerebri. Prof. Goltz of Strasburg, it will be remembered, exhibited a dog, and Profs. Ferrier and Yeo a monkey. The brains of these animals were handed over to a Committee, consisting of Dr. Klein, Mr. Langley, and Prof. Schäfer. The report of this Committee is preceded by a memoir on the normal structure of the dog's brain, by J. N. Langley (plates 7 and 8), and the report consists of a report on the parts destroyed on the right side of the brain of the dog operated on by Prof. Goltz, by J. N. Langley (plates 9 and 10); of a report on the parts destroyed on the left side of the brain of the same dog, by E. Klein (plate 11); and of a report on the lesions primary and secondary in the brain and spinal cord of the Macaque monkey exhibited by Profs. Ferrier and Yeo, by E. A. Schäfer (plate 12).

The *Journal of the Royal Microscopical Society* for December, 1883, contains:—On some new Cladocera of the English lakes, by Conrad Beck (plates 11 and 12).—On an improved method of preparing embryological and other delicate organisms for microscopical examination, by Edward Lovett.—On the relation of aperture and power in the microscope, by Prof. E. Abbe.—On a new camera lucida, by Dr. Hugo Schröder.—On optical tube length, an unconsidered element in the theory of the microscope, by Frank Crisp.—Also the usual summary of current researches relating to zoology, botany, and microscopy.

The *American Naturalist* for December, 1883, contains:—On the development of a dandelion flower, by John M. Coulter.—Notes on *Chætonotus larus*, by C. A. Fernald.—Notes on the aborigines of Cooper's Creek, Austialia, by E. B. Sanger.—Zoological gardens, a critical essay by Theodore Link.—The Copperhead, by Dr. R. E. Kunze.—Experiments with the antennæ of insects, by C. J. A. Porter.—On the position of the Compositæ and Orchideæ in the natural system, by J. F. James.—On the habits of certain sunfish, by C. O. Abbott.—Recent literature, and general notes.

Revue Internationale des Sciences Biologiques, October 15, 1883, contains:—Translations of Mr. W. S. Duncan's—Probable region of man's evolution, and of Prof. Huxley's—Living beings and the method of studying them; Dr. Hubrecht—on the ancestral form of the Chordata; and Dr. W. G. Parker—on the people and language of Madagascar.

The number for November 15, 1883, contains:—An essay by Dr. Lanessan, on Buffon: his ideas, his *rôle* in the history of science, his work, and on the development of the natural sciences since his epoch, which essay is to serve as an introduction to a complete edition of Buffon's works, including his correspondence, to be shortly published by Le Vasseur, Paris.

Rendiconti del Reale Istituto Lombardo, Milan, December 29, 1883.—Reports on the work of the various physical, literary, ethical, mathematical, and political sections of the Institute during the year 1883, by the Secretary.—Meteorological observations made at the Brera Observatory, Milan, during the month of December, 1883.

Nachrichten von der K. Gesellschaft der Wissenschaften und der Universität zu Göttingen, December 1, 1883.—On the formation of isomerous derivatives of toluol, by Paul Jannasch.—On the irreducibility of linear differential equations, by Leo Königsberger.—On the polar repulsion, the coefficient of induction, and temperature of a magnet, and on the determination of the moments of inertia through bifilar suspension, by F. Kohlrausch.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 10.—"Extracts from a Report on the Volcanic Eruption in Sunda Strait by Commander the Hon. F. C. P. Vereker, H.M.S. *Magpie*, dated Singapore, October 22, 1883." Communicated by Sir Frederick Evans, K.C.B., F.R.S.

. . . On the 18th inst. I entered Sunda Strait, passing east of Thwart-way Island. This island had been reported to be split by the eruption into several portions. This is incorrect.

The island is intersected by low valleys in several places; these being covered with tall trees did not show so prominently formerly as they do now. The whole of the vegetation having been swept away by the tidal wave, the island at a short distance off is apparently divided, the low necks joining the higher portions being only visible on close approach.

The surface of the Strait in this neighbourhood is covered with extensive fields of floating pumice-stone, often in one to two foot cubes, through which the ship easily forced her way. . . .

I inclose sketches which I trust will convey the general appearance better than a written description. The whole of the neighbourhood is covered with greenish yellow mud, and all traces of vegetation everywhere destroyed.

I communicated personally with the captain of the Netherlands frigate *Queen Emma* stationed on the spot, and was informed by him that the changes are considerably more extensive than was at first thought, and that Verlaten Island is still in a state of activity as well as Krakatoa itself.

From observation he thinks that another eruption is impending, but that Verlaten Island will be the centre of disturbance.

The Netherlands Government vessel *Hydrograaf* obtained a sounding of 100 fathoms without reaching bottom, in the centre of the group and off the cliff falling from Krakatoa Peak.

The two new islands are low mud and pumice banks, their configuration is continually altering, and I was informed that they are gradually subsiding. . . .

It is still impossible to examine Lampong Bay, but the pumice-stone is now beginning to float out.

The light on Fourth Point (Java) has been temporarily replaced by one of the 6th order, visible five miles, but beside this there are no signs of life on the Java shore. The whole coast is covered with the debris of trees, &c., demolished by the earthquake sea-wave, and over all lies a thick incrustation of volcanic mud.

During the height of the eruption a terrific whirlwind and a fierce south-westerly gale, apparently local, was experienced. . . .

Victoria Institute, February 4.—Mr. Ernest Budge, B.A., of the Oriental Department of the British Museum, read a paper upon a new and important inscription of Nebuchadnezzar the Great. Two copies of the same text had been brought to England by Mr. Rassam, one of which was much mutilated, but by a careful comparison of the texts Mr. Budge has succeeded in gaining a nearly perfect copy of the inscription. It related chiefly to the restoration of the fortifications of Babylon—the great walls, gates, and quays along the river bank, which had been thrown down by the conquering armies of Sowgon, Sennacherib, and Assurbanipal. It also stated the area of the citadel of Babylon was 4000 square cubits. The inscriptions described the restoration of the famous temple of Belus, which was made "bright as the beauty of heaven," with gold, silver, crystal, and precious stones; the roof of the "house of the oracle" was of cedar wood, plated with gold. The King recorded the restoration of many other public and sacred edifices, and among others the Tower of Borsippa, known as the Tower of Babel, according to Babylonian tradition. In concluding the inscription, the King, in a most beautiful prayer, commended his pious works to the keeping of "Merodach, King of Heaven and Earth," to whom he prayed "for long life, fullness of glory, and a widespread dominion."

EDINBURGH

Mathematical Society, February 8.—Mr. A. J. G. Barclay, vice-president, in the chair.—A presidential address was delivered by Mr. Thomas Muir, F.R.S.E., on the promotion of research. Attention was drawn to the backward state of mathematical research in Scotland, particularly when compared with the activity of Germany in the same department. Some of the causes of this were discussed, and methods were suggested for bringing about a reform.—Mr. H. H. Browning, Glasgow, contributed a paper on illustrations of harmonic section; and Mr. Muir communicated a theorem regarding the area of a polygon of $2n$ sides.

PARIS

Academy of Sciences, February 4.—M. Rolland in the chair.—Note on the necessity of establishing a branch of the Observatory outside of Paris, by Admiral Mouchez.—On a new application of the mercurial level suggested by M. Renouf for calculating the altitude of the stars at sea when the horizon is invisible, by Admiral Mouchez. This ingenious contrivance, which is available on land as well as on sea, almost completely removes the difficulties hitherto experienced in obtaining altitudes within 4′ or 5′ at night or in foggy weather. The apparatus, made by M. Hurlimann, mechanician, has been for some time in use on board the Transatlantic steamers plying between France and the United States. M. Mouchez describes it as much simpler and more exact than any other system hitherto invented.—On an optical phenomenon observed during a fire that broke out at Joly on January 31, by M. E. Chevreul. For three-quarters of an hour the light of the street gas presented the complementary colours of the light of the fire, that is, from yellow-green to green and bluish, the sensations being referable at once both to the simultaneous and successive contrast, according as the observer beheld both lights simultaneously, or one only at a time.—On Faraday's law regarding an electric current traversing a series of electrolisable salts during the same time, by M. Berthelot. The author argues that Faraday's law is in general more simply expressed by means of the equivalents than by the atomic weights, both for the electro-positive and for the electro-negative elements.—Reply to M. Richet's remarks on the method of anæsthesis by means of the titrate mixtures of chloroform and air, by M. Paul Bert.—Curves registered by the mareograph established at Colon (earthquakes at Santander, Guayaquil, Chios, &c.), by M. de Lesseps. The curves recorded on October 13 and 14, 1883, appear to have indicated the underground disturbances caused by the earthquakes that occurred on those dates at Santander on the Atlantic, Guayaquil on the Pacific, Chios in the Mediterranean, and elsewhere. Yet nothing abnormal was registered by the mareograph of the island of Naos, Gulf of Panama.—On the quantities forming a group of nonions analogous to the quaternions of Hamilton, by M. J. J. Sylvester.—*Résumé* of the meteorological observations made during the year 1883 at four points in the Upper Rhine and Vosges districts (Colmar, Munster, Schlucht, and Thann), by M. G. A. Hirn. Referring to the recent twilight effects observed at these stations, the author feels justified in concluding that the particles, whether gaseous or in the form of dust, lit up by the solar rays, were situated, at least to a large extent, beyond the terrestrial atmosphere, in any case at elevations where no traces have ever been observed either of cirrus or vapour of water.—On the late twilight phenomena, by M. de Gasparin. The author considers that the chief features of these phenomena were their rapid appearance from fifteen to sixteen minutes after sunset, and their constant recurrence in a given place for a period of sixty-six days.—On an instrument capable of producing in the same telescope the images of two stars at the moment when they are at the same altitude, and of furthe determining by a single observation the astronomic time of the place, its latitude, and exact position for the wh horizon, by M. Ch. Rouget.—On biquadratic involutions, by M. C. Le Paige.—On a class of abelian functions and a hyperfuchsian group, by M. E. Picard.—Note on the exact number of variations obtained in the multiplicati of the integral polynome $f(x)$ by the binome $x + a$, by M. E André.—Transelementation of glyoxal into glycolic acid, by M. de Forcrand.—On the thermal properties of the numerous ox chlorides of mercury, by M. G. André.—Researches on the formation of the crystallised fluoride of antimony and its dissolution either in pure water or in solutions of fluorhydric acid, by M. Guntz.—On the heat of transformation of the prismatic oxide of antimony into octahedric oxide, by M. Guntz.—On the liquefaction of hydrogen, by M. S. Wroblewski. From the results already obtained, the author supposes that the temperature required for the complete liquefaction of hydrogen is about that which may be obtained by means of boiling oxygen.—On a case of isomerism of chloronitrous camphor, by M. P. Cazeneuve.—On the segmentary organs and the podocyst of the embryos of the slug family, by M. S. Jourdain.—On the Tongrian deposits at Longjumeau, Department of Seine-et-Oise, by M. Stan. Meunier.—On some freshwater formations of the Tertiary period in Algeria, by M. Ph. Thomas.—On the influence of oxygen under increased pressure on the cultivation of *Bacillus anthracis*, by M. J. Wosnessenski.—On the cause of the twilight effects of 1883, by M. G. Tissandier. Accepting M. Angot's assumption that hypotheses inapplicable to the year 1831 must be rejected for 1883, the author shows that the atmospheric conditions of both years resembled each other in every respect. The circumstances attending the eruptions in the Sicilian waters in 1831, when the volcanic island of Pantellaria made its appearance, were completely analogous to those of the Krakatoa eruption in 1883. On both occasions the optical phenomena were immediately preceded by igneous disturbances ejecting into the atmosphere vast quantities of gaseous products and fine dust. Hence the probability that to volcanic eruptions were due the optical manifestations in both years.—On the twilight effects of the last few months, by M. Perrotin. This author also argues that the twilights of 1831 prove nothing against, but rather confirm, the volcanic theory adduced to account for those of 1883.

THURSDAY, FEBRUARY 21, 1884

THE MODERN LANGUAGES OF AFRICA

A Sketch of the Modern Languages of Africa, accompanied by a Language Map. By Robert Needham Cust. 2 vols. (London: Trübner, 1883.)

WHY this work has been restricted to the "modern" languages of Africa is not apparent, seeing that there are not half a dozen ancient or extinct African tongues altogether of which science has any knowledge. The limitation is the more remarkable that every one of these ancient tongues is duly recorded and dealt with in its place, partly lest it should "seem to have been overlooked," partly seemingly for no other reason than that the author has forgotten the restriction so needlessly imposed upon himself. Yet when we are told that Gíz, the most important of them next to Old Egyptian, "may be deemed the *Lingua Franca* of Abyssinia"! (p. 88), and when Rinn's remark on the possible reconstruction of an Archaic Berber "offering analogies to the languages of High Asia" (p. 105) is quoted without comment, one begins to feel that after all it might have been wise to have adhered to the restriction.

But Mr. Cust does not profess to be critical or even scientific, and although in one place science is declared o be his "sole object," it is elsewhere explained that his "chief motive" is to assist the missionaries, "the peculiar outcome, the most wondrous development, and the great glory of the nineteenth century" (p. 461). He hastens even to assure us that personally he knows "absolutely nothing" of the subject, and in one not very lear passage he seems to take the anticipated charge of "his entire absence of training in any school of comparative philology" as "a compliment" (p. 15). Most people, however, will probably feel that some knowledge of the principles of comparative philology would at all events have been an advantage, if not an absolute *sine quâ non*, in a writer undertaking to give us "a sketch of the modern languages of Africa." Anyhow, in the absence of such a qualification it is the less surprising to find the hand of the amateur betrayed in almost every page of the present work, which supplies abundant evidence that it is written by a person sure neither of himself nor of his subject. Great vagueness, inaccuracies, and incoherencies of all sorts, commonplace platitudes gravely put forward as important truths, the existence of well-known or historical people, such as the Funj (Fung) of Senaar, referred to as doubtful, such expressions as "parallels of longitude," "Hervas, the Father of Comparative Philology"! and the like, everywhere reveal an essentially unscientific habit of thought. This is strikingly manifested in the treatment of the Bantu prefixes, which are described as "an intolerable nuisance," as indeed they must needs have proved themselves to be to a writer ignorant of their very meaning. He refers (p. 12) to "languages of the Hamitic group, such as *Wa*-Galla," where the form should obviously be *Ki*-Galla, *Wa* indicating the people, *Ki* their speech. Hence the difficulty presented by these troublesome particles is perhaps not unnaturally met by the naïve plan of making a clean sweep of them. Thus we have everywhere Swahili, Suto, Chuana, Ng'anga (Nyanja), for Ki-Swahili, Se-Suto, Se-Chuana, Chi-Ng'anga, and so on; nor can it be denied that at least on the score of simplicity this plan may possibly recommend itself to the ordinary reader.

To a writer ignorant of comparative philology, the phonetics, structure, and general morphology of the languages must necessarily have proved equally "intolerable nuisances." Hence this difficulty is also met by the same simple expedient of elimination, and we are accordingly quietly warned (p. 15) that "it lies outside the purport of this sketch to dwell upon the grammatica peculiarities of languages, or families, and groups of languages," the object being "to give a sketch of the whole subject, not to write an account of each language." Certainly a zoologist might in the same way undertake to write a "sketch" of the animal kingdom without reference to the comparative anatomy, osteology, general morphology, or other structural "peculiarities" of his various orders and families. But by so doing he would perform a remarkable *tour de force*, if he thereby either added to his own reputation or conferred any substantial benefit on his readers.

Nevertheless, it cannot be denied that, heavily handicapped as he was, Mr. Cust has contrived to produce a work of value to linguistic students. This he has done by wisely restricting himself to what may be called the topography and bibliography of the subject. Abundance of time and means, industrious habits, and the opportunities of procuring information afforded by his connection with a number of learned bodies in England and abroad, have enabled him to deal with these useful branches almost exhaustively. Apparently following somewhat on the lines suggested by the linguistic and ethnological appendixes to Stanford's Compendium, he has collected from all quarters copious materials bearing on the history, habitat, literature, bibliography, and classification of almost every known language and dialect still current amongst the African aborigines. The bibliographical references, perhaps the most valuable feature of the work, are reserved for a very full appendix, containing "a bibliographical table of languages, dialects, localities, and authorities." The other materials, generally brought well up to date, are distributed over the various chapters devoted to the "prolegomena" of the subject, and to the several linguistic families of the African continent. Here the author unfortunately still follows Fr. Müller's classification, apparently unaware that on some material points this writer's views have lately been completely exploded. Thus the Tibbu of the Eastern Sahara, although clearly shown by Nachtigal (*Sahârâ und Sudan*) to be essentially distinct both in speech and physical type from the Negro, are still grouped with that division. The consequence is that in the accompanying coloured language-map by Mr. E. G. Ravenstein, the Negro domain is extended beyond the Sudan northwards to Fezzan and Tripoli, at least 7° of latitude beyond its proper limits. The nomenclature is here also both confused and, as frequently elsewhere, at variance with the text. Thus we have "Teda or Tibbu" instead of Teda or Northern Tibbu, and below it "Dâza or Gora'an" for "Dâza or Southern Tibbu." And in quoting Nachtigal's work why does Mr. Cust go out of his way to give us a false prosody (*Sahâra*), where the author was so careful to write correctly *Sahârâ*?

A more serious blunder is his retention of the unfortunate "Nuba-Fulah" family, which has no objective existence, and which he has rashly taken upon himself even to enlarge. On this subject he writes in the true style of the amateur:—"This arrangement [an arrangement absolutely unscientific] commends itself to my judgment from its convenience, as enabling me to pass on from the confines of the Hamitic language-field, and sweep into this new group all that is not strictly Bántu, or which cannot be conveniently treated as Negro" (p. 142). So in their reports on Egyptian Sudan our officials "sweep" into the Arab group all that is not strictly Negro, and *vice versâ*. And so nearer home our popular ethnographists "sweep" into the "Turanian" group all that is not strictly Aryan, and so on. The scope that this sort of thing gives to discursive writing is about as boundless as is the mischief it does to the cause of scientific progress. In future editions Mr. Cust ought relentlessly to exscind this "convenient" Nuba-Fulah group, and relegate to one of his numerous appendixes "all that cannot be conveniently treated" under any recognised divisions.

These remarks will apply with equal force to the "Hottentot-Bushman Group," of which Mr. Cust again writes: "Following F. Müller and T. Hahn, I constitute a separate group, and take the opportunity of enlarging its dimensions, so as to sweep in certain tribes speaking apparently languages which differ entirely from any above described" (p. 434). It will be seen that Mr. Cust has constituted himself a sort of African "Spazzacammino," sweeping up and down the continent with an airy recklessness which may astonish the groundlings but "cannot but make the judicious grieve." The result in this instance is to scatter over the southern half of Africa a number of tiny little enclaves, all coloured alike and reaching as far north as Abyssinia, which make Mr. Ravenstein's otherwise excellent map look like nothing so much as one of those coloured maps of Scotland with fragments of Cromarty, Elgin, and the other northern shires strewn promiscuously over the face of the land. Now in Scotland these fragments have literally a *tribal* connection, but the connection between the African enclaves—Tua, Sarwa, Nena, Sania, Akka, Twa, Doko, &c.—is of a purely negative character. None of them speak Negro, Fulah, or Bantu idioms; therefore let us sweep them together. It is the old joke about elephant and tea-cup, which are said to resemble one another because neither can climb up a tree.

Besides the general classification, the whole text will need careful revision before the book can be accepted as a standard work of reference on the points with which it professes to deal. Almost on every other page we read such statements as these:—There is "nothing savage" in the Somali nature. There is little doubt that Kandáke was Queen of Napata on the Middle Nile, and a Hamite. The very existence of the Niger was unknown before the present century. The Siwah language is of no importance whatever, &c. The account given (p. 110) of the word *Tamashek* is hopelessly muddled. It is stated to have been applied to the people "by the Arabs, and not by the tribes themselves, who scarcely recognise it, and call themselves Imoshagh, or Amazirg," the fact being that Imoshagh and Tamashek are the same word, the former masculine, indicating the people, the latter feminine, indicating their language. About the closely related Kabail dialect again, Mr. Cust writes: 'I was unable to satisfy myself on the subject of this language until I had personally visited Algeria, Tunisia, and the Sahara, conferred with men on the spot, and seen with my eyes the conformation of the country" (p. 106). Here there seems to be some mystification. It is not obvious at first sight what the conformation of the country has to do with the language; and it is still less obvious how a visit to the Sahara, of which we now hear for the first time, could throw any light on a language scarcely current within the frontier of that region.

At the same time it is but fair to state that, with all its inevitable shortcomings, it often betrays evidence of extreme labour profitably bestowed on obscure languages. A good idea of the general treatment of the subject is afforded by the subjoined account of the little-known Komóro group:—"There is no doubt that these languages are African, and not Malayan, like the Malagási. Several names are recorded, and it is presumed that they are dialects:—(1) Hinzua, (2) Angazidya, (3) Antilote, (4) Mohilla. Elliot left in manuscript a vocabulary of Hinzua, the dialect of the Island of Johanna, compiled by himself. Hildebrandt supplies a considerable one of Ki-Nzuáni compiled on the spot. Casalis in his Suto [Se-Suto] grammar gives a dozen words picked up by chance. Bleek in the 'Languages of the Mozambík' gives words picked up by Peters during a week's residence in the island. Hildebrandt remarks that this dialect is only spoken in the Johanna Island, but that the dialects of the other islands only differ a little. It is never committed to writing. For purposes of business the people use the Swahíli language in the Arabic character. Steere printed in 186 a short vocabulary of the language of Great Komóro called Angazidya, supplied by the sons of one of the kings of the islands. Van der Decken remarks that it is only a dialect of Swahíli, greatly altered in pronunciation and affected by the contact of Malagási. Gevrez, a French *employé* in Mayotte, one of the islands, and a French colony, published an account of the group from personal knowledge in 1870. He divides the population into fractions: one-tenth are Arabs, one-tenth are Malagási, four-tenths are Antilote—a mixture of Arabs and Africans, and four-tenths are of the Bántu family, though not entirely pure. The Antilote speak a mixture of Malagási and Swahíli. Very few in the island speak or write pure Arabic, but Swahíli, which is the language of the schools, the towns, and good society. The character used for writing is a corrupted form of Arabic."

RECENT TEXT-BOOKS OF DETERMINANTS

Die Anfangsgründe der Determinanten. Von Dr. H. Kaiser. (Wiesbaden, 1882.)

Die ersten Elemente der Determinanten Theorie. Von Prof. Wilh. Bunkofer. (Tauberbischofsheim, 1883.)

Éléments de la Théorie des Déterminants. Par P. Mansion. (Paris, 1883.)

Teoría elemental de las Determinantes. Por D. Darí Bacas y D. Ramón Escandón. (Madrid, 1883.)

THE literary activity of Germany seems to make necessary that a new Introduction to Determinant shall appear at least once a year. What amount of goo results from this is not quite apparent to an outsider: it is even probable that there is none, unless the unintended reflex benefit, in the form of experience in book-making, which the authors thereby obtain.

Here we have two elementary booklets, one of 40 pp., the other of 28 pp.; and a very short examination of them suffices to show that the writers could have spent their time and energy to much better purpose, if it was the public that they intended to benefit. What they have written is probably not worse than what has been in use for years; but certainly it is not any better. Indeed Germany has always had more really good elementary expositions of the theory of determinants than any other country, and two or three of these have passed through several editions. Dr. Kaiser and "Professor" Bunkofer are quite capable men for the work they have undertaken: on this score little fault can be found. The latter sketches his "Notes of Lessons," as young English teachers would call them, with pedagogic ability and skill; the former is more wooden, and more unwisely ambitious, and we cannot, unsupplicated, pardon him for saying that Gauss in coining the word "determinant" thereby introduced a definite new idea into analysis, but he goes about his work in a sufficiently workmanlike manner, and is on the whole sure of the ground he treads. We only wish both authors "more power," and next time a happier selection of subject.

Prof. Mansion's "Elements" is a book of a higher type. The present edition, however, is the fourth; and therefore no detailed examination can be looked for. Suffice it to say that there is really no better introductory book published; the exposition and arrangement are admirable, and it has, what so many Continental text-books want, small collections of suitably graduated exercises for the learner. There is only one point which it seems desirable that Prof. Mansion should reconsider, viz. the nomenclature of the special forms of determinants. He employs, for example, both Sylvester's term "persymmetric" and Hankel's "orthosymmetric." Should not one of these immediately receive decent burial, and should not the latter be that one? It is not shorter, it is not more descriptive, it is not more accurate in its description than its rival, and its rival was by several years first in the field. As for "doppelt-orthosymmetrisch," its author is simply unconscionable; it is one of those words which, as Mark Twain puts it, are alphabetical processions and have a perspective: we should have been glad if Prof. Mansion had dealt more summarily with it. In another instance, that of "skew" determinants, we have confusion worse confounded. Cayley's first paper regarding them appeared in *Crelle* (1846), and was written in French, the title being "Sur quelques propriétés des déterminants *gauches*." The term *gauche* (Eng. *skew*, Germ. *schief*, Italian *gobbo*) was at once accepted and employed, as well it might, by all the standard writers. Of late years, however, there have been busy times with the mathematical coiners on the Continent, and in consequence we have as substitutes for "skew"—

"symmetrale,"
"congruente" (not in Mansion),
"pseudosymétrique."

Surely it is too tiresome and quite unnecessary to wait until by a process of artificial selection the fittest or unfittest of these shall survive. Prof. Mansion's "Elements" and the German translation of it have deservedly a large circulation on the Continent, and thus have much power to propagate good or evil. We would therefore earnestly ask him to consider whether it would not be better to recognise throughout his work only *one* name for each special form, and to relegate all synonyms to the index.

The last text-book on our list is Spanish. Although it is the largest (200 pp.) and most pretentious of the four, we regret that it is impossible to say a good word regarding it. The authors have most manifestly no grasp of the subject, and advance with a gay step and light heart through inaccuracy after inaccuracy. Their model unfortunately is Dostor, and equally unfortunately they are more than faithful to him. At the very outset they show their hands. The so-called "notation of Cauchy" is not Cauchy's; what is really Cauchy's is not attributed to him; and the "notation of Leibnitz" is more Cauchy's than Leibnitz's, but belongs to neither. Nor is this wild start of Book I. redeemed by a good end. On pp. 96-98 five examples of skew determinants are calculated at length with a complacent unconsciousness of the simple property which makes all the calculation unnecessary; and pp. 99-101 are taken up with the rather epoch-making definition—

$$\left\Vert \begin{matrix} a & b & c \\ a' & b' & c' \end{matrix} \right\Vert \equiv \left| \begin{matrix} 1 & 1 & 1 \\ a & b & c \\ a' & b' & c' \end{matrix} \right|,$$

and some perfectly legitimate deductions from it. Book II. deals with the so-called applications of determinants, and closely follows Dostor. The most amusing part of it, as is the case also with Dostor, is the chapter devoted to "Applications to Trigonometry." Dostor, however, is outdone on his own ground. For example, after it has been proved that $\cos A = (b^2 + c^2 - a^2)/2bc$, one whole octavo page is occupied in showing, *by means of determinants*, that $\sin \frac{1}{2} A = \sqrt{(s-b)(s-c)/bc}$. This *tour de force* is like that of Hudibras, *telling the clock by algebra*; and the moral in both cases is the same.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Mr. Lloyd Morgan on Instinct

I HAVE read with much interest Mr. Lloyd Morgan's very able paper on "Instinct" in the current issue of NATURE, and I feel it is desirable, without following him over all the ground which he has traversed, briefly to consider those parts of his communication which have special reference to my own work.

The broad question with which he begins—viz.: "Is there a science of comparative psychology?"—is not a question which I feel specially called upon to answer, inasmuch as almost every one who has hitherto written upon psychology has taken it for granted that there is such a science. Nevertheless I may state the justification which I am myself prepared to give of this universal assumption.

When we say that a dog is a more intelligent animal than a sheep, we do not doubt that we are making as real a proposition as when we say that the President of the Royal Society is a more intelligent man than Dick, Tom, or Harry. Now in all cases where there is a general consensus of feeling of this kind, there is an antecedent presumption that the common sense of which it is the expression is in the right, and that any ingeniously-constructed argument of scepticism is in the wrong. We may therefore approach Mr. Lloyd Morgan's argument with the antecedent presumption that there must be something wrong about it somewhere; and I do not think that it requires much reflection to see where the error lies.

According to the argument as stated by my critic, there is a true science of human psychology, because, although my knowledge of another human mind is no less ejective than is my knowledge of a dog's mind, yet "by means of language human beings can communicate to each other the results which each has obtained, and each human being is able *to submit these results to the test of subjective verification.*" But how, let us ask, in its last analysis is this verification obtained? By language, no doubt; but what in its last analysis is language? As spoken by my neighbour, it is for me nothing more than my own interpretation of a meaning presented by the observable activities of an organism. Therefore, if on such a basis I am entitled to affirm that such interpretations as I make are of the nature of "subjective verifications" of conclusions drawn from the introspective observation of my own mind, why am I not entitled to a similar view when the eject of my contemplation is the mind of a dog? The dog cannot speak, but he can display other activities which, so far as they go, are quite as valid as a basis on which to construct my "subjective verification" as are the activities manifested in language. Of course language is able to convey immeasurably more information touching the ejective mind than can be conveyed by any other kind of activity; but this fact is merely due to the further fact that language is a system of activities expressly designed for this very purpose. The higher value of language in this respect is therefore nothing more than an expression of the higher development of intelligence, which enables the mind to perceive the desirability of devising a system of bodily activities expressly designed to serve as the vehicle of communication between subject and eject,—as is proved by the fact that any system of bodily activities which may be agreed upon (such as gesture, lip-reading, writing, &c.) are alike available for this purpose. Language, then, of any kind is merely a conventional system of bodily activities which, because *intended* to convey information from mind to mind, we call signs. But now, the element of *intention* on the part of my neighbour is in no wise essential to my ejective interpretation of his bodily activities, or to what Mr. Morgan calls my subjective verification of them. The involuntary groan of pain, the pallor of fear, and a thousand other unintended "expressions of the emotions," as well as a thousand other unintended expressions of thought (*e.g.* the act of pocket-picking under the eye of an unseen detective), are, as it is proverbially said, "more eloquent than words."

I submit, therefore, that, although a dog cannot give us any large measure of ejective information intentionally, or by purposive signs (he does, however, give us some even of this), we have still abundant material furnished by his other bodily activities for constructing our ejective inferences. For example, the dog gives very much the same indications of pain under the whip that a boy gives under the cane; therefore the gamekeeper has no more doubt that he is hurting the dog than the schoolmaster has that he is hurting the boy—nor would the schoolmaster be more satisfied on this point by asking the boy whether the cane did hurt.

If I have been followed thus far, I should be inclined to go still further, and to say that in my opinion the "unpremeditated art" of natural movements (whether in men or animals) is a surer basis on which to build ejective conclusions than is the more indirect information supplied by intentional gesture or language, *so far as the low or simple intelligence to which animals attain is concerned.* Poets and moralists are fond of insisting upon this point as regards young children, where the level of intelligence may be even considerably above that of the most intelligent animal. The immense service of language in ejective analysis is rendered in those higher and more complex regions of intellectual life to which man alone attains. Still, I doubt not that if animals could speak, so that we could interrogate them as to their mental operations, we should obtain a great deal of supplementary information; only of course this supposition is an impossible one, seeing that, if an animal could speak, its intelligence would no longer be "animal intelligence."

On the whole, then, as concerns the question whether there is a science of comparative psychology, I should say that there certainly is such a science, in the same sense as there is a science of human psychology. For it seems to me, in view of the above considerations, that the argument adduced by Mr. Lloyd Morgan against the former is quite as applicable against the latter. In both cases alike our ejective inferences can only be founded on the observable activities of organisms, and if it is true that of these observable activities language affords an exceptionally meaning class, it is also true that where language is absent the mental processes which stand to be ejectively analysed are of a comparatively simple nature. I therefore see no reason to recede from the position which I have taken up in the works to which Mr. Lloyd Morgan refers, where I observe with reference to the peculiar standing of psychology (both human and comparative) among the sciences in the matter which we have been considering—"although the evidence derived from ejects is practically regarded as good in the case of mental organisations inferred to be closely analogous to our own, this evidence clearly ceases to be trustworthy in the ratio in which the analogy fails; so that when we come to the case of very low animals—where the analogy is least—we feel uncertain whether or not to ascribe to them any ejective existence" ("Mental Evolution in Animals," p. 22). And again, with reference to such objections as that of Mr. Morgan—"Scepticism of this kind is logically bound to deny evidence of mind, not only in the case of the lower animals, but also in that of the higher, and even in that of men other than the sceptic himself. . . . This is evident because, as I have already observed, the only evidence we can have of ejective mind is that which is furnished by objective activities; and, as the subjective mind can never become assimilated with the ejective, so as to learn by direct feeling the mental processes which there accompany the objective activities, it is clearly impossible to satisfy any one who chooses to doubt the validity of inference, that in any case, other than his own, mental processes ever do accompany objective activities" ("Animal Intelligence," p. 16). And, by parity of reasoning, the same argument may be used against Mr. Morgan's sceptical objection to comparative psychology as a science. In whatever measure he is *on principle* a sceptic touching the inferences which this science is able to draw as to the existence and nature of animal psychology, in that measure I think he ought in consistency also to be a sceptic with reference to the same points in the science of human psychology.

Coming now to Mr. Morgan's strictures on my psychological definition of instinct, I understand that they are made, not with reference to any defect in my definition as a psychological definition, but with reference to the possibility of any such definition whatever. In his view there can, from the nature of the case, be no psychological definition of instinct; there can only be a physiological definition of the cerebral processes which are concerned in actions termed instinctive. Here, then, is a broad issue, although it only constitutes a part of the still broader one which we have just been considering.

I may say first of all that, if we want a physiological definition of instinct, I do not think that the one which is furnished by Mr. Lloyd Morgan is valid. This definition is that reflex actions are due to a general type of nervous organisation, instinctive actions to a specific type, and intelligent actions to an individual nervous organisation. Now, this threefold definition presents none of that "definiteness of application" which Mr. Morgan implies, nor does it tend, as he supposes, to add any "clearness to our ideas concerning the things of which we speak." For it is open to the fatal objection of arbitrarily classifying as instinctive many actions which are now universally regarded as reflex; while, conversely, a still greater number of actions now universally regarded as instinctive would, under this definition, become classified as reflex. That is to say, there are, on the one hand, many reflex actions which we should all feel it absurd to call instinctive, and which are nevertheless manifested by only one species (in our own organisations, for example, we may mention the "patellar reflex," and the convulsions produced by tickling the soles of the feet); and, on the other hand, there is a very much greater number of instinctive actions which we should all feel it absurd to call reflex, but which are nevertheless manifested by many species of a genus, others by many genera of an order, and so on, until in such cases as those of nidification, incubation, &c., we arrive at instincts general to a whole class. The truth, therefore, is that a zoological classification, being made with reference to the whole organisations of animals, has no such special application to the refined structure of their nervous systems (which, indeed, we can only appreciate by its effects on conduct) as would be required for the groundwork of

Mr. Morgan's physiological definitions of reflex action, instinct, and intelligence. If we want such a definition it must be made independently of any zoological classification, *and with exclusive reference to the point whether the adaptive action requires for its performance the operation of the higher nerve-centres*—a point which can only be determined by vivisectional experiment. In other words, on the side of objective psychology the only distinction that can be drawn between a reflex and an instinctive action, is as to whether the action can be performed by the lower nerve-centres alone, or requires likewise the cooperation of the higher nerve-centres. And this is just what we should expect to find to be the case on the objective side if, as I have endeavoured to show, the one peculiarity which distinguishes actions classed as reflex from actions classed as instinctive, consists in the latter exhibiting in their performance a mental or conscious element which is not exhibited in the former.

Now, if the *raison d'être* of the term "instinct" is thus to denominate a class of adaptive actions in which there is a subjective, or rather let us say an ejective element, I cannot see that anything but confusion is to be gained by forcing this term into objective implications. Were any term needed to designate the neurosis of instinctive action, it would be far better to coin a new one than thus to abuse an old one. I am fully sensible of the difficulty which often arises in deciding whether a particular action should be assigned to the instinctive or to the reflex class; but, as I observe in "Mental Evolution in Animals," "this difficulty does not affect the validity of the classification any more, for instance, than the difficulty of deciding whether Limulus should be classified with the crabs or with the scorpions affects the validity of the classification which marks off the group Crustacea from the group Arachnida."

For the rest, Mr. Morgan's criticism on my psychological definition of instinct hangs entirely upon his previous criticism as to the possibility of a science of comparative psychology, and as I have already endeavoured to answer the latter, I need not go over the same ground again by answering the former. There are only two points raised by his paper to which this general answer does not apply, and with these, therefore, I shall conclude.

The first of these two points is a charge of inconsistency. My critic observes that, after having said "it is enough to point to the variable or incalculable character of mental adjustments as distinguished from the constant and foreseeable character of reflex adjustments," I go on to define instinctive actions as mental adjustments which are nevertheless of a constant and foreseeable character. Now I think, if any one will read my chapter on "The Criterion of Mind," he will see that this apparent inconsistency is not a real one. It would be a real one if the passage above quoted referred only to this and that particular action of an animal, apart from all the other actions of the same animal, which, according to my criterion of mind, are competent to inform us whether or not the animal in question is a *choosing* and *perceiving* animal. But the passage quoted refers to the whole constitution of an animal so far as we can know it by observation of activities, and therefore the question whether this or that particular activity is to be regarded as mental or non-mental (instinctive or reflex) requires to be answered by all that we learn concerning the other activities of that animal. If none of its activities are other than those of a constant and foreseeable character, we have no reason to suppose that it is a choosing or perceiving animal; but if some of its other activities are indicative of choice and perception, our knowledge of this fact must be allowed due weight in any attempt that we may make at classifying this or that particular action as reflex or instinctive. The case, in short, is just the converse of that which I thus state in the chapter referred to:—"Many adjustive actions which we recognise as mental are, nevertheless, seen beforehand to be, under the given circumstances, inevitable; but analysis would show that this is only the case when we have in view agents whom we already, or from independent evidence, regard as mental."

The second point to which I have referred as the only one that now remains for me to consider, is to the effect that I have mistaken "Mr. Spencer's position with regard to the 'very subordinate importance of natural selection as an evolving source of instinct,' and with regard to the question of 'lapsed intelligence.'" Here I can afford to be brief, inasmuch as any one who cares to do so can compare my interpretation of Mr. Spencer's writings with the passages in those writings to which I refer. It seems to me perfectly clear that, although both the principles in question are alluded to by Mr. Spencer, neither of them holds the same prominence in his theory of the development of instincts from reflex action as they hold in the theory of Mr. Darwin.

In conclusion, I trust Mr. Morgan may feel that, in writing this somewhat elaborate reply to his criticism, I am marking as emphatically as I can my sense of its ability. And if the general effect of this discussion is to show that the phenomena of instinct present peculiar difficulties to any attempt at a fundamental analysis, I should like no less emphatically to express my conviction that such an analysis is not to be facilitated by closing our eyes upon the entire class of phenomena to which alone the word is applicable. We may, of course, abstain from any attempt at such analysis, and devote our attention exclusively to the physical as distinguished from the mental side of the subject. Only in this case we may not speak of *instinct*.

GEORGE J. ROMANES

"Mental Evolution in Animals"

MR. ROMANES' comment on my communication in NATURE of February 7 (p. 335) is not quite satisfactory. I do not suppose that he has any spite against my skate; but as he does not know me, and did not see the incident in the Manchester Aquarium, I think it is very possible that he may have been naturally predisposed to underrate the significance of the story. I do not admit that I can be reasonably blamed for saying that a repetition of the conditions would have been useful, if possible, while at the same time pointing out that the result would not necessarily have settled the question. Test experiments are always useful, even if they do not settle the main question. Mr. Romanes' terrier story was not necessary to make clear what he means by "accident," and there is no analogy between it and my skate story. In one case a trained, or at least tamed, dog did as he was told, and the conditions of success were prearranged; in the other, a fish spontaneously did something for his own advantage. As for the fish smelling the food, this does not harmonise with the circumstances as I described them, and had Mr. Romanes seen the incident I do not think this explanation would have occurred to him; the whole series of actions was too rapid, and had too much the appearance of co-ordination. The propulsion of the food into the ready mouth was the work of an instant. Had the mouth not been ready, as the cricketer's bat is the instant the ball leaves the bowler's hand, the morsel would have been missed. Finally, Mr. Romanes tells us ("Animal Intelligence," p. 351) that the bear observed by Mr. Hutchinson was a Polar bear. Now this species is "almost marine in its habits." It lives upon seal-flesh and also upon dead meat which it finds floating in the water. It is not infrequently cast adrift on an ice-floe or an iceberg. It is therefore not at all improbable that the method of fishing described may be an instinct developed hereditarily. The fact that two bears behaved in precisely the same manner strengthens this supposition. Mr. Darwin does not say whether the bear observed by Mr. Westropp in Vienna was a Polar bear or not, but he observes that the action in question "can hardly be attributed to instinct or inherited habit," as it would be "of little use to such an animal in a state of nature." It seems to me that such action would be very useful to Polar bears in a state of nature.

Manchester, February 11 F. J. FARADAY

The Remarkable Sunsets

AT the present stage of the discussion upon the "green sun" and rosy sunsets it seems to me it would be well to recall attention to a few facts, for there seems to be a tendency on the part of some correspondents to allow imagination to carry them beyond the region of fact into that of fancy. First, then, I would point out that my observations show conclusively that at the time of the green sun there was an altogether abnormal amount of moisture in the upper regions of the atmosphere, while the ordinary hygrometric observations showed the air near the ground to be comparatively dry. I have studied the rain-band spectrum almost daily for the last six or seven years, and I have never before known such a long continuance of the heavy rain-band in a comparatively clear sky—a sky in which there was only a light haze. At sunset and sunrise the intensity of the bands was such as I have before seen only from an altitude of some six or seven thousand feet, and even then rarely. In this connection it may be well to point out that the spectrum as observed by Mr. Donnelly (NATURE, vol. xxix. p. 132), though, as remarked by Mr. Lockyer, resembling that observed here in some respects, yet differed from it in some important points. The "low sun-bands" appeared weak rather than strong, partly perhaps by contrast with the great intensity of the rainband, and the rainband itself was easily divided into lines, of which eight are recorded in my note-book as being seen with a one-prism spectroscope. The band between *b* and F, observed by Mr. Lockyer, was also seen here, and was found to be one ascribed to aqueous vapour, W.L. 504. A spectrum almost in all respects similar to that observed here can be seen by any one who will examine the absorption produced by a *small* cloud passing over the sun as seen with the spectroscope, having a lens in front of the slit. The contrast with the bright spectrum of the sun shows the general absorption in the red very clearly, and if the sun be near the horizon the other bands will be, in most cases, fairly well seen.

It is worth noting that we have had an unusually early and heavy monsoon, ushered in by a remarkable thunderstorm and followed by a period when the spectrum showed an abnormal freedom from vapour, the rainband at times being quite invisible. During this latter period we have had beautiful rosy after-glows, the sunlight being apparently reflected from thin, almost invisible, cirrus clouds.

If the presence of dust can be proved, these phenomena, as I previously indicated, can be readily explained in accordance with the facts so beautifully illustrated by Mr. John Aitken (*Trans. R.S.E.*, vol. xxx. p. 337), for the dust particles would condense moisture in the upper parts of the air, and we would have a light haze, such as was observed here, not sufficiently dense to cause actual clouds, but deep enough to give the special absorption effects, while the dust itself would assist in producing the general absorption.

Against the idea of Java dust, however, have to be set a number of facts of which the following are a few:—The maximum phase of greenness was on the same day (September 10), all over Ceylon and South India, and as far west as long. 64° (at sea). The green sun was not seen at Rangoon nor at the Andaman Islands, though at the latter place the sounds of the eruption were heard. The first rain that fell here afterwards was subjected to careful microscopic analysis, and showed no trace of volcanic dust. The phenomenon reappeared on September 22.

For my own part I think there is strong evidence that the influence of the Javan eruption was an electrical one, and that that was not necessarily propagated by the actual transference of matter. Mr. Whymper's very interesting letter is of course by no means conclusive as regards the effects of dust, for it is, I believe, regarded as virtually proved that the mere existence of dust in large quantities in volcanic ejecta proves the presence of an abundance of water vapour. C. MICHIE SMITH

P.S.—There is a misprint in my letter to Sir William Thomson which, as I have seen it twice quoted, ought to be corrected. It is in vol. xxix. p. 55, line 8, which should read: "After the electricity had gone to *negative*." C. M. S.

The Christian College, Madras, January 23

SINCE the end of October, when I first observed an unusual red glow for a considerable time after sunset, I have been a close observer of the atmospheric phenomena so fully described by your correspondents. For some time past they have appeared with little of their former brilliancy, until the evening of the 7th inst., when there was a remarkably fine display, equalling in many respects those of December. Of this I shall particularly mention but one feature which I had seen three times previously, but never displayed with such intensity and clearness of definition. At 5.30, when the after-glow was at its maximum, a lovely crimson arc appeared opposite it in the eastern horizon, in every respect as described by Mr. Divers in his letter dated from Japan, which appeared in NATURE of January 24 (p. 283). I may remark that I have observed here, from November 10 to this date, but latterly with much diminished intensity, every one of the phenomena he so graphically describes. A. C.

Roscommon, February 11

"The Indians of Guiana"

IN the notice of Mr. Im Thurn's work on the Indians of Guiana, in the current volume of NATURE (p. 305), Mr. Tylor writes: "What is still more curious is that the rude method of making thread by rolling palm or grass fibre into a twist with the palm of the hand on the thigh may be commonly seen in Guiana, although the use of the spindle for spinning cotton is also usual." As such a fact appears to be curious to so eminent an anthropologist as Mr. Tylor, it may be of interest to some of your readers to learn that this mode of twisting fibres is still by no means uncommon in India, though spinning must there have been familiar to the natives for unnumbered generations. I have frequently seen Hindus of various castes twist a mass of jute-fibre into a compact and firm rope of considerable length, between the palm of the hand and the inside of the thigh, and by the same means they will frequently produce long pieces of strongly coherent twine when the need for it arises. From my experience, which, though confined to a small geographical area, comprehended an acquaintance with both Hindus and Mohammedans imported into the tea-districts from almost every part of British India, I should suppose that this custom of twisting fibres into rope and twine is universal throughout the country, though doubtless it is resorted to rather as a makeshift than as a regular mode of manufacturing twisted cords. That such a means should be resorted to by the wild tribes of the north-eastern frontier is by no means strange, though these have acquired not a little skill in spinning and weaving cotton, but that so primitive a method should still prevail amongst peoples so highly cultured as the Hindus and Mohammedans of India often struck me as remarkable.

While noticing Mr. Tylor's interesting article, I cannot refrain from questioning the justice of the supposition that pile-dwellings on the land are due to the "survival of the once purposeful habit of building them in the water." That in New Guinea such is the case there can be little doubt, as Dumont d'Urville and Mr. Wallace, as well as Prof. Moseley, have remarked. And that Mr. Im Thurn's supposition with regard to the natives of Guiana is also correct there can hardly be a doubt. But these two cases scarcely seem to me sufficient upon which to generalise, even when added to Prof. Moseley's pretty and ingenious view as to the origin of the Swiss châlet. As has been pointed out to me by my friend Mr. W. E. Jones, F.R.I.B.A., Lecturer on Architecture in the Bristol University, a somewhat similar development of single-storied into two-storied dwellings is to be traced in the stone buildings as well as in the less substantial dwellings of Western Asia, between the twentieth and the twelfth centuries B.C., and though of course it is not impossible, it certainly seems improbable that a race of ancient lake-dwellers should have perpetuated on sandy plains a practice which must altogether have ceased to be useful long before it reached a region so far removed from its original home. And indeed it seems to me that pile-dwellings may be observed in localities in which it is scarcely possible that the practice could have originated in lake-dwellings, or in any dwellings of any sort erected in water, whether fresh or salt. I allude more particularly to the raised dwellings of the Nagas, Kukis, Cacharis, Khasias, and other hill-tribes of the north-eastern frontier of India, in the midst of which I lived for several years. That these people should ever have dwelt so near the sea that they acquired the habit of erecting pile-dwellings therein seems to me highly improbable when it is remembered that their racial and linguistic affinities place them undoubtedly in that great Mongolian group of which the Thibetans and Burmese are examples; and that therefore they may be regarded as immigrants from more Eastern Asia, rather than as tribes which have been gradually driven back from the Bay of Bengal by the encroaching civilisation of the Hindus. Nor does it seem probable that their pile-dwellings were originally erected in lakes amongst the hills, for in fact the lakes nowhere exist. There are indeed extensive *bheels* or marshes, which during the rainy season sometimes contain a good deal of water. But these *bheels* are, during at least a portion if not the whole of the year, so pregnant with fever and ague that I cannot believe that they were ever employed, as were the lakes of Switzerland and Italy, for the protection of the habitations of man. Yet these north-eastern frontier tribes for the most part build their houses upon piles. These are generally of bamboo, and so of course are very perishable, but occasionally small timber is employed. The floor or platform (of coarse bamboo matting) is seldom raised more than from twenty-four to thirty inches above the ground, though, if my memory serves me, I have occasionally seen it raised as much as between six and seven feet. Beneath this platform a good deal of lumber generally accumulates, and the poultry and pigs frequently congregate for shelter, but I think I never saw an instance of the lower portion of the erection being inclosed by matting to form a "ground floor." Were these pile-dwellings confined to the low, flat lands upon which the Bengali delights to place his paddy-fields, it would be obvious that they were adopted for the purpose of obtaining a dry, wholesome floor, and security against unanticipated floods. But so far is this from being the case that only very rarely is a Naga or Kuki village to be found on low-lying ground, and generally they are to be seen upon the sides and even the summits of considerable elevations, where any danger from floods is quite out of the question. Again, it might be supposed that these elevated dwellings were adopted as a protection against wild animals but for a curious practice occasionally observable amongst the hill-men. This is the habit of building upon the steep side of a hill in such a manner that the back of the dwelling rests directly upon the ground, while the front is supported upon piles which are of a height sufficient to render the floor, throughout its length, horizontal. Such a plan as this reduces the protection afforded from vermin and wild animals to a minimum, and seems to justify the belief that the fear of these creatures at least could have little or no influence upon the architectural habits of the hill-tribes of this part of India; and I long ago came to the conclusion that here at least the object of the pile-dwellings was simply to attain in the easiest way a floor which should be exempt from the damp exhalations of a tropical soil.

JAMES DALLAS

"Probable Nature of the Internal Symmetry of Crystals"

UNDER this head Mr. Barlow has published in NATURE of December 20 and 27, 1883 (pp. 186 and 205) an interesting and ingenious memoir. The subject being very important, but also very difficult and intricate, a discussion of the new theory may perhaps contribute to render our ideas a little more precise.

Whilst Haüy, Frankenheim, Delafosse, Bravais, and others think a crystal built up of mere congruent particles, which may be either the chemical molecules or rather certain aggregates of them, Mr. Barlow considers the arrangement of the different chemical atoms in the interior of a crystallised compound, and illustrates some facts by this manner of viewing them. I purpose in the following submitting some objections which arise against the deductions of the author. These objections are of a geometrical, chemical, and physical nature; let us begin with the geometrical ones.

The first problem of Mr. Barlow is "to inquire what very symmetrical arrangements of points or particles in space are possible." He comes to this result: "It would appear that there are but five." Then he describes these five arrangements. What conditions are to be fulfilled by an arrangement of points in space which is to be "very symmetrical," is nowhere said. According to this indefiniteness of the fundamental notion, the five kinds of very symmetrical arrangement seem to be found rather by divination than by systematic reasoning. Therefore the foundation of the theory appears somewhat arbitrary; and we may suspect that it is incomplete. We are in fact confirmed in this presumption if we consider the results of a geometric research published in my "Entwickelung einer Theorie der Krystallstruktur" (Leipzig: Teubner, 1879). In this book I have specified all possible arrangements of points that are regular and infinite, I have called a system of points *regular* if the points are disposed around every one point of the system in precisely the same manner as around every other. *There are sixty-six such regular systems of points possible.* According to the peculiarity of their symmetry they are subdivided into groups, which correspond strictly to the known crystallographic systems. Many of those arrangements of points have a hemihedric or tetartohedric character; others have the structure of a screw; and amongst the latter I could even suggest one particular system which represents the internal structure of quartz. The latter result was obtained (*loc. cit.* pp. 238–245) by comparing the crystallographical and optical properties of quartz with those of the known combination of thin laminæ of mica arranged in the manner of winding-stairs, described by Prof. Reusch fourteen years ago. All sixty-six systems are in agreement with the principal law of crystallography, the law of rational segments of the axes (Wiedemann, *Annalen der Physik*, 1882, vol. xvi. p. 489). For example, if we have reason to suppose that a certain one of these systems should represent the structure of a given substance crystallising in hexagonal pyramids, then we derive geometrically the same series of possible pyramids which nature actually exhibits.

Four of Mr. Barlow's five kinds of "very symmetrical arrangements" prove to be extremely particular cases of four general systems of mine. The first, second, and third kinds of Mr. Barlow's result from the systems which I have called the "rhombendodecahedric, cubic, and octahedric system with 24-points-aggregates" ("Entwickelung," pp. 165-168), if we suppose the twenty-four points of the so-called "24-punkter" coinciding in one point, and if we identify this point with the centre of a sphere of Mr. Barlow. Mr. Barlow's fourth kind of "very symmetrical arrangements" results as a particular case from my "3-gängiges 6-punkt-schraubensystem" (*loc. cit.*, Fig. 46), if the sides of all hexagons are supposed to touch one another, and the layers to have convenient distances. Mr. Barlow's fifth kind of symmetry, not being regular in the sense defined above, cannot be found amongst my sixty-six systems. Though every point is surrounded by six neighbouring points at equal distances, the latter have not throughout an identical arrangement. Every point of the first, third, fifth, &c., layers is situated at the centre of a perpendicular prism (with regular triangular base) whose angles bear the six neighbouring points of the system, but around every point of the second, fourth, sixth, &c., layers, the six neighbouring points are situated at the angles of two regular triangles, which do not lie parallel over one another as before, one of them being turned round in its plane 60°.

As my sixty-six systems comprise four of Mr. Barlow's kinds of symmetry, it may be expected that they include other arrangements besides, which may also pass as "very symmetrical." For example, in a cubic aggregate of points, the centres of the edges of all cubes determine a very symmetrical arrangement of points, where every point has equal distances from the next eight surrounding points (cf. "Entwickelung," &c., p. 160). From this I believe I have shown that the geometrical foundation of Mr. Barlow's theory is somewhat arbitrary and incomplete.

I now come to the chemical objections, which I will explain by an example. A chemical compound of two kinds of atoms, present in equal number—for example NaCl—could, according to Mr. Barlow, crystallise into the first or second of his five kinds of symmetry, for either of these two kinds allows the regular arrangement of two kinds of particles in equal number. In the first kind of symmetry (for example) spheres are so arranged that they constitute a cubic system of points, in which the centre of each cube bears also a point of the system. By putting atoms of one kind (Na) on the angles, and atoms of the other kind (Cl) on the centres of the cubes, we have built up the structure of a crystal of NaCl. Thus eight atoms of Na stand in exactly identical manner around an atom of Cl (and also eight atoms of Cl around an atom of Na). The atom of Cl seems consequently to be in equally close connection with eight atoms of Na; it has exactly the same relation to these eight atoms. It appears therefore as *octovalent*, certainly not as univalent; for it would be entirely arbitrary to suppose any *two* neighbouring atoms of NaCl in an especially close connection and to take this couple for the chemical molecule of NaCl. By this example we see *that from Mr. Barlow's point of view both the notion of chemical valency and of chemical molecule completely lose their present import for the crystallised state.* This objection, of course, will not destroy the theory of Mr. Barlow, since chemical valency does not yet belong to perfectly clear and fixed notions, and since the idea of the chemical molecule in a crystal is also not evident and clear. The author, however, is at all events obliged to show why these two notions, of such great moment for substances in a gaseous state, should become completely insignificant, as soon as crystallised bodies are in question.

Finally for a physical objection. With respect to the fact that most substances change their volume in congealing, Mr. Barlow admits that the atoms themselves undergo an expansion (positive or negative) in the act of crystallisation. Thus he attributes to the atoms variability of volume, *i.e.* one of those qualities, for the explanation of which the atomic theory has been devised. Well, let it be so, but this hypothesis of atomic expansion is not even found sufficient everywhere, but must be assisted occasionally by auxiliary hypotheses. Thus for explaining the isomorphism of substances which contain atoms of the same kind (*e.g.* $CaCO_3$ and $FeCO_3$) Mr. Barlow supposes that the expansion in the act of crystallising is confined to the common atoms, whilst the different atoms in both substances remain unaltered.

All these objections do not overthrow the author's theory, but they shake it. Perhaps they will induce Mr. Barlow to establish

his theory in a more solid and more general way, and in this case also I shall have attained my aim.

Holothurians

THE observations which I made in 1883 among the coral-reefs of the Solomon Group on the habits of the Holothurians support the view that these animals do not subsist on living coral. I carefully examined the material voided by about twenty individuals, and found its composition to be of a mixed character. In addition to the calcareous sand and gravel which formed its bulk, there were numerous tests of the large foraminifer—Orbitolites—and several small univalve and bivalve shells, besides the joints of a stony alga and the operculum of a young nerite, &c. This observation is supplementary to those contained in my previous letter on this subject (NATURE, vol. xxvii. p. 7).

Traders in this group tell me that when collecting a species known in the trade as the "large tit-fish," they have frequently found a small eel inside the animal, which usually escaped before it could be secured. One man received a smart electric shock, whilst handling a trepang containing one of these eels.

Unconscious Bias in Walking

SURELY Mr. W. G. Simpson has written from imperfect memory when he tells us in NATURE (vol. xxix. p. 356), "if the majority of people, as Mr. Darwin argues, are left-legged, they would circle to the *left* in a mist, as Mr. Larden says they do." In Mr. Larden's letter (p. 262) the following passage occurs: "This theory (his own) involving as further consequences that those in whom the left leg is the strongest would circle to the *right*," &c.; again, "I myself am right-legged and in a mist I always circle to the left." Although Mr. Simpson has misquoted Mr. Larden, he has arrived at the same conclusion that I did (see NATURE for January 31, p. 311), but gives his views in different words, namely, that "there is a bias *towards* the stronger limb, irrespective of length."
JOHN RAE

The Storm of January 26

THE lowest reading, reduced to the sea-level, of the barometer here, about six miles south-east of Omagh, during the gale on Saturday, the 26th ult., was 27·68, and occurred at 4.15 p.m. Dublin time.

PALESTINE EXPLORATION

THE following communication has been forwarded to us for publication:—

Mediterranean Hotel, Jerusalem, January 18, 1884

DEAR PROFESSOR OLIVER,—A chest in a waterproof cover leaves here to-morrow for London to Messrs. Cook and Son, Ludgate Circus. It should arrive on February 25 or sooner, and I have directed that it should be forwarded immediately to Kew. I hope to arrive soon after. It contains all my dried plants. They are made up in various packages, with localities written outside. Of course you will have them kept dry and looked after, but I think they had better not be overhauled until I come, as I should like to open them as they are, while the contents of each package and its associations are fresh in my memory. The earlier desert plants are in many cases only valuable for recognition, I fear, as they are withered remains, but I frequently obtained a lingering flower and many seeds. All my seeds and bulbs I have sent according to promise to Mr. Burbidge, of the College Botanic Garden, Dublin. In the mountains about Sinai and Jebel Catherine I obtained better specimens, and things gradually improved to Akaba. We got through a good deal of unexplored country and had a most efficient conductor. Along the Wady Arabah I made frequent detours into the mountains on either side, and was especially fortunate in having a good collection on Mount Hor and at Petra and its neighbourhood. The flora of Mount Hor (5000 feet) is extremely rich—a warm sandstone. I also collected mosses and lichens in the desert, and am still gathering all I can. My collections reach to here, including a run down to the Jordan. The pace is now (horses) often too rapid, but the camel was an admirable companion on a long march. We were delayed in the Ghor-en-Safiet, at the south-east end of the Dead Sea for ten days, an unparalleled sojourn in this most interesting place. It was early a little, but I made large collections there, and was very glad of the difficulties that opposed our departure. I found many unexpected plants—three ferns, for instance, on Mount Hor, and a *Stapelia*. I knew the names of very few of the things, and had no books, but Redhead and Lowne's papers were a help, though they gave a very poor idea of the real state of affairs. There is a fine *Acacia* in the Ghor-en-Safiet, distinct in many respects and far finer than *A. seyal*. It is the true "scent" about which there seems a lot of confusion. Hoping my collections will be satisfactory,

I remain yours very truly,
(Signed) HENRY CHICHESTER HART

P.S.—Here in Jerusalem there are about six plants in flower; down below in the Jordan I gathered about a hundred two days ago!
(Signed) H.

FAIRY RINGS

THE dark green circles of grass known as "fairy rings" formed the subject of a paper in the *Philosophical Transactions* of the new-born Royal Society in 1675; but it was only last year that the Rothamsted chemists, Messrs. Lawes, Gilbert, and Warington, announced what is no doubt a correct explanation of these phenomena.

The original theory of the electrical origin of the rings was succeeded by that of "chemical causes" propounded by Dr. Wollaston at a meeting of the Royal Society in 1807, and by Prof. Way in a paper read to the British Association in 1846. Besides the "mineral theory" which was here pressed into the service of a discussion that commenced, as already stated, more than two hundred years ago, De Candolle applied his famous "excretory theory" to its elucidation. At Rothamsted, however, the causes of fairy rings were still regarded as having been unsatisfactorily explained.

Sir John B. Lawes and his colleague Dr. Gilbert commenced their inquiries on this subject many years ago. Almost from the commencement of their experiments at Rothamsted they had regarded the alternate growth of fungi and grass as a striking example of what may be called the "natural rotation" of crops. As long ago as 1851 they described fairy rings in the *Journal of the Royal Agricultural Society* as "a beautiful illustration of the dependence for luxuriant growth of one plant upon another of different habits." It will be remembered that the experiments at Rothamsted led to the substitution of what is called the "nitrogen theory" for the "mineral theory" of former days, and practical agriculturists who know the value and the cost of nitrogen as an all-important agent of fertility will learn, perhaps without surprise, that the rich verdure of a fairy ring is due to the effect of nitrogen. Nitrogen is the *sine quâ non* of plant growth, and fungi require a large amount of it. From what source do they obtain it? At the present time few, if any, chemists would maintain that they obtained it by the absorption of free nitrogen from the atmosphere, but in 1851 the eminent investigators at Rothamsted attributed the nitrogen of the fungi to their extraordinary power of accumulating that substance from the atmosphere; and this they thought enabled them to take up the minerals which the grasses, owing to their more limited power of obtaining nitrogen, could not appropriate from the soil. They assumed that it was the nitrogen rather than the mineral constituents of the fungi to which the manuring action was mainly to be attributed, and in this they were right; but the theory has required some correction nevertheless, inasmuch as they have since proved the source of nitrogen in the fungi to be the soil, not the atmosphere.

As doubts were entertained at first on this point, direct experiments were tried at Rothamsted, and in 1874 samples of soil were taken within a fairy ring, immediately upon it, and outside, and these yielded on analysis the lowest percentage of nitrogen in the soil within the ring, a higher percentage under the ring, and a higher still outside it. The soil therefore had lost nitrogen by the growth of the fungi, and the obvious conclusion was that the fungi possess a greater power than the grasses of abstracting nitrogen from the soil.

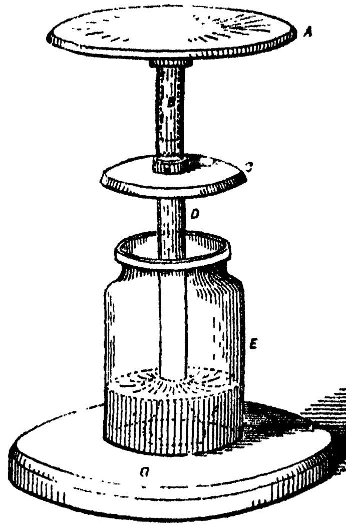
The analyses of the various species of fairy-ring fungi do not greatly differ. Two species occurring at Rothamsted—*Agaricus prunulus* and *Marasmius orcadum*—contain nitrogenous compounds to the amount of one-third of their dry substance, the ash being rich in potash and phosphoric acid. Their occurrence on pastures, like that of the common mushroom, is probably due to the manuring of the ground by animals and their continuance and growth depend on certain conditions of soil and season. They are rarely developed on rich soils, or on those which are highly manured, or in seasons favourable to the general herbage of the turf; and when they do appear under these conditions they will probably not be reproduced, or only in patches. The recent wet seasons have dispersed fairy rings in situations where they have usually proved persistent. They prevail wherever the growth of the grasses is inferior, especially on the poor downs of the chalk districts, and on poor sandy soils where the natural herbage is wanting in vigour.

The history of fairy rings, as it has now been written at Rothamsted, will attract close attention from all who are interested in the nutrition of plants, including the student of agriculture, and all, in fact, who are specially concerned in the question of the food supply. It was not previously known that any kind of plant could feed directly on the organic nitrogen of the soil itself. It was recognised that the root-development of plants differed, and that the greater extension of their roots enabled some plants to secure a larger proportion of the constituents of the soil than others. But here is a race of plants possessing quite unsuspected powers of assimilation! Instead of rising from the ashes of the phœnix they feed upon its undecayed body, that is, upon the organic nitrogen of the soil. The Leguminosæ, for example, such as beans and clover, are known to assimilate more nitrogen from a given soil than the Gramineæ, such as wheat and barley, and this has been attributed to absorption by their leaves, or to the superior development of their roots. Another alternative is now suggested, and possibly a new departure may be taken in the science of agriculture, as the result of the recent discoveries in connection with fairy rings. HENRY EVERSHED

A CHEAP INSULATING SUPPORT

INSULATING-SUPPORTS are so indispensable in the work of an electric laboratory that several forms have come into extensive use. The plan devised by Sir W. Thomson for securing high insulation by surrounding a glass stem with concentrated sulphuric acid to absorb the moisture which otherwise would condense from the air and form a conducting film over the surface of the glass is remarkably efficient, and has many advantages. Modifications of this form of insulator have been largely used by Prof. Clifton, F.R.S., in the Clarendon Laboratory, and by Profs. Ayrton and Perry in the laboratories of the Technical College at Finsbury. Another modification due to M. Mascart, was described in NATURE, vol. xviii. p. 44; and this pattern has come into extensive use under the name of the *support isolant Mascart*. Though excellent in every way it is very expensive, as its manufacture necessitates a special piece of glass-blowing. The central support of glass is solidly fused into the bottom of a glass vessel with a very narrow neck into which acid is poured through a tubulure at the side.

The insulating support which I have recently described before the Physical Society of London is a much simpler affair, and can be made very quickly and cheaply from the materials at hand in every laboratory. The figure shows the form of the support. A wide-mouthed glass bottle, E, about 10 cm. high, and from 5 to 6 cm. diameter, is selected. A piece of stout glass tubing about 20 cm. long is then taken. One end is closed in the blowpipe flame, and blown into a thick bulb; and while yet hot the bulb is flattened, so as to form a foot for the stem. The flattened bulb should be as large as is compatible with its insertion into the mouth of the bottle. To hold it in its place some paraffin wax is melted in the bottle—from 50 to 70 grm. is quite sufficient—and when it has cooled so as nearly to have become solid the stem, previously warmed, is inserted. When cool, the paraffin holds the stem firmly in its place. To keep out the dust a disk cut out of sheet guttapercha is fitted on as a lid. If dipped into hot water for a minute it can be moulded to the required form. It fits loose-tight upon the stem, as shown at C, and when the stand is not in use is slid down over the mouth of the bottle. A brass disk, A, having a short brass stem, B, below it, slips into the upper open end of the tube, and forms the top of the stand. It is also found convenient to make from rods of glass other supports, shaped at the top in the form of hooks, which can be slipped down into the central tube. These are very useful for holding up wires that pass over the experimenting table and require to be well insulated. The bottle is let into a wooden foot, G. In cases where very perfect insulation is required I have poured a little strong sulphuric acid into the bottle above the paraffin. In practice, however, the insulation of the paraffin is amply sufficient for most purposes, provided dust is properly excluded.



SILVANUS P. THOMPSON

JOHN HUTTON BALFOUR

IN Prof. Balfour, whose death we announced in our last issue (p. 365), has passed away another of that group of eminent teachers, including Goodsir, Syme, Simpson, Christison, &c., which maintained the reputation and added lustre to the fame and prestige of the Medical School in our great northern University during the middle decades of this century; one, too, of that band of working British botanists of the first half of the century which counted amongst its members the Hookers, Munby, Carmichael, Greville, Walker Arnott, Babington, Parnell, Prior, the Macnabs, &c., the majority of whom have now left us; and where are their successors? By his death a figure—in later years picturesque with grey locks and patriarchal beard—familiar all over Scotland, and where scientific men do congregate, has been removed. Few men were more universally esteemed and popular, and few quit their sphere of active and busy life leaving behind them more pleasant reminiscences than he whose decease we have recorded. Compelled by failing health to retire about five years ago from public life, his powers since then gradually weakened, until on the 11th inst. he quietly breathed his last.

John Hutton Balfour was born in Edinburgh on September 15, 1808. Related, as his name indicates, to James Hutton, the famous author of "The Theory of the Earth," he possessed much of the enthusiasm and fire which characterised his ancestor. His early education was completed at the High School of Edinburgh, then at the zenith of its reputation, under Pillans and Carson, and he subsequently studied in the Universities of Edinburgh and St. Andrews, in the former of which he graduated in Arts and Medicine. His first intention appears to have been to enter the Church, and to this aim his studies were directed; but he afterwards abandoned this purpose and commenced to practise medicine in Edinburgh, having spent some preparatory time in Continental schools, and having become a Fellow of the Royal College of Surgeons of Edinburgh. During his early years he was devoted to botany, and his taste received a great stimulus by the teaching and example of Graham, then Professor of Botany in the University of Edinburgh. Whilst engaged in the active work of his profession, he found time to foster his bent and love for nature, and gathered around him many of those who, like himself, were keen students of natural science, and thus was formed the nucleus of the Botanical Society of Edinburgh, of which he was, in 1836, the founder—a society which has done much to promote the study of botany in Scotland, and in which, throughout his whole life, he was a guiding spirit. In 1840 Balfour found time amidst his medical duties to commence lecturing on botany in Edinburgh, and his ability as a lecturer was at once proved by the large numbers attracted to his classes. But it was not until 1842, when he was appointed to the Chair of Botany in the University of Glasgow, vacated by the translation of Sir William Hooker to Kew, that he was able to give up medicine, and devote himself solely to botany. After four years in Glasgow, the death of Prof. Graham made an opening in the East of Scotland, and Balfour was elected Professor of Botany in the University of Edinburgh, shortly thereafter obtaining the appointments of Regius Keeper of the Royal Botanic Garden and Queen's Botanist for Scotland. Subsequently he undertook the duties of Dean of the Medical Faculty in the University, and his energy on behalf of the Royal Society of Edinburgh led to his appointment as Secretary. From all these positions he retired in 1879, when a fitting tribute to the value of his services was paid by the presentation of his portrait, and he was then elected Assessor in the University Court for the General Council, and each of the three Universities with which he had been connected conferred on him the degree of LL.D. For many years he was an F.R.S., and also a member of a vast number of British and foreign scientific societies.

As a botanical investigator Balfour was a systematist, belonging to that school which is now, by a species of reaction, often held in contempt by those within whose reach the modern developments of physics and chemistry have placed methods of morphological and physiological research denied their predecessors. He had an acute perception of resemblances and a keen eye for a species. But it is not upon his original investigations that Balfour's reputation rests; his work of that character was not extensive, for the time which might have been devoted to it was fully occupied by his official duties as Dean of the Medical Faculty and Secretary of the Royal Society, and he was one of those who sacrificed scientific laurels for the good of the institutions he served. But as a teacher his fame was world-wide, and as a great teacher he will be remembered. He had in a remarkable degree the power of lucid exposition, and the inestimable qualification of infusing in his pupils the enthusiasm which possessed himself. Painstaking and conscientious in his work, no trouble was too great for him if it could contribute to the better comprehension by his students of the subject taught, and the wealth of illustration and the earnestness of manner which clothed his lectures impressed all who heard him. Though the natural cast of his own mind made taxonomy his favourite branch of botany, yet in his teaching, especially in his earlier years, this was given no undue prominence; his success, indeed, was in great part due to the way in which all branches of the science were handled, and he had the credit of being the first to introduce in Edinburgh classes for practical instruction in the use of the microscope. His text-books reflect the character of his teaching, and "if," as a critic remarked on their first appearance, "we recall the dry and dictionary-like manuals to which students were forced to have recourse in our young days—as inviting as so many pages of Johnson's Dictionary—we can but envy their successors." In later years his books and he himself fell behind—and who does not?—in the rapid march of science; but any one examining his books cannot fail to recognise how thoroughly they represent the state of science at their date of publication, and to appreciate the industry and the skill with which the author seems to have exhausted every source of information.

Another feature of Balfour's teaching was the "excursion." Amongst the 8000 students whom it was his pride to have passed through his classes will be many to whom the announcement of his death will recall pleasant recollections of these outings on hill and in glen; how, as they neared the habitat of some rare Alpine herb, the wiry and energetic Professor—"Woody Fibre" as they called him—would outstrip all in his eagerness to secure it; or how, toiling up some long barren slope, his constant flow of jokes and puns would enliven and rouse their flagging spirits. In these rambles, to which many will look back as not only healthful and recreative, but as giving them their first lessons in accurate observation of nature, Balfour visited almost every part of Scotland, ascended every important peak, and gathered every rarity in the flora. No one knew Scotland and its plants better. In this way Balfour became associated with his students in a way no other Professor did, and his position as Dean of the Medical Faculty brought him still more in contact with them. The Rhadamanthus of the examination-hall he enjoyed a unique popularity, and the esteem with which old pupils regarded him may be traced to the intimate relationships thus established, to the way he identified himself with and interested himself in them and showed himself always anxious to merge the professor in the friend. In all he did Balfour was methodical, and his powers of organisation and administration found exercise in the management of the Royal Botanic Gardens, which, under his direction and with the Macnabs—father and son—as curators, was greatly increased in extent, provided with a magnificent palm-house and other plant-houses, as well as with a botanical museum and improved teaching accommodation, and made one of the finest in the country. The latest addition to the garden—the arboretum—accomplished just before he retired from public life, was part of a scheme (perhaps chimerical) he encouraged with the view of establishing a School of Forestry in Edinburgh—a scheme now receiving some attention in Scotland.

Ready and rapid with his pen, Balfour's contributions to botanical and other literature are very numerous. Besides contributing to several Encyclopædias, he was for many years one of the editors of the *Annals of Natural History* and of the *Edinburgh New Philosophical Journal*. Of independent works, his text-books, to which we have already alluded, were very popular in their day, and are now valuable for reference, and he published works on Botany and Religion, Plants of the Bible, &c.

We should fail to give an adequate idea of the veteran Professor were we not to allude to that which gave a character to all he did—his religion. To him all nature was a symbol. He was one of that band of which Faraday, Clerk Maxwell, Greville, Wm. Allen Miller, and others were in the van, who "recognised the harmony between the word and the works of God," and who saw "in the objects of nature around indubitable evidences of a great designing mind."

By those who knew him—and his was a wide circle of friends—he will be remembered as a genial companion with the best attributes of humanity, and his name will always remain inseparably linked with the progress of botany in Scotland during this century, and as that of one of the eminent teachers in the University and city to which he belonged.

CAPTAIN HOFFMEYER

In the early death of Niels Hoffmeyer, which occurred at Copenhagen on the 16th inst., modern meteorology has lost one of its most diligent and successful students, and one whose place it will be hard to fill.

Like more than one of our own physicists, Hoffmeyer was an artillery officer, and had attained the rank of captain in the service. At the close of the Prussian war he had fallen into bad health, and accordingly, on the reduction of the Danish army which then ensued, his name was placed on the retired list, and he was for a time unoccupied.

The Danish Meteorological Institute was organised in 1872, and Hoffmeyer was nominated its first director. There could scarcely have been a more fortunate appointment, for Hoffmeyer was gifted not only with unusual energy, but also with a very pleasant manner, so that he made friends for the new office and for its work wherever he went. He will best be known by his Atlas. He undertook to prepare daily weather-maps of the Atlantic—in great measure at his own expense—and he actually published them for a period of three and a quarter years, from September, 1873, to November, 1876. It is only a few months ago that he announced his intention to resume the work in combination with Dr. Neumayer, of the Deutsche Seewarte at Hamburg.

The most important results which Hoffmeyer had deduced from his own maps were contained in his pamphlet, "Étude sur les Tempêtes de l'Atlantique Septentrional, et Projet d'un Service Télégraphique International Relatif à cet Océan," Copenhagen, 1880; and up to the very last he never ceased to use his utmost efforts for the establishment of a meteorological telegraphic service with America, *viâ* the Faroes and Iceland.

While Hoffmeyer's chief work was in the domain of synoptic meteorology, he by no means disregarded climatology, and the service which the Danish Office has rendered to that science by the maintenance of stations in Iceland and Greenland has been very material.

When Capt. Hoffmeyer was in London last summer as Danish Commissioner to the Fisheries Exhibition, he was complaining of great weakness of the heart. During December he was laid by for some time, but he had somewhat recovered, when he was seized last week with rheumatic fever, to which he soon fell a victim. He leaves a widow, but no children. He was an Honorary Member of the Royal Meteorological Society (London). He had been one of the secretaries of the Meteorological Congress at Rome, 1879, and of the Conference on Maritime Meteorology in London, 1874, but his chief official service of this nature was as Secretary to the International Polar Commission, where his loss, coming after that of Weyprecht, will be severely felt.

NOTES

The Council of the Royal Society of Edinburgh has awarded the Keith Prize for the biennial period 1881–83 to Mr. Thomas Muir for his researches into the theory of determinants and continued fractions, the most recent instalment of results obtained by him being in a paper on permanent symmetric functions. Also the Macdougall-Brisbane Prize for the period 1880–82 to Prof. James Geikie for his contributions to the geology of the north-west of Europe, including his paper on the geology of the Faröes, published in the *Transactions* of the Society, 1880–81. And the Neill Prize for the triennial period 1880–83 to Prof. Herdman for his papers in the *Proceedings* and *Transactions* on the Tunicata.

We learn from the *Standard* that the Royal Astronomical Society has awarded Mr. Ainslie Common its gold medal for his photographs of celestial bodies. This high award has, it is believed, been mainly bestowed on account of the magnificent photograph he has succeeded in taking of the great nebula in Orion, of which we gave an illustration in a recent number.

We regret to learn of the death of M. T. du Moncel, editor of *La Lumière Électrique*, and author of numerous works in theoretical and practical electricity.

The needs of the higher education of women in London are gradually being met in the manner that has been found so satisfactory at Oxford and Cambridge, where women students have long enjoyed the advantages of collegiate life. On Monday, February 11, there was a gathering of many of the most influential friends of the movement to inspect an important extension of the College Hall of Residence established at Byng Place, Gordon Square, in October 1882. The success which attended the first development of the scheme, and the growing demand on the part of students for admission, has encouraged the committee to provide additional accommodation by adapting the adjoining house, No. 2, Byng Place. With the new extension they look forward to a yearly surplus instead of a deficit. With the power of accommodating thirteen extra students the receipts would be increased by 876*l.* for the short session, and there would not be a proportionate increase in the expenditure. The advantage of holding the two houses is therefore evident. The second house was opened at the commencement of the current term, and there are now seventeen students in residence. Of this number two are pursuing the course of instruction provided at University College for the B.A. degree, two that for the matriculation examination of the London University, and another, a foreign lady, is a student of English literature at the same college; another student is preparing for the examination of the Pharmaceutical Society. Four ladies are students of the London School of Medicine for Women, and preparing for the M.B. degree (Lond.), and the remainder are studying art at the Slade School and elsewhere. The first student of the Hall who went up for the examination for the B.A. degree passed successfully last October, and has now an appointment as teacher at a school in York. The expenses for board and residence vary, according to the size and position of the room occupied, from 51 to 75 guineas for the

University College session of about thirty-three weeks. Even these fees, moderate as they are, are beyond the means of a large number of students, so that the committee, without such assistance as would be afforded by exhibitions, are unable to extend to them the advantages of the Hall. Besides help in this direction a need is felt for a reference library, as the books necessary for many of the courses at University College and the School of Medicine are numerous and costly. A special fund has been started for this purpose, and it is hoped that further subscriptions may be obtained. It is worth mention that the committee have recognised a principle which, so far as we know, has never been adopted in institutions of this kind. We refer to the representation of students on the governing body. This liberal measure, which invites the co-operation of students and gives them a means for the legitimate expression of opinion, will enable the students in residence to have a member elected annually as their representative on the committee. It is hoped that the benefit of this may be felt in strengthening the bond of a common interest. We have not touched on many of the advantages of the Hall which are felt by those who know the difficulties incident on a student's life in lodgings, as they were dwelt upon when we recorded in this journal the commencement of the scheme in the winter of 1882. It is therefore only necessary to state that the Hall in its enlarged scale offers the same comfortable and well adapted academic residence as that originally provided, and that under Miss Grove, the able principal, the high tone which has marked the institution from the beginning is still maintained. When we point out that the scheme has received the support of the late and present Presidents of the Royal Society, the late Sir William Siemens, Sir John Lubbock, M.P., Mr. Samuelson, M.P., Dr. Gladstone, Prof. Carey Foster, and many others, we have said enough to commend it to all our readers. In the nature of things Science and Art, as well as Literature, will gain by this and similar attempts to put the higher education on a more satisfactory basis.

Dr. Reusch has communicated to *Naturen* the result of his analysis of a portion of volcanic ash from the Krakatoa eruption, given him by Prof. Kjerulf, who had received it direct from Batavia. He finds the principal constituents of the ash to be ordinary pumice-stone, some fragments of which are more than 1 mm. in length, while others are reduced to a condition of colourless or slightly brownish vitreous pumice-powder. Intermixed in the general mass are fragments of larger crystals of felspar (Plagioklas) and of some rhomboidal mineral of the nature of augite.

At a meeting of the Norfolk and Norwich Naturalists' Society on the 29th ult., an account was read from the *Perth Enquirer* of a volcanic eruption in Western Australia, contributed by a highly respected settler who had lived in that district some years. The phenomenon he describes was witnessed by him on the same day as that on which the calamity occurred in the Sunda Straits, although he was in total ignorance of that disturbance at the time. He writes:—"I was travelling inland with a flock of sheep, when late in the afternoon of Saturday, August 25, to my profound astonishment, a shower of fine ashes began to rain upon me and my party. The fall of the ashes commenced just about sunset, and the shower, which was at first but very slight, soon became thicker, until it resulted in a steady and heavy rain of light calcined fragments. After the sun set I noticed a bright ruddy glare on the horizon towards the north-east; this was at first only just perceptible, but as the time wore on it increased in both brilliancy and extent. The glare was not at all diffused, and it was of such a nature that it was impossible to mistake it for a display of the *Aurora Australis*. On the contrary, I could easily see that the source of the glare was strictly circumscribed, or, in other words, it was confined to one spot; but as it increased in intensity the fervid glow mounted higher and higher in the heavens. So far as I could roughly calculate, the source of this extraordinary illumination must have been situated about 400 miles inland to the north-east of Roeburne. The showers of ashes ceased just after sunset, and I observed that the steady glare was still to be seen until before sunrise, but as the sun rose the lurid appearance of that portion of the horizon gradually decreased, and at last quite died away when the orb of day made its appearance. Fortunately, I afterwards had an opportunity of questioning some natives who had recently come from that part of the country, and they described the cause of the glare plainly enough. 'Big mountain burn up big,' they said; and then they added, 'He big one sick. Throw him up red stuff, it run down side and burn grass and trees. We frightened and run away, and fire-sticks (*i.e.* I presume the ashes) fall on us. Two, three days after we go look again; mountain only smoke then, and red sick turned black and hard, just like stone.' A plainer description of a volcano in a state of eruption could hardly be given by uncivilised beings; and I am therefore compelled to conclude that I was the far-distant witness of the first eruption of a volcano that has occurred in Australia within the memory of living men."

Nine lectures on the principal types of the human species will be delivered in the theatre of the Royal College of Surgeons, on Mondays, Wednesdays, and Fridays, at 4 o'clock, commencing on Monday, February 25, by Prof. W. H. Flower, LL.D., F.R.S., as follows:—Introduction, anthropology and ethnology; Physical or zoological anthropology; Nature and extent of the differences between the permanent types or races of men, illustrated by comparison between the European and the Tasmanian native; Methods of estimating the differential characters of the various modifications of the human species, elements of craniometry; Characteristics of the black, or frizzly-haired races, in their typical and modified forms; Characteristics of the yellow, or so-called Mongolian races; Characteristics of the white, or so-called Caucasian races; Races not readily grouped under either of the above principal types; Classification of the races of the human species. The course will conclude on Friday, March 14.

We regret to learn that the Council of the Geographical Society have decided to discontinue the examinations which they have held for a number of years for pupils attending our public schools. The number of candidates has been diminishing every year. The Council are, we understand, considering a scheme for establishing a Professorship of Geography; but, while we recognise their anxiety to promote in this way their branch of science, we confess that we are doubtful if this is the best means of attaining the object. The sphere of geography is at present quite undefined; in Germany it embraces something of nearly every science, while in this country it is often regarded as almost synonymous with topography.

Preparations for the holding of the International Health Exhibition are proceeding rapidly. The General Committee now numbers nearly 400 members, and from these 17 Sub-Committees have been formed. These have all been doing valuable work in advising the Executive Council as to the nature of objects which it is desirable should be fully illustrated, in obtaining the co-operation of many persons of eminence in the various branches on which the Exhibition will treat, and in supervising the applications for space. The allotment of space, which has been largely applied for, is being rapidly proceeded with, and applicants will soon be informed of the decision of the Executive Council with regard to their applications. In response to a request made by His Royal Highness the Prince of Wales, President of the Exhibition, the eight Water Companies of London have resolved to exhibit, in a pavilion which is being erected for them, their appliances for the supply, filtration, &c., of water, together with diagrams showing the various processes and localities; and a powerful Sub-Committee, under the active chairmanship of Col. Sir Francis Bolton, has been formed to carry out this branch of the Exhibition. The Water Companies have also determined to put up in the grounds a large fountain, which will be illuminated at night by electricity. It is impossible, as yet, to give any definite information with regard to foreign countries; but, so far as one can judge at present, Belgium, China, and India will be the best represented.

According to information received in St. Petersburg everything is well with the Russian Meteorological Expedition wintering at Cape Sagasta at the mouth of the Lena. Every preparation was made last autumn for the wintering—the second one—the Governor of Yakutsk having provisioned the station most plentifully. During the previous winter—1882-83—the cold was rarely before January 40° C. below zero, but in January and February the thermometer frequently fell lower. The greatest cold occurred on February 9, when it fell to 52·3° C. below zero. In March even the cold was 40° in the night and 19° in the day. One of the members of the expedition, Dr. Bunge, has forwarded to St. Petersburg some valuable reports on the fauna in and about the mouth of the Lena.

The Academy of Sciences has received a requisition from M. Ferry to appoint three delegates to the International Commission which is to meet at Washington on October 1 next in order to determine the choice of a first meridian. It is the first time that places have been offered to the Academy on a diplomatic commission.

Prof. Hull, who has returned with his party, brings with him, it is stated, materials for the construction of a geological map of the Holy Land very much in advance of anything which could hitherto be attempted. He is reported to have traced the ancient margin of the Gulfs of Suez and Akaba to a height of 200 feet above their present level, so that, according to Prof. Hull, the whole country has been submerged to that extent, and has been gradually rising. As one result of this rise, the Professor is of opinion that at the time of the Exodus there was a continuous connection of the Mediterranean and the Red Sea. As regards the Dead Sea, Prof. Hull believes he has discovered that it formerly stood at an elevation of 1400 feet above its present level—that is to say, 150 feet above the level of the Mediterranean. The history of this gradual lowering of the waters will form a special feature in Prof. Hull's forthcoming report. He believes he has also found evidences of a chain of ancient lakes in the Sinaitic district, and of another chain in the centre of the Wady Arabah, not far from the watershed. The great line of the depression of the Wady Arabah and the Jordan Valley has been traced to a distance of more than a hundred miles. The materials for working out a complete theory of the origin of this remarkable depression are stated to be now available. They are bound to differ in many details from the one furnished by Lortet, whose patient observations have hitherto been received with respect. The terraces of the Jordan have been examined, the most important one being 600 feet above the present surface of the Dead Sea. The relation of the terraces to the surrounding hills and valleys shows, according to Prof. Hull, that these features had already been formed before the waters had reached their former level. Sections have been carried east and west across the Arabah and Jordan Valley. Two traverses of Palestine have also been made from the Mediterranean to the Jordan. Prof. Hull has in hand, besides his scientific report, a popular account of his journey, which will first appear in the *Transactions* of the society. Captain Kitchener's map-work is in the hands of Mr. Armstrong, who was for many years on the survey of Western Palestine. He has himself been ordered on service up the Nile; but it is hoped that his absence will not retard the publication of a new and very interesting piece of geographical work.

We have received the following communication from the Royal Victoria Coffee Hall:—"By the kindness of the Gilchrist Trustees the Committee of the Royal Victoria Coffee Hall, Waterloo Road, have been enabled to arrange another series of Penny Science Lectures on Tuesday evenings, as follows:—March 4, Prof. H. G. Seeley, F.R.S., on Ancient English Dragons; 11, Wm. Lant Carpenter, B.Sc., F.C.S., on Air, and why we Breathe (with experiments); 18, P. H. Carpenter, M.A., D.Sc., on Fossils, and what they teach us; 25, Edward Clodd, on the Working-Man 100,000 Years Ago. April 1, E. B. Knobel, F.R.A.S., F.G.S., Hon.Sec.R.A.S., on the Planets; 8, J. W. Groves, on the Dangers and Safeguards of Beauty in Animals. All the lectures will be illustrated by means of the oxyhydrogen lantern. If any of your readers can distribute handbills among working people, or cause window bills to be displayed in suitable situations, we shall be grateful for their help, and beg they will communicate with the Honorary Secretary. The difficulty of making anything known in this crowded, busy London is acknowledged on all hands, but it is believed that if these lectures could be made known in the right quarters, people would come long distances to hear them."

It appears from the report of Drs. Brouardel, Segond, Descout, and Magnin, who conducted the autopsy of Tourguenief, that the brain of this eminent Russian author weighed 2012 grms. This extraordinary weight, which is only known to have been exceeded in the case of Rudolphi, is inexplicable, for Tourguenief, although tall, was not of exceptionally high stature. The brain is said to have been remarkably symmetrical, and distinguished by the extreme amplitude of the convolutions. According to generally accepted views, however, symmetry of the circonvolutions is not a favourable cerebral characteristic.

An Anthropological Society has been founded at Bordeaux with Dr. Azam as president, and Dr. Testut as vice-president; both being members of the Faculty of Medicine of Bordeaux.

A special commission has been established by the French Government to investigate the several processes proposed as a cure for phylloxera. It was stated officially at the last meeting of this body that every suggestion had proved abortive.

King Oscar of Sweden has personally conferred upon Mr. Carl Bock the Order of St. Olaf.

"In our issue of December 14," *Science* states, "we published an article on 'The Signal-Service and Standard Time,' criticising the action of the chief signal-officer in not adopting the new standards of time at signal-service stations. We have since learned that our criticism was not well founded, as the information upon which it was based gave an incomplete idea of the position of the service in this matter. It is true that the observers of the service are still governed by the local times of their respective stations; but this is only a temporary arrangement, and will be changed as soon as possible. The reason of the delay is this: the international observation, which is taken at many stations of observation throughout the whole world, is made at 7 a.m., Washington time. It is proposed to make this observation eight minutes earlier, or at 7 a.m. of the time of the 75th meridian, which is exactly Greenwich noon; but, before this change can be made, the cooperating weather-services and numerous independent observers must first be notified, and their consent obtained. Correspondence has already been begun, and a circular letter sent to all who cooperate in the international work asking consent to the proposed change. Favourable replies are being received; and there is little doubt that the change will be made, probably Jan. 1, 1885. It should be remembered that the international observation is made largely by observers who kindly cooperate with the chief signal-officer, but who are not under his orders: a change of this kind cannot, therefore, be summarily ordered, but must be made by mutual consent."

THE Commissioners on Technical Education have now practically concluded their labours, and are likely to have only one more meeting to formally sign their Report, the greater part of which is in type. It will consist of at least five octavo volumes, it being found impracticable, even after careful consideration, to bring the mass of evidence and information within smaller compass. It is stated that any *résumé* of the series of conclusions and recommendations at which the Commission have arrived would not be useful or fully intelligible to the public without the explanatory details with which they will be accompanied. It is, however, hoped that the complete Report may be presented soon enough to permit of the House of Commons proceeding during the present session with such legislation, based upon the recommendations, as may be thought necessary. Meantime it is understood that technical training will form an important part of the measures of which the Government and Mr. A. O'Connor have given notice with regard to education in Ireland.

MESSRS. W. EAGLE CLARKE and W. Denison Roebuck, Leeds, are preparing a supplement to their "Handbook of the Vertebrate Fauna of Yorkshire," and would be glad to have notes of additions or corrections to that work, or notices of the occurrence of any species of quadrupeds, birds, reptiles, or fishes in Yorkshire which their friends may be pleased to communicate. As they wish to publish in the April magazines, it is hoped that the desired information may be sent in immediately. Communications may be addressed to No. 9, Commercial Buildings, Park Row, Leeds.

AT the Royal Institution Prof. Tyndall will begin a course of six lectures on "The Older Electricity—its Phenomena and Investigators," on Tursday next (February 28), illustrated by experiments; and Capt. Abney, R.E., will begin a course of six lectures on "Photographic Action, considered as the Work of Radiation," on Saturday (March 1). Prof. Hughes will give a discourse on Friday evening next, on "The Theory of Magnetism," illustrated by experiments.

WE have already referred to the International Ornithological Congress which is proposed to be held in Vienna on April 16-23, under the protectorate of the Crown Prince Rudolf. It is now announced that arrangements are in progress for an International Ornithological Exhibition, which is to precede the Congress, and which will occupy from April 4-14. Single specimens and collections of living birds of all kinds, including domestic birds; all apparatus serving for the protection, cultivation, breeding, and conveyance of birds; implements used in bird catching and bird shooting, falconry, carrier-pigeon-post; aviaries, and bird cages; scientific objects and products which originate in or refer to the feathered world, will all be included in the programme of the Exhibition. All details will be furnished to intending exhibitors or partakers in the Congress by the Secretary of the Vienna Ornithological Society, Dr. Gustav von Hayek, III. Marokkanergasse 3 Vienna. The main subjects to be discussed at the Congress are—(1) An international law relating to the better protection of birds; (2) the establishment of a system of ornithological observing stations all over the inhabited globe; and (3) investigations concerning the origin of the domestic fowl, and measures for the amelioration of the cultivation and breeding of domestic birds generally.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Miss Furniss; two Common Roe (*Capreolus capræa* ♀ ♀) from Dorsetshire, presented by Messrs. Charles Hambro and J. C. Manuel Pleydell; a Passerine Owl (*Glaucidium passerinum*), European, presented by Mr. G. R. Lake; a Naked-necked Iguana (*Iguana delicatissimus*), a Banded Basilisk (*Basilicus vittatus*) from Nicaragua, presented by Mr. Albert Vidler; two Prairie Marmots (*Cynomys ludovicianus*) from North America, a Shaw's Gerbille (*Gerbillus shawii*) from North Africa, a Military Macaw (*Ara militaris*) from South America, two Iceland Falcons (*Hierofalco islandus*) from Sweden, deposited; a Red-eared Monkey (*Cercopithecus erythrotis* ♀) from Fernando Po, two Slow Loris (*Nycticebus tardigradus*) from the Malay Countries, a Red-eyed Ground Finch (*Pipilo erythrophthalmus*) from South America, an Eyebrowed Weaver Bird (*Hyphantornis superciliosus*) from West Africa, four Asiatic Quails (*Perdicula asiatica* ♂ ♂ ♀ ♀) from India, purchased.

OUR ASTRONOMICAL COLUMN

AUSTRALIAN OBSERVATORIES.—The eighteenth Annual Report of the Director of the Observatory at Melbourne to the Board of Visitors (who in their turn report to the Governor of Victoria) has been issued. The new transit-circle was expected in a short time, and would find the new circle-room ready to receive it, but the instrument which had been in use for twenty years continued to give excellent and trustworthy results; nevertheless each year had forced upon Mr. Ellery the necessity of greater optical scope for the meridian work. The inevitable loss of reflective power in the great telescope increases a little year by year, but does not yet sensibly affect the work upon which it is employed. Indeed, Mr. Ellery says, "Some photographs of faint objects obtained lately are clear evidence of the immense light-gathering power it still possesses, and of the trivial loss occasioned so far by the slight tarnish apparent." The instrument had not been kept quite so closely to its special work—the revision of the southern nebulæ—as before, owing to the number of nights occupied with the great comet and in experimenting in celestial photography. Among the subjects of observation Mr. Ellery refers to the transit of Venus, the Port Darwin Expedition for determination of longitude of Australian observatories, and measures of differences of declination of the minor planets *Sappho* and *Victoria* for determination of the solar parallax, according to the scheme arranged by Mr. Gill. The great comet of 1882 was kept in view for 250 days, or until April 26. A large portion of the work connected with the telegraphic determination of the longitude of Australian observatories from Greenwich fell upon the Melbourne establishment, which is now assumed to be in longitude 9h. 39m. 53·37s. E., subject perhaps to some very small correction. As soon as the new transit-circle was properly adjusted, it was Mr. Ellery's intention to devote it to the revision of a rather large catalogue of stars at the request of the "Astronomische Gesellschaft," besides its more special work. The great telescope would be applied more exclusively to the continuation of the revision of Sir John Herschel's nebulæ, several of which, by the way, the Melbourne observers have not been able to find.

Mr. H. C. Russell sends us an historical account of the Observatory at Sydney and of the observations which preceded the erection of the present one in that colony. With the details of the actual observatory the reader will be probably acquainted through the volumes of results which have been issued therefrom; that for 1877-78 contains a general view of the building; but Mr. Russell mentions circumstances attending the erection of the first observatory on Australian soil which are perhaps little known. He extracts from the "History of New South Wales," by Col. Collins, the following note:—"Among the buildings that were undertaken shortly after our arrival [that of the first colonists in 1788] must be mentioned an observatory which was marked out on the western point of the cove, to which the astronomical instruments were sent, which had been sent out by the Board of Longitude for the purpose of observing the comet which was expected to be seen about the end of this year. The construction of this building was placed under the direction of Lieut. Dawes, of the Marines, who, having made this branch of science his peculiar study, was appointed by the Board of Longitude to make astronomical observations in this country." The observatory was erected as soon as the colonists landed, but, being found small and inconvenient, a new one for the better reception of the instruments and the residence of Lieut. Dawes was built of stone, for which ample materials were found upon the spot.

The comet to which reference is here made was that of 1661, supposed to have been identical with the comet of 1532, and again expected about the end of 1788 or beginning of 1789. It is not difficult to explain how this body came to be associated with the arrival of the first Australian colonists. Halley, who had calculated the orbits of the comet observed by Apian in 1532, and that observed by Hevelius in 1661, gave very similar elements in his "Synopsis of Cometary Astronomy." Pingré considered the comets identical, and thought he had recognised several previous appearances, as detailed in his "Cometographie," which was published in 1783. Maskelyne appears to have adopted Pingré's opinion, and was at the trouble of preparing sweeping ephemerides, which he communicated to the Royal Society, and we may conclude that it was through his interest with the Board of Longitude that Lieut. Dawes was supplied with instruments and charged with a search for the comet. Mr. Russell says there is no record of what was done at the Dawes' Point Observatory, but since the comet was not observed as expected, we may infer there were only negative results to be reported, though Lieut. Dawes did occupy himself in other ways to assist in the progress of the colony.

CHEMICAL NOTES

THE water supply of Boston (U.S.A.) became contaminated about a year ago with some substance or substances which imparted to it a peculiarly nauseous odour and taste. Chemical examination resulted in showing a large percentage of "albuminoid ammonia," and also that the "free ammonia" increased somewhat rapidly when the water was kept. The production of ammonia, and also the odour and taste, was finally traced to the decomposition of a freshwater sponge (*Spongilla fluviatilis*, Anct.) present in large quantities on the sides and bottom of one of the storage basins; removal of this sponge was followed by improvement in the water (see *Analyst*, viii. p. 184).

PROF. CLEVE describes, in the August number of the *Journal of the Chemical Society*, methods for extracting and purifying the earth *samaria*. From determinations of the amount of sulphate obtained from quantities of this oxide, Cleve deduces the number 150 as the atomic weight of the metal *samarium*. Various salts of samarium are described; the metal is closely allied to didymium.

HARTLEY showed some time ago (*C.S.J. Trans.* for 1882, p. 84 *et seq.*) that the ultra-violet spectra of elements belonging to the *same series* (in the nomenclature of the periodic law) exhibit fairly marked analogies as regards general character; recent observations of the spectrum of beryllium and comparison of this spectrum with that of allied metals have led Hartley to the conclusion that this metal probably belongs to the group which contains magnesium, calcium, &c., and not to that containing aluminium, scandium, &c. But if this is so, oxide of beryllium must be represented as BeO, and the atomic weight of the metal—about which there has lately been so much dispute—must be taken as 9 (*C.S.J. Trans.* for 1883, p. 316).

V. MEYER has recently separated, from benzene oils, a compound to which he gives the name of *Thiophen*. The composition of this body is represented by the formula C_4H_4S; it presents the closest analogy in general reactions with benzene, yielding a sulphonic acid, a methyl derivative, &c.; it reacts with diketones to form highly coloured compounds. The further study of this interesting compound, now being carried on in Prof. Meyer's laboratory, is likely to lead to important results (*Berichte*, xvi. 2968).

OSTWALD has recently made a further advance in his study of chemical affinity. He has examined the action of acids on methylic acetate, determining the velocity-coefficients of various acids, and from these calculating the relative affinities of the acids in terms of hydrochloric acid taken as 100. His results are entirely in keeping with the theory of Guldberg and Waage, and confirm the supposition that each acid possesses a specific affinity constant. The determination of affinity constants for groups of compounds must evidently be a work of preeminent importance to chemical science. Ostwald's results, *e.g.* for acetic and trichloracetic acids, enable us to see that in these constants we shall find materials for constructing a theory which will represent the connection between molecular structure and reactions as resting on a real basis, and not, as is done at present, on a purely formal conception (*J. für pract. Chem.* (2) xxviii. 449).

A NUMBER of redeterminations of atomic weights have recently been published. The most important are these :—

Thorpe, Ti = 48·0, *Berichte*, xvi. 3014.
Baubigny, Ni = 58·75, *Compt. Rend.* xcvii. 951.
„ Cu = 63·46, „ „ 906.
Brauner, Te = 125·0, abstract in *Berichte*, xvi. 3055 (original in Russian).
Marignac, Bi = 208·16, *Archiv. des Sci. Phys. et Nat.* (3) x. 5.
„ Mn = 55·07, „ „ „
„ Zn = 65·29, „ „ „
„ Mg = 24·37, „ „ „
Löwe, Bi = 207·33, *Zeitschr. Anal. Chem.* xxii. 489.

IT is known that Dr. Landolt, after laborious researches into the refracting power of chemical compounds, arrived at the conclusion that it may be expressed, for organic bodies, by a very simple equation: the refracting power of the compound is equal to the sum of the same powers of carbon, hydrogen, and oxygen, multiplied each by the number of atoms of each of these bodies which enter into the compound. This law proved, however, not to be quite exact with regard to several organic bodies, and the researches of Herr Bruhl established that in the lower compounds the refracting power received from the equation must be increased by two units for each double pair of atoms of carbon. These results had been arrived at with liquid compounds. As to the solid ones, which were the subject of the researches of Dr. Gladstone, it was desirable to pursue these researches to the same degree of accuracy as the researches of Landolt and Bruhl. M. Kanonnikoff has prosecuted this work on a great many solid bodies belonging to both groups of the fatty series, the aromatic series and the group of terebenes and camphors. He publishes now in the *Memoirs* of the Kazan University and (abridged) in the *Journal of the Russian Chemical Society* (vol. xv. fasc. 7) the results of his researches. It appears from them that the method of determining the refracting power of a solid from its solution, applied by Dr. Gladstone, is quite satisfactory, the dissolved body not changing its refrangibility when dissolved, and that the laws discovered by Landolt and Bruhl for liquid bodies are quite true also with regard to solids. This inquiry at the same time enables M. Kanonnikoff to arrive at most interesting conclusions as to the structure of the investigated bodies.

THE atomic weight of tellurium not corresponding to what it ought to be according to Prof. Mendeléeff's theory of periodicity, M. Brauner has tried to determine it again with greater accuracy. The chief difficulty is to have the tellurium free from selenium, but this difficulty has been overcome, and the body has been obtained in beautiful crystals. As to Berzelius's method for the transformation of tellurium into anhydride, M. Brauner discovered that it is liable to considerable losses, and to avoid them he has had to take the most minute precautions. The process was controlled also by transforming tellurium into a new salt, $Te_2O_4SO_3$, and by the synthesis of the telluric copper, Cu_2Te. The results are four series of figures varying from 124·94 to 125·40, which would give, on the average, an atomic weight of 125, that is, corresponding to the theory.

WE find, in the last number of the *Journal of the Russian Chemical Society*, an interesting theory of solutions, by M. Alexeyeff; the forces of gravitation, cohesion, and chemical affinity being considered as three different degrees of one single force, which differ from one another only by the distances at which the action of the force is exercised. M. Alexeyeff asks, Which of these two last forces, of cohesion or of chemical affinity, is manifested in solutions? and pronounces himself for the former. The simplest cases of solutions are, in fact, those where there is no chemical affinity between the bodies dissolving and dissolved. Such cases were well known long since for gases and solid bodies. The solution of gases in solid bodies is quite analogous to imbibition of solids with liquids, and the much greater solubility of gases in liquids may be easily explained by the easier penetration of gases between the molecules of a liquid; the law of solubility of gases given by Dalton is perfectly agreeable with the supposition that the dissolved gases maintain their own aggregation when dissolved. The same is true with regard to solutions of liquids. The simplest of these is the solution of phenol and aniline in water. The stability of the compound formed by phenol with aniline shows that both have no affinity to water. Further, M. Alexeyeff discusses the applicability of his theory to bodies which easily pass from one state to another, and the relations of water to colloids. The solutions of liquids in liquids being, on his hypothesis, quite like emulsions. He is engaged now in experiments intended to show that the common emulsions have the properties of solutions.

M. **Flavitsky** proposes, in the *Journal of the Russian Chemical Society*, the following interesting theory of chemical affinity. According to this theory, the atoms of each simple chemical body, when its molecule is dissociated, move in circles parallel to one another, and to a certain plane, the position of which is constant in space. Each chemical element has its own plane of motion, and the circles described by the atoms of different elements cross one another under different angles. Besides, the atoms of opposite elements (such as metals and haloids) move in opposite directions. The chemical relations between different elements would thus depend upon the masses of the atoms, their velocities, their positions on their orbits, the direction of the motion, and the angles between the orbits; while the chemical combinations would be nothing more than the mutual destruction (or rather equilibration) of the velocities of the atoms of the respective chemical elements which enter into a combination. This supposition would explain all the variety of chemical relations even without a great difference in the masses of the atoms and their velocities; a complete stop might be brought only when the orbits are parallel, or the orbits being inclined with regard to one another—when a certain number of velocities acting under different angles make together the necessary resultant. This mutual action of the atoms on one another could be imagined—the author says—at a distance, by means of the ethereal medium which would be thus the medium of transformation of the physical energy into the chemical one.

TECHNICAL EDUCATION[1]

General Objects

The object of the Central Institution is to give to London a College for the higher technical education, in which advanced instruction shall be provided in those kinds of knowledge which bear upon the different branches of industry, whether manufactures or arts.

Just as the Royal School of Mines gives a technical training to mining engineers, so the Central Institution is intended to afford practical scientific and artistic instruction which shall qualify persons to become—

1. Technical teachers.
2. Mechanical, civil, and electrical engineers, architects, builders, and decorative artists.
3. Principals, superintendents, and managers of chemical and other manufacturing works.

The main purpose of the instruction to be given in this Institution will be to point out the application of different branches of science to various manufacturing industries; and in this respect the teaching will differ from that given in the Universities and in other institutions in which science is taught rather for its own sake than with the view to its industrial application. In order that this instruction may be efficiently carried out, the Institution, in addition to the lecture theatres and class rooms, will be fitted with laboratories, drawing offices, and workshops; and opportunities will be afforded for the prosecution of original research, with the object of the more thorough training of the students, and for the elucidation of the theory of industrial processes.

Students

It is probable that the students seeking admission into the Central Institution will belong to one or other of the following classes:—

1. Persons who are training to become technical teachers.

These will be students entering the College by means of exhibitions under category 2 (*b*); or students selected at the May examinations in technology who pass with special distinction in the Honours Grade; or teachers of the Institute, registered under the scheme of technological examinations, who, during certain months of the year, when they are disengaged, will receive gratuitous instruction, and will have the opportunity of using the laboratories, collections of machinery, instruments, and apparatus with which the College will be provided.

2. Persons not under sixteen years of age who, having passed a matriculation or entrance examination, are prepared to take a complete course of instruction with a view to some professional or industrial occupation. These students will probably belong to two classes—

(*a*) Persons who pay full fees, and will receive in this Institution an education similar, in many respects, to that which they may acquire in one of the technical high schools of the Continent.

(*b*) Persons who are received into the Institution from the Finsbury Technical College, or other similar colleges in the provinces, by means of exhibitions, which will cover the whole or part of their educational and other expenses.

It is probable that many of the persons in sub class (*b*) will be select pupils from the public elementary and national schools, who, having received a preliminary science training, and distinguished themselves at the Finsbury Technical College or elsewhere, will proceed to the Central Institution in the hope of qualifying themselves for some of the higher posts in engineering or manufacturing industry.

3. Persons who, having been already engaged in industrial pursuits, desire to attend special courses, with the view of acquainting themselves more fully with the scientific principles underlying their work.

Conditions of Entrance

The matriculation or entrance examination for students intending to take the ordinary science curriculum, with the view of subsequently obtaining a diploma, will include mathematics, pure and applied; chemistry; physics; drawing, and modern languages. Whilst considerable freedom will be allowed to students entering the College as regards the courses of instruction which they desire to follow, a definite scheme of instruction will be drawn up for each of the different branches of industry, and students intending to spend two or three years in the College and to devote their whole day to study will be recommended to follow the scheme laid down. The fee for the courses to be pursued by a matriculated student will be about 30*l*. per annum, and a fee of about 20*l*. per annum will be charged to students wishing to take special courses and to occupy themselves for the greater part of the day with laboratory practice and research work. With the view of encouraging research work, the Institution will be provided with separate laboratories in which the students will have the opportunity of working without distraction or disturbance. The permission to use these laboratories will be reserved for the advanced students who have previously passed through the ordinary courses of the College, and for non-matriculated students under very special circumstances.

Subjects of Instruction

As the object of this Institution is to train technical teachers, proprietors and managers of chemical manufactories and of other industrial works, as well as mechanical, civil and electrical engineers, architects, builders, and persons engaged in art industries, the Institution will comprise five chief divisions, viz.:—(1) Chemical Technology; (2) Engineering, mechanical, civil, and electrical; (3) General Manufactures; (4) Architecture and Building Construction; (5) Applied Art; and the subjects of instruction may accordingly be grouped under the general headings of Chemistry, Engineering, Mechanics and Mathematics, Physics, Manufacturing Technology and Art. Inasmuch as the Royal School of Mines is already established as a training school for mining engineers, no provision will be made for the instruction of students in this branch of industry; and consequently the sciences of geology, mineralogy, and metallurgy will not necessarily be included in the subjects of instruction at the Central Institution.

Professorial Staff

Chemistry.—The main object of the instruction in this department will be to afford to students facilities for acquiring a knowledge of the highest branches of Chemistry, and of its application to such industries as alkali manufacture, the manufacture of artificial colouring matters, brewing, soap boiling, the manufacture of oils and varnishes, dyeing, &c. To provide the requisite instruction in this department, it will be necessary to have one chief professor, who shall devote the whole of his time to the work of the Institution, and who will be expected to direct and superintend the students in his department and to train them in the methods of original research. In addition to this appointment, it will be advisable to have two assistant professors, who shall respectively take charge of the research and of the technical departments. A separate laboratory will be placed under the direction of each professor; and the arrangements of the building, which provide three large laboratories, besides several smaller rooms which may be used as such, render possible this division of the work. Besides these professors, demonstrators, laboratory and lecture assistants and attendants will be required to complete the staff in this department.

---

[1] The scheme for the organisation of the Central Institution of the City and Guilds of London Institute, recommended to the Council for adoption at a meeting of the Executive Committee held January 21, 1884, is now being circulated. We regard the matter as so important, and the scheme so perfect in its way, that we give it in full.

Engineering.—The instruction to be given in this subject will have for its object the practical scientific training of persons who intend to enter any branch of the engineering profession. The instruction will be adapted to those who have already spent some time in the office of a civil engineer or in engineering works, as well as to those who desire to obtain in the College a sound theoretical knowledge of the principles of science applicable to their future career, and an insight into the practice and manipulative work in which they will be subsequently engaged. The professor appointed to take charge of this department will be expected to devote the whole of his time to the work of the College, and to lecture on such subjects as the strength of constructive materials; the construction of docks, roads, bridges, and roofs; machine designing; hydraulic and other machinery; steam-engines, gas-engines, &c. He will also be required to give instruction in levelling and surveying, to superintend the laboratory practice of the students in the testing and engine rooms, and to direct their work in the machine shops and drawing offices. He will need the assistance of a teacher of machine drawing, and of a workshop instructor, besides one or two laboratory demonstrators, and the necessary attendants to look after the engines and machines. Later on, an additional professor will be required to take charge of some of the work of this department.

Mechanics and Mathematics.—Immediately connected with the teaching of engineering and physics is the instruction required by the students of a technical college in mechanics and mathematics. There is little doubt that the student's progress in the several branches of engineering depends very much upon his possessing such a knowledge of pure and applied mathematics as enables him to use it as an instrument of his ordinary work, and for this purpose it is necessary that his knowledge should be in advance of such applications of it as he may at any time be required to make. The professor appointed to this post will be expected to give practical instruction in the application of mathematics and mechanics to the solution of engineering and physical problems. He will be required to devote the whole of his time to the work of the College, and to give courses of instruction, illustrated by laboratory practice, on the principles of dynamics and of mechanicism, on graphical statics, on descriptive geometry, and on some of the higher parts of pure and applied mathematics. He will need the services of two demonstrators to assist in the mechanical laboratory and in the drawing office.

Physics.—In view of the present and future applications of electricity to engineering problems, considerable importance attaches to the character of the instruction to be given under this heading. The teaching of practical physics has only recently been introduced into schools of applied science, and the number of students receiving laboratory instruction in this subject in our own colleges, and in foreign polytechnic schools, is still very limited. The large number of students in attendance at the courses of electricity in the Finsbury Technical College shows that there is already a strong demand for instruction in the practical applications of this important branch of physical science. In order to supply the requisite teaching staff in this subject, it will be necessary, in the first instance, to appoint a professor, who shall devote the whole of his time to the work of the College, and who shall be responsible for the work of his department. This appointment will be supplemented by that of an additional professor, whose duties will depend very much upon the particular branch of physics to which the chief professor may devote his attention. Whilst it is highly desirable that every facility should be afforded in the Central Institution to students desiring to become electrical engineers, of receiving practical instruction in the theory and application of electricity to such technical subjects as telegraphy, electric lighting and the transmission of power, for experiments in which subjects special laboratories will be set apart, it will be the duty of the chief professor or of the additional professor to give courses of lectures on heat, light, and sound; to superintend and encourage laboratory practice in these branches of physics; and to take up from time to time the consideration of other technical subjects, such as the principles of thermo-dynamics in their application to the theory and working of steam-engines, gas-engines, ventilation, &c. To complete the teaching staff of this department, the professors will require the assistance of one or more demonstrators, according to the number of students in attendance at their laboratories.

Technology.—Under this heading is included instruction in the processes and practical details of various manufactures, some of which will be treated of by the professors of the several departments already referred to, whilst others will need the assistance of specialists who will be engaged to give lectures on these subjects. The gentlemen appointed to give these lectures will be either the Institute's examiners in technology, or other persons equally well acquainted with the technical details of particular manufacturing processes. They will be appointed from time to time as required, and will not necessarily form part of the permanent staff of the College.

The lectures will probably be of two kinds, according as they are delivered during the session or during the long vacation. The one course will form part of the curriculum of the ordinary students of the College, whilst the other course will be especially arranged for the instruction of teachers of the Institute, registered under the scheme of Technological Examinations. The lectures given during the session will be attended by the matriculated students towards the close of their regular course of study, those delivered during the recess by teachers of technical classes in London and the provinces, who will be invited to hear them without payment of fee. Arrangements will also be made by which other persons seeking information on technical matters may be admitted to these lectures.

The lectures will embrace several of the subjects included in the programme of Technological Examinations, such as Alkali Manufacture, Spirit Distilling, Glass Manufacture, Pottery and Porcelain, Printing, Weaving, the Manufacture of Cotton, Wool, Linen, &c., and will treat of the technical details involved in these and other industrial processes. For the illustration of the lectures, specimens of materials in various stages of manufacture, models and diagrams of machinery, will be required; and these should be found ready for use in the Museum of Technology, a room for which has been provided in the Institution. Facilities will be afforded to the lecturers and students for carrying on experimental work in explanation of the lectures; and considering the varied character of the work which may have to be performed in connection with this department, for which it is impossible to make provision at the outset, it is very important that here and there rooms should be left available to be fitted with such arrangements and apparatus as experience may show to be desirable. These lectures will form a special and characteristic feature of the instruction to be given in the Central Institution.

Architecture and Building Construction.—To give completeness to the instruction which this Institution should afford, a department of Architecture and of Building Construction should be added to those already enumerated. The establishment of a special school for Architects and Builders would not involve any great addition to the professorial staff which it is suggested should be provided for the other departments of the College. But as the funds at the disposal of the Institute are not sufficient to enable the Council to give effect at starting to a complete scheme of higher technical instruction adapted to all the differen industries of the country, it would seem advisable at first to restrict within certain limits the work to be carried on in the Institution, and to defer for some little time the organisation o this special school.

Applied Art.—Under this heading instruction might be given in decorative art, and in several special branches of applied art particularly in those in which artistic effects are produced by combination of art with processes involving applications o science, such as Chromo-lithography, Enamelling, Photo engraving on Metals, Photo-lithography and Photography Lectures might be delivered on these subjects, and on the scien tific principles connected with them; and the processes them selves might be practically illustrated under the direction of e perienced teachers in the workshops of the building. Lesson might also be given in designing for, and in the executio of, glass painting, mosaic work, wood and ivory inlaying, th inlaying of metals into various substances, wood-engraving and wood-carving.

Instruction of this kind would be very serviceable in creating and developing art industries in this country, and it would be especially valuable in the training of teachers; and it is hoped that means will be found, at a very early date, for giving such instruction.

Modern Languages.—In view of the increasing importance to students of applied science of being able to read foreign scientific and trade journals so as to understand what is being done abroad in the particular branch of industry in which they are engaged, the students will have the opportunity in the Central Institution of pursuing their studies in the French and German languages. It is true that they might obtain these lessons elsewhere, but it is found, as a fact, that students very rightly object to the loss of time involved in going from place to place in pursuit of the instruction they require, and commonly neglect the lectures which they have not the opportunity of attending in the Institution in which they pass the greater part of their day. Moreover, students are attracted to a place of learning in which they can obtain all the instruction they need. For these reasons, it is thought desirable that teachers of French and German should, as soon as possible, be appointed. At the same time it is hoped that, as the teaching of modern languages becomes so far improved that students, seeking admission to the College, will be able to translate with ease passages from French and German into English, the necessity of supplementing the technical instruction, which the Institution is intended to afford, by providing for this branch of education will cease to exist.

COURSES OF INSTRUCTION

Systematic courses of instruction will be drawn up for matriculated students, which will be obligatory upon those who seek the Diploma of the Institute. These courses will cover a period of three years, and will be varied according to the branch of engineering or of manufacturing or art industry for which students are preparing. The details of these courses will be best settled in consultation with the several professors; but it is understood that, besides the general and special lectures and class work already referred to, the instruction will consist largely of laboratory practice in chemistry, mechanics, and physics; and that for students who may not previously have acquired any manipulative skill, the workshops of the Institution will be available; whilst machine drawing will form an important part of the ordinary curriculum. It is hoped, too, that the professors will have opportunities of conducting their students to some of the different factories and works in and near London.

DIPLOMAS

It is desirable that the Institute should grant diplomas, in accordance with the power conferred upon the Council by the Articles of Association, Sec. 51. The diplomas should be of two kinds, the Associateship of the Institute, and the Fellowship of the Institute.

The Associateship should be awarded to students of the Central Institution, who shall have gone through the complete course of instruction as laid down for them, and have satisfactorily passed their several examinations. Of these examinations, the first would be the Matriculation or Entrance Examination, and candidates unable to pass it would be recommended to spend one year, at least, in some suitable College, in preparation for it. A subsequent examination would be held at the end of each year on the College work, and the final examination, at which external examiners would be selected to assist the Professors of the Institution, would be essentially practical in character. The diploma might be granted to students educated at any other College affiliated to, or associated with, the Institute, who should pass the Matriculation and other examinations.

The Fellowship would be conferred upon persons who, having obtained the Associateship, and spent at least five years in actual practice, should produce evidence of having done some original and valuable research work, or of having otherwise contributed to the advancement of the industry in which they are engaged.

EVENING INSTRUCTION

Although, at the outset, the education of day students is all that can with advantage be attempted, it is desirable that, later on, the experiment shall be made of giving evening instruction in the Central Institution.

The instruction so given should consist of courses of lectures dealing with some of the applications of science or art to special branches of industry, and serving the double purpose of imparting information and of showing the importance of more systematic technical teaching. These lectures should be somewhat of the character of the Cantor lectures periodically delivered at the Society of Arts, and somewhat similar to the well-attended and varied courses held at the Conservatoire des Arts et Métiers at Paris. Whilst differing from class lessons, they would have a distinctly educational value; and, as distinguishing them from the Cantor lectures as well as from those given at the Paris Conservatoire, opportunities would be afforded to some of the students attending them of themselves doing laboratory work on one or more evenings of the week. It would be necessary that the evening instruction should be so arranged as not to interfere with the ordinary day courses.

APPOINTMENT OF CHIEF PROFESSORS

Should the scheme now proposed for the organisation of the Central Institution be adopted, there are numerous details connected with it which will need to be carefully worked out. But before entering further into the consideration of these details, it is desirable that the chief professors should be appointed, not with the view of their entering immediately upon their duties, but in order that the Sub-Committee may confer with them as to the courses of instruction to be given, and as to the fittings of the several laboratories and class rooms, the preparation of which will occupy some considerable time.

It is recommended, therefore, that the Committee should at once appoint—

A Professor of Chemistry.
A Professor of Engineering.
A Professor of Mechanics and Mathematics.
A Professor of Physics.

These gentlemen having been elected, the appointment of the other professors, the demonstrators, and lecturers on technology may be deferred, it being understood that some of these additional posts must be filled before the opening of the first session. Meanwhile, however, the work of preparing the fittings and of arranging the courses can be advanced.

MANAGEMENT

The following Rules have been drawn up for the regulation of the educational and administrative work of the Central Institution:—

1. There shall be a Board of Studies, composed of the Professors of the Institution, for the consideration of all matters connected with the education of the students.

2. Any lecturer holding an annual appointment and giving a separate course of instruction may be appointed by Sub-Committee A as a member of the Board.

3. Subject to a general scheme of instruction to be laid down by the Institute, the Board shall arrange courses of instruction for students, and shall recommend to the Institute with respect to the appointment and removal of instructors, teachers, demonstrators, and attendants.

4. The Organising Director and Secretary of the Institute shall have a branch office in the Central Institution, and shall have a right to visit its classes, laboratories, and workshops, and to call for any information he may think necessary for the use of the Sub-Committee A. He shall also have a right to be present at any time he may think it desirable at the meetings of the Board, and to take part in the discussions, but without a vote.

5. All communications from the Board to the Institute shall be made in writing, and shall be addressed to the Organising Director and Secretary.

6. The Institute, at the outset, shall appoint, for the period of a year or longer, from among the professors, a Dean, who shall preside at the meetings of the Board, and who shall attend any meeting of Sub-Committee A at the request of the Sub-Committee or of the Board for consultation on any special business.

7. The minutes of the meetings of the Board shall be recorded, and shall be laid on the table at the meetings of Sub-Committee A.

8. The chief clerk of the Central Institution shall act as secretary to the Board, receiving in that capacity his instructions from the Dean, and shall take minutes of the proceedings.

9. The Dean shall consult with the Organising Director and Secretary, who shall confer with the Chairman of the Executive

Committee, or, in his absence, with one of the honorary secretaries, with respect to any *ad interim* arrangement that may have to be made requiring the subsequent sanction of Sub-Committee A.

10. All the administrative work of the Central Institution, general questions of discipline, and the superintendence of the library and museum, shall be in charge of the Organising Director and Secretary of the Institute, who shall act under instructions from Sub-Committee A.

GEOLOGICAL SURVEY OF THE UNITED KINGDOM[1]

THE completion of the one-inch Geological Survey Map of England and Wales affords a fitting opportunity for directing public attention to the history and progress of this great national undertaking.

As far back as the year 1832 that enthusiastic geologist, Henry T. De la Beche, began at his own expense to prepare geological maps of the mining districts of Cornwall and Devon. Being impressed with the great public utility of such maps in a country deriving so large a portion of its wealth from its mineral resources, he applied to the Government of the day for recognition and assistance. Eventually he and his two or three assistants were incorporated as a portion of the staff of the Ordnance Survey. From this modest beginning De la Beche's genius conceived the idea of founding a great central establishment in London, in which specimens of all the ores and other mineral products of the country should be selected and arranged for public inspection and reference, and where should also be preserved copies of the plans of mines and collieries, from which it would be possible to learn at any moment what areas had been exhausted and the condition of the abandoned underground workings. But besides the practical applications of science, he contemplated the foundation of a school in which all the sciences concerned in mining operations should be taught by the ablest professors in the country, and of a museum in which the rocks, minerals, and fossils of the British Islands should be thoroughly illustrated and made completely available to the public for instruction as well as for economic purposes. Being gifted with indomitable perseverance and no common measure of personal tact, he succeeded in impressing his views upon the Government. By degrees the Geological Survey was fully organised and equipped, and the Mining Record Office and the Royal School of Mines were established, De la Beche himself becoming the Director-General of the whole scheme. The accommodation afforded him at first in the buildings in Craig's Court soon proving inadequate, Parliamentary sanction was in the end obtained for the erection of the present establishment in Jermyn Street, which was opened in 1851, and which, as was then said by the late Sir Roderick I. Murchison, "stands forth, to the imperishable credit of its author, as the first palace ever raised from the ground in Britain which is entirely devoted to the advancement of science."

In the meantime, while its offshoots were showing such vigorous growth, the original and parent Geological Survey was extending its operations over the country. The objects for which it was created were twofold. In the first place it was meant to advance geological science by the production of an accurate and detailed geological map of the United Kingdom, with the necessary sections and descriptive memoirs, and by the collection of a full series of specimens to illustrate the mineralogy, petrography, and palæontology of the various geological formations. In the second place it was designed to be "a work of great practical utility bearing on agriculture, mining, road-making, the formation of canals and railroads, and other branches of national industry." This original conception of the object of the Survey has been steadily kept in view. From the districts first surveyed in Devon and Cornwall the mapping was pushed forward into the south-west of England, and then into South Wales. In 1845, the importance of the work having now been fully realised by the Government, some changes were made in the organisation. In particular, the charge of the whole scheme was transferred from the Board of Ordnance to the Office of Woods and Works. A branch of the Survey was likewise equipped for the investigation of the geology of Ireland, where some progress had already been made by Capt. Portlock, R.E. Nine years later—viz. in 1854—the operations of the Survey were extended to Scotland, and the whole establishment was finally placed under the Science and Art Department, which had now been created. The basis of the Geological Survey map is the one-inch map of the Ordnance Survey. In Ireland and Scotland, where Ordnance county maps on the scale of six inches to a mile have long been in existence, the geologists of the Survey made use of this larger scale for their field work, which was subsequently reduced and published on the one-inch scale. In England corresponding six-inch Ordnance maps having meanwhile appeared, the Geological Survey of the northern counties was carried on upon them. The surveys of the northern coalfields and other mineral tracts have been engraved and published on this larger scale. These maps embody a mass of accurate information regarding the structure and resources of our mineral districts, and have been much appreciated by those who are practically interested in the development of this branch of the national industry.

The Ordnance Map of England and Wales is divided into 258 squares, known as sheets or quarter-sheets. These can now be procured as sheets of the Geological Survey, except those last completed, which are now in preparation. As the whole ground has been surveyed, the remaining maps may be expected to appear with no great delay. To make the maps fully available for the information of the public, sections and memoirs are issued. The sections are of two kinds. One of these, called Horizontal Sections, of which 130 have been published, are drawn on a true scale of six inches to a mile, the profile of the ground being accurately shown by levelling, with the geologica structure underneath. Many of these sections are accompanied by explanatory pamphlets. For various economic purposes, such as railway-cutting, tunnelling, water-supply, mining, road-making building, and so on, these Horizontal Sections are of the utmos value. The second kind, called Vertical Sections, are drawn o the scale of forty feet to an inch, in explanation of the detaile structure of our coalfields. One of the most valuable parts of th work of the Survey is embodied in its "Memoirs." At first thes were issued in goodly octavo volumes, either embracing a num ber of disconnected essays, some of which, like Edward Forbes' famous paper on the history of the British flora, have becom classics in geological literature, or devoted entirely to the d scription of a particular area, such as John Phillips's well-know treatise on the Malvern Hills. After 1855, when, on the deat of Sir Henry De la Beche, Sir R. I. Murchison became Directo General, this form of memoir was postponed in favour of short explanatory pamphlets with which each sheet or quarter-shee was to be accompanied. These were designed to suppleme the map and sections, and to make their information at once i telligible to the public by giving detailed information regardin the natural sections, characteristic fossils, economic mineral &c., in each district. It was fully determined, however, tha as the Survey advanced, ample monographs should be prepar for each geological formation or important district. Amo the other publications of the Survey are the "Decades and "Monographs" of organic remains, of which sevente have been issued; the "Mineral Statistics" of the Mini Record Office, which have appeared as an annual volume for t last thirty years; and various catalogues and other works, whi swell up the total separate printed publications of the Survey the United Kingdom to upwards of 270. It ought to be stat here that, first under De la Beche, and subsequently und Murchison, the work of the Survey depended largely for efficiency and breadth of view on the Local Director, Prof. (n Sir A. C.) Ramsay, who on Murchison's death was appoint Director-General in 1872, and continued in that post until retirement from the service at the end of 1881. He was th succeeded by Prof. Geikie, who had for more than fourteen ye held the office of Director of the Survey in Scotland, and w since his appointment has pushed on the completion of the o inch map of England and Wales, which is now announced him as accomplished. The completion of the map of what termed the "Solid Geology" of England and Wales—that the rocks underlying the superficial deposits—terminates ind an important part of the work of the Survey.

But much remains to be accomplished. The one-inch map Ireland will be completed in a few years; but that of Scotla not having been begun till much later, and having always ha much smaller staff, will require longer time. From the published report of the present Director-General we learn t such of the staff as are qualified for the difficult mountain area of Scotland will be transferred to that region as soon they have prepared their recent work for the engraver. The staff retained in England will have to complete the survey of the superficial deposits, which is so valuable as a basis for the agricultural valuation of land, as well as for other purposes. For some years past the mapping of these deposits has advanced simultaneously with that of the rocks underneath them. Two kinds of maps are supplied to the public, one indicating the superficial accumulations, and therefore invaluable as an agricultural map, and the other showing the "solid geology" or older rocks that lie below. The importance of mapping the superficial deposits, however, both from an industrial and scientific point of view, was not recognised until comparatively recently. Over the larger part of the country, therefore, these deposits are not expressed upon the Survey maps, and it is to the completion of this work that one part of the energy of the staff must now be directed. It will be desirable also to resume the survey of the coalfields on the scale of six inches to a mile, which has been temporarily interrupted in order to hasten the completion of the one-inch map. The South Wales coalfield, for example, was mapped some forty years ago, and so much has been done in the interval towards the development of that vast mineral basin that the maps are so antiquated as to be of comparatively little practical value. We learn from the same report that the most important work lying before the Survey in England and Wales is the *geological description of the country*. As the issue of explanatory pamphlets to accompany the one-inch maps was not begun until 1857, there is a large area of ground of which no published account has been given, except on the maps and sections. Printed explanations of each sheet are now to be supplied, and from these and all the data in possession of the Survey a series of Memoirs or Monographs is to be compiled which will embrace a generalised view of the geological structure and of the minerals and industrial resources of the whole country. It is the fate of geological maps, as well as of other human productions, to get out of date. As the nation has expended so ungrudgingly to carry on a Geological Survey which is acknowledged to stand at the head of the geological surveys of the world, it would be worse than folly to lose the benefit of all this expenditure by allowing the maps to become obsolete. New openings are continually being made which throw fresh light on what lies beneath us. It will be the duty of Parliament to see that a permanent staff, which need not be a large or costly one, is always retained for the purpose of keeping the maps up to date. Meanwhile it is pleasant to see that the work of this worthy national enterprise is being carried on with vigour, and that its staff are fully alive to the importance of the duties that still lie before them.

---

[1] From the *Times*.

THE ORIGIN OF THE SCENERY OF THE BRITISH ISLANDS[1]

THE Scottish Highlands must be looked upon as the relics of an ancient tableland cut out of highly crumpled and plicated schists. Among the eastern Grampians large fragments of the plateau exist at heights of more than 3000 feet, forming wide undulating plains terminating here and there at the edge of precipices. In the Western Highlands, the erosion having been more profound, the ridges are narrower, the valleys deeper, and isolated peaks are more numerous. It is the fate of a tableland to be eventually cut down by running water into a system of valleys which are widened and deepened, until the blocks of ground between are sharpened into ridges and trenched into separate prominences. The Highlands present us with far advanced stages of this process. In the youngest of British tablelands—that of the volcanic region of Antrim and the Inner Hebrides—we meet with some of the earlier parts of the change. That interesting tract of our islands reveals a succession of basaltic sheets which appear to have spread over the wide valley between the Outer Hebrides and the mainland, and to have reached southwards beyond Lough Neagh. Its original condition must have been like that of the lava-fields of Idaho and Oregon—a sea-like expanse of black basalt stretching up to the base of the mountains. What may have been the total thickness of basalt cannot be told; but the fragment remaining in Ben More, Mull, is more than 3000 feet thick. So vast has been the erosion since older Tertiary time that the volcanic plateau has been trenched in every direction by deep glens and arms of the sea, and has been reduced to detached islands. It is strange to reflect that all this revolution in the topography has been effected since the soft clays and sands of the London Basin were deposited.

The intimate relation of a system of valleys to a system of drainage lines, first clearly enunciated by Hutton and Playfair, has received ample illustrations from all parts of the world. Yet the notion is not yet extinct that in some way or other valleys have been as much, if not more, determined by subterranean lines of dislocation as by superficial erosion. Some favourite dogmas die hard, and though this dogma of fracture has been demolished over and over again, it every now and then reappears, dressed up anew as a fresh contribution to scientific progress. We have only to compare the surface of a much dislocated region with its underground structure, where that has been revealed by mining operations, as in our coal-fields, to see that valleys comparatively seldom, and then only as it were by accident, run along lines of dislocation, but that they everywhere cut across them, and that faults rarely make a feature at the surface, except indirectly by bringing hard and soft rocks against each other.

In Britain, as in other countries, there is a remarkable absence of coincidence between the main drainage system and the geological structure of the region. We may infer from this fact that the general surface, before the establishment of the present drainage system, had been reduced to a base-level of denudation under the sea, the original inequalities of configuration having been planed off irrespective of structure; or at least, that the present visible rocks were buried under a mass of later unconformable and approximately level strata, on the unequally upraised surface of which the present drainage system began to be traced. Where the existing watershed coincides generally with the crest of an anticline, its position has obviously been fixed by the form of the ground produced by the plication, though occasionally an anticline may have been deeply buried below later rocks, the subsequent folding of which along the same line would renew the watershed along its previous trend. Where drainage lines coincide with structure, they are probably, with few exceptions, of secondary origin; that is, they have been developed during the gradual denudation of the country. Since the existing watershed and main drainage lines of Britain are so independent of structure, and have been determined chiefly by the configuration of the surface when once more brought up within the influence of erosion, it may be possible to restore in some degree the general distribution of topography when they were begun.

One of the most curious aspects of the denudation of Britain is its extraordinary inequality. In one region the framework of the land has been cut down into the very Archæan core, while in the immediate vicinity there may be many thousands of feet of younger strata which have not been removed. This inequality must result from difference in total amount of upheaval above the base-line of denudation, combined with difference in the length of exposure to denudation. As a rule the highest and oldest tracts will be most deeply eroded. Much of the denudation of Britain appears to have been effected in the interval between the close of the Carboniferous and end of the Triassic period. This was a remarkable terrestrial interval, during part of which the climate was so arid that salt lakes were formed over the centre of England. Yet the denudation ultimately accomplished was enormous, thousands of feet of Carboniferous rock being entirely removed from certain areas, such as the site of the present Bristol Channel. An interesting analogy to this condition of things is presented by the Great Basin and adjoining tracts of Western America, where at the present time great aridity and extensive salt-lakes are accompanied by great erosion.

This deeply-eroded post-Carboniferous land was eventually screened from further degradation, either by being reduced through denudation to a base-level or by being protected by submergence. It was to a large extent covered with Secondary rocks, though the covering of these may have been but thin over what are now the higher grounds. The present terrestrial areas emerged at some period later than the Chalk. In England there were three tracts of land—Wales, the Pennine Chain, and the Lake District. The eastern half of the country, covered with Secondary rocks, was probably the last portion to be uplifted above the sea; hence the watersheds and drainage lines in that tract may be regarded as the youngest of all.

The history of some of the valleys of the country tells the story of the denudation. The Thames is one of the youngest rivers, dating from the time when the Tertiary sea-bed was raised into land. Originally its source probably lay to the west of the existing Jurassic escarpment of the Cotswold Hills, and it flowed eastward before the Chalk escarpment had emerged. By degrees the Chalk downs have appeared, and the escarpment has retreated many miles eastward. The river, however, having fixed its course in the Chalk, has cut its way down into it, and now seems as if it had broken a path for itself across the escarpment. As all the escarpments are creeping eastward, the length and drainage area of the Thames are necessarily slowly diminishing. The Severn presents a much more complex course; but its windings across the most varied geological structure are to be explained by its having found a channel on the rising floor of Secondary rocks between the base of the Welsh hills and the nascent Jurassic escarpments. The Wye and Usk afford remarkable examples of the trenching of a tableland. The Tay and Nith are more intricate in their history. The Shannon began to flow over the central Irish plain when it was covered with several thousand feet of strata now removed. In deepening its channel it has cut down into the range of hills north of Limerick, and has actually sawn it into two.

---

[1] Abstract of the third of a course of lectures given at the Royal Institution, February 19, by Archibald Geikie, F.R.S., Director-General of the Geological Survey. Continued from p. 348.

SCIENTIFIC SERIALS

THE *American Journal of Science*, January, 1884.—The effect of a warmer climate on glaciers, by Capt. C. E. Dutton. The author fully discusses the theory of those who argue that the more copious snowfall required for a more extended system of glaciation implied more atmospheric moisture, greater evaporation, and a generally higher temperature; in fact, a warmer climate than at present, due probably to a greater rate of solar radiation. He concludes that the possibility of obtaining a greater snowfall by a warmer climate would be necessarily limited to the Arctic regions, or to altitudes far above the present snow line. Elsewhere a higher temperature would add to the rainfall, and actually diminish the snowfall. The advocates of the theory have failed to perceive that the additional moisture postulated could fall only as rain. Not until the air has discharged as rain all the moisture in excess of the quantity which saturates it at zero, can it begin to yield snow.—On the application of Wright's apparatus for distilling, to the filling of barometer tubes (one illustration), by Frank Waldo.—Account of a new method of measuring the energy expended on or rendered by a dynamo or a magneto machine in connection with the production of electricity in a large way, by C. F. Brackett. —On some points in climatology: a rejoinder to Mr. Croll, by Simon Newcomb. The assumed lower mean temperature of the northern hemisphere at some former geological epoch is attributed by Mr. Croll to a greater eccentricity of the earth's orbit, combined with a position of the perihelion near the northern solstice, causing a short perihelion summer and a correspondingly long aphelion winter. To this the author replies that too little is known of the laws of terrestrial radiation of heat through the atmosphere to justify the establishment of any theory of the glacial epoch, and that, in any case Mr. Croll fails to show why the mean temperature should be different at the supposed periods. Hence the conclusion, not that Mr. Croll's theory is false, but that it is not proven.—An account of some recent methods of photographing the solar corona without an eclipse, and of the results obtained (one illustration), by Dr. W. Huggins.—Elliptical elements of comet 1882 I., by F. J. Parsons.—The Minnesota Valley in the Ice Age, by Warren Upham.—On the so-called dimorphism in the genus Cambarus, by Walter Faxon. —Evolution of the American trotting horse, by Francis E. Nipher. In reply to the criticism of Mr. W. H. Pickering, the author argues that the known facts are not opposed to the conclusion that the trotting horse may finally trot his mile in about the same time that the running horse will cover the same distance.—On the origin of jointed structure, by G. N. Gilbert.—A theory of the earthquakes of the Great Basin, by the same author.

Revue d'Anthropologie, tome vi. fasc. 4, Paris, 1883.—The larger portion of this number is devoted to M. Mathias Duval's lecture on Transformism, of which two parts have already appeared in the earlier fascicules of the *Revue* for 1883. For English readers generally the address lacks the interest of novelty, as it is little more than an exposition of the works and opinions of Darwin and of the principal authorities, chiefly English, whose observations corroborate his views. It is satisfactory, however, to find that, while maintaining with patriotic zeal Lamarck's claim to be regarded as the originator of the theory of evolution, M. Duval recognises in Darwin the one man who, through varied yet profound scientific acquirements, intellectual qualifications, and special personal and social conditions, was alone capable of giving to novel conclusions of such extraordinary significance the authoritative force and stability of a true science.—On so-called Wormian or supernumerary bones in domestic animals, by M. Cornevin, Professor in the Lyons Veterinary College. The author finds that while in man such bones are generally cranial, in animals they are facial, and he believes himself justified in drawing from his observations two important conclusions (which, however, need support) that in animals the Wormians appear some time after birth, developing more and more with age, and that they are of frequent occurrence in the less carefully bred races, while they are very rarely found in the high breeds of horses, oxen, sheep, pigs, &c.—On the Kalmuks, by M. Deniker. The author, who is a native of the regions which he describes, has made the presence of an encampment of Kalmuks in the "Jardin d'Acclimatation," at Paris, the occasion for bringing together all the most reliable historical, geographic, ethnic, and socio-physical data in connection with this people, whose various migrations, including their great exodus from the region of the Volga in the eighteenth century, he treats at great length. He considers the oblique opening of the eye, which most writers accept as an ethnic characteristic, as of little scientific value, since it is not of specially frequent occurrence among pure Mongols such as are the Kalmuks; but he recognises, on the other hand, that such an ethnological peculiarity is to be found in a peculiar introversion of the upper eyelid which in young Kalmuk children has often the effect of obliterating the eyelashes; while the general narrowness of the opening imparts a triangular form to the eye. Black, scantily developed hair, dark brown eyes, slightly yellow skin, and a stature somewhat below the mean (the adult Kalmuk presenting the proportions of Europeans of thirteen to fourteen years of age), constitute the chief physical characteristics of the Mongol race. The paper, which is illustrated by an admirable map of the Kourghees and Kirghees territories of South Russia and West Thibet, will be continued in a subsequent number.

Journal of the Russian Chemical and Physical Society, vol. xv. fasc. 7.—On the relations between the refracting power and the chemical constitution, by S. Kanonnikoff.—On the velocities of chemical reactions, by A. Potylitzin. The thermo-chemical equivalents obtained separately for several pairs of elements allow to foresee only the direction which will be taken by the reaction when they are brought together; the heat disengaged by one pair of elements brought into reaction in the presence of other bodies, which are also liable to chemical modifications, is not equal to the whole of the thermo-chemical work of the pair, a part of it being employed for chemical work in the accessory bodies; the thermo-chemical equivalents are proportionate to the velocities during the first moments of the reaction.—Sketch of the present state of the theory of explosive substances, by S. Tcheltsoff. The actual tendency of the technics to substitute determined chemical combinations, instead of the mixtures which were used at first as explosives, is quite rational. Not only the decomposition goes on with more regularity in a chemical compound, but also the potential energy is greater.—On the chloride of pyrosulphuryl, by D. Konovaloff.—On the cause of the changes in the galvanic resistance of selenium under the influence of light, by N. Hesehus. The author concludes in favour of the dissociation transmitted into the interior of the body as the cause of this change, and, following the hints of Messrs. Bidwell and Siemens, tries to prove it by mathematical arguments.—Notes on radiophony, by M. Geritch; and on resounding tubes, by M. Bachmetieff.

Zeitschrift für wissenschaftliche Zoologie, vol. xxxix. Part 2, November 6, 1883, contains:—Researches on the brain structures in Petromyzons, by Dr. F. Ahlborn (plates 13-17). A very excellent and detailed memoir, based chiefly on the brain in *Petromyzon planeri* and *P. fluviatilis*.—On the biology and anatomy of Clione, by N. Nassonow, assistant in the Zoological Museum of Moscow (plates 18 and 19). These investigations were carried on at the biological station at Sebastopol, and on an apparently new form called *C. stationis*, found in the shells of *Ostrea adriatica*, in it the oscula are prominent orange-coloured. Branching plasmodia were traced through the shell-structure, reminding one of the mycelial threads of a fungus.—Contributions to the histology of the Echinoderms, by Dr. Otto Hamann (part 2).—The nervous system of the Holothuria pedata: Cuvier's organ. The nervous system and sense organs of the Holothuria apedata (plates 20-22).—On some new species of Thalassema, by Kurt Lampert, Erlangen.

Vol. xxxix. Part 3, December 21, 1883, contains:—On the Rotifers of the environs of Giessen, by Karl Eckstein, natural history student, Giessen (plates 23-28), enumerates and describes in detail fifty species (one new genus Distyla, with two new species, *D. giessensis* and *D. ludwigii*). A list of all known genera is given, with a general description of the anatomy, development, and habits of the group. A very complete bibliography is appended.—On the digestive apparatus of the Decapods, by Dr. F. Albert (plates 29-31, and woodcuts).

Vol. xxxix. Part 3, December 31, 1883, contains:—On Bucephalus and Gasterostomum, by Dr. H. Ernst Ziegler (plates 32 and 33) (*Bucephalus polymorphus* was found in considerable quantities in *Anodonta mutabilis*).—On the central nervous system in *Periplaneta orientalis*, by Dr. Max Koestler (plate 34).—On the varieties of the cerebral fissures in Lepus, Ovis, and Sus, by Dr. Victor Rogner (plate 35).—On the structure and fissiparity of *Ctenodrilus monostylus*, sp. nov., by Max Graf Zeppelin (plates 36 and 37).—On the nervous system of the snout and upper lip in oxen, by Ivan B. Cybulsky (plates 38 and 39).—On the anatomy and physiology of the proboscis in Musca, by Dr. Karl Kraëpelen (plates 40 and 41).—On the connective tissue of the epiphyses in Plagiostomes, Ganoids, and Teleostea, by Dr. J. Th. Cattel.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 10.—"On the Amount of Light Reflected by Metallic Surfaces." By Sir John Conroy, Bart., M.A. Communicated by Prof. Stokes, Sec.R.S.

In a paper which Prof. Stokes did me the honour of communicating to the Royal Society, and which appeared in the *Proceedings*, vol. xxxv. p. 26, I gave an account of some experiments I had made on the amount of light reflected by polished metallic surfaces when ordinary unpolarised light was incident upon them.

The light of a paraffin lamp fell either directly, or after reflection from the metallic surface, on a photometer, and the readings were made by altering the distance at which another similar lamp had to be placed from the photometer in order to produce an equal illumination.

I have repeated the experiments with the steel and speculum metal mirrors with polarised light. The polish of the tin and silver mirrors being defective, it was not thought worth while to re-examine them.

The general arrangement of the apparatus remained the same; but in order to obtain a more intense light, a magic lantern (the one known as the "Sciopticon" being used) was substituted for the paraffin lamp carried by the goniometer.

The metal plates were clamped to the vertical stage, and their adjustment examined by placing a second, or analysing, Nicol in the path of the reflected light and crossing the Nicols, the former being placed with its principal section either in or perpendicular to the plane of incidence, and adjusting the stage screws till the light reflected from the plate was completely extinguished.

The experiments were made in the manner described in the former paper, the light being polarised in, or perpendicularly to, the plane of incidence by the Nicol. It was found that the illumination of the paper varied with the position of the Nicol, being always greatest when the light which fell on the paper was polarised in the plane of incidence.

Four sets of observations and their means, made with the steel and speculum metal mirrors, are given in the tables.

TABLE I.—*Steel, with Light Polarised in the Plane of Incidence*

Angle of incidence	A	B	C	D	Mean
30°	57·01	61·67	63·06	61·05	60·70
40	61·73	64·04	68·18	62·90	64·21
50	65·31	67·41	71·97	69·41	68·52

80	40·51	38·67	41·22	41·15	40·39

The amount of light which, according to Cauchy's theory, ought to have been reflected by the mirrors was calculated out by the formulæ, the principal incidences and azimuths for the two mirrors having been determined—

$$J^2 = \frac{\theta^2 + \cos^2 i - 2\theta \cos \epsilon \cos i}{\theta^2 + \cos^2 i + 2\theta \cos \epsilon \cos i}$$

and

$$I^2 = \frac{\theta^2 \cos^2 i + 1 - 2\theta \cos \epsilon \cos i}{\theta^2 \cos^2 i + 1 - 2\theta \cos \epsilon \cos i},$$

and the observed and calculated results are set forth in Tables V. and VI.

TABLE V.—*Amount of Light Reflected by Steel Mirror*

	Observed		Calculated	
°	J^2	I^2	J^2	I^2
30	60·70	50·19	63·17	54·95
40	64·21	46·28	66·44	51·31

75	86·01	24·73	86·85	29·46
80	87·87	26·60	90·97	32·39

TABLE VI.—*Amount of Light Reflected by Speculum Metal Mirror*

	Observed		Calculated	
°	J^2	I^2	J^2	I^2
30	64·55	59·16	69·78	62·82
40	67·74	54·50	72·53	59·74
50	71·45	50·05	76·18	55·37
60	77·70	43·18	80·77	49·59
65	80·01	40·10	83·42	46·38
70	83·29	37·45	86·32	43·53
75	85·52	35·84	89·44	42·29
80	88·74	40·39	92·77	45·88

As far as regards the general character of the phenomena the agreement is complete and in accordance with the observations of

M. Jamin, but the actual values of the observed intensities always fall short of the calculated intensities, the difference being least with the steel mirror.

The polish of the mirrors was examined at the end of the experiments by the method suggested by Prof. Stokes, and described in the paper already referred to; both the mirrors stood the test satisfactorily, the polish of the steel being very slightly the best.

These experiments appear to show that the generally received formulæ for metallic reflection are approximately correct, but that the actual intensity of the reflected light is always less than the theoretical intensity, and that therefore, unless this be due to defects in the metallic surfaces, the formulæ do not completely express the laws of metallic reflection. If, as appears to be the case, a change in the reflective power of a plate can occur without any change in the values of the principal incidence and azimuth, it is necessary to regard the formulæ as only approximately true, and there is additional reason for thinking that, as Prof. Stokes has suggested, three constants are required to define a metal optically.

Linnean Society, February 7.—Sir J. Lubbock, Bart., president, in the chair.—Mr. Henry Groves of Florence and Mr. F. L. Keays of Cobham were elected Fellows.—Mr. F. O. Bower showed specimens of the leaf of *Tomeia menziesii*, with adventitious buds situated at the base of the lamina. These buds appear at the same point in all the leaves, and under normal circumstances, so that their development seems to be a constant character of the species. Their origin is exogenous, and the buds are found already present at the period when lignification of the xylem of the young vascular bundles begins. Mr. Bower compared this development with that already known in *Cardamine pratensis* and *Athyrurus ternatus*.—There was exhibited, on behalf of Mr. Arthur C. Cole, a box containing mounted preparations illustrative of his "Studies in Microscopic Science," a work devoted to animal and vegetable histology, now being issued in parts.—A note on the gemmæ of *Aulacomnion palustre* was read by Mr. F. O. Bower. Specimens kept in a warm and damp atmosphere flourished well, but showed no sign of sexual organs. It was found, however, that the ordinary vegetative axes often bore towards their apices structures which were undoubtedly of a foliar nature, with a special adaptation for effecting asexual or vegetative reproduction of the plant. Indeed, these gemmæ were found to be capable of immediate germination when laid on damp soil or even floating on water.—The second part of the Rev. A. E. Eaton's monograph on the recent Ephemeridæ or mayflies was read in abstract, its contents being a descriptive account of the genera and species from *Potamanthus* to *Callibætes* inclusive.—Another paper taken in abstract was by the Rev. A. M. Norman, on European and North Atlantic Crustacea. In this an attempt has been made to gather together all the present known and recorded forms of the group. Notices of many of the species are only to be found in obscure periodicals, &c., difficult of access almost in every language; consequently, since the production of Milne-Edward's "Histoire Naturelle des Crustaces" in 1834, the numbers have increased nearly threefold—revision therefore being highly necessary.—Mr. B. T. Lowne gave an interesting communication embodying his researches on the compound vision of insects. He compares the structures of the simple ocellus with those of the compound ocellus (common in larval insects), and with those of the compound eye. The compound eye, according to him, is but composed of aggregated compound ocelli, or one of the latter in the larval insect is merely equivalent to a single segment of a compound eye. He refers to the development of the compound eye, and points out that in many larvæ during the moulting stages the "segregate" retina is finally replaced by another. He describes a deep, spindle-like layer in intimate connection with the nervous structures, and which layer he regards as playing an important part in the phenomena of compound vision rather than that this kind of vision is solely dependent on the number of corneal facets.

Mathematical Society, February 14.—Prof. Henrici, F.R.S., president, and subsequently Sir J. Cockle, F.R.S., vice-president, in the chair.—Messrs. A. B. Basset and D. Brocklebank were admitted into the Society.—The following communications were made:—On the intersections of a triangle with a circle, by H. M. Taylor.—On the difference between the number of $(4n + 1)$ divisors and the number of $(4n + 3)$ divisors of a number, by J. W. L. Glaisher, F.R.S.—On a general theory, including the theories of systems of complexes and spheres, by A. Buchheim.—Prof. Sylvester, F.R.S., made some remarks on matrices with reference to nonions, &c. (see forthcoming paper in the *American Journal of Mathematics*).

Chemical Society, February 7.—Dr. W. H. Perkin, president, in the chair.—It was announced that a ballot for the election of Fellows would be held at the next meeting of the Society (February 21). The following papers were read:—On the expansion of liquids, by D. Mendeléeff; translated from the Russian by B. Brauner. In this paper the author, principally from data furnished by Thorpe (*Chem. Soc. Journ. Trans.*, 1880, p. 141), gives the equation $V = \frac{1}{1 - \kappa t}$ as expressing approximately the expansion of liquids. κ is named the "determinator of expansion." It is a coefficient characterising each liquid, just as each liquid has a specific gravity, boiling point, &c. The author states that the above expression, although many liquids deviate slightly from it, is sufficient in the majority of physico-chemical investigations.—Researches on secondary and tertiary azo-compounds, by R. Meldola, No. 2. The author describes, in continuation of his former researches, the action of diazotised paranitraniline upon tertiary monamines. In the case of dimethylaniline the resulting product is paranitrobenzenazo-dimethylaniline. This, on reduction with ammonium sulphide, furnishes an amido-compound, which is a most delicate test for nitrous acid. The nitro-azo compounds of the meta-series could not be reduced by ammonium sulphide without complete decomposition. The author concludes that the β-naphthylamine compounds of para- and meta-nitrodiazo-benzene do not contain an amido-group, as they yield with nitrous acid nitroso derivatives.—Note on the nitrogenous matters in grass and ensilage from grass, by E. Kinch. The author has determined the albuminoid and non-albuminoid nitrogen in a sample of grass and in the ensilage made from the grass. In the grass 9 per cent. of the nitrogen was non-albuminoid; in the ensilage 55 per cent. of the nitrogen was non-albuminoid. The albuminoids were determined by the phenol, the copper hydrate, the mercuric hydrate, and the lead hydrate methods. The author points out the importance of this serious diminution in the albuminoids, with reference to the food-value of ensilage.—On the influence of the temperature of distillation on the composition of coal-gas, by L. T. Wright. The author finds that more gas is obtained at high temperatures, but that it contains more hydrogen and less hydrocarbons.

Physical Society, February 9.—Prof. R. B. Clifton, president, in the chair.—Annual General Meeting.—The motion to make past presidents permanent vice-presidents was carried, and the articles of the Society altered accordingly.—Prof. Clifton read a report on the business of the past year, which showed that steady work had been done by the Society. Dr. Atkinson read the balance-sheet, showing a flourishing condition of the Society. A proposal to adopt certain letters to indicate membership of the Society when placed behind the name was, on the motion of Prof. G. Forbes, supported by Prof. Adams, Prof. McLeod, and others, held in abeyance for the present. The officers and Council for the ensuing year were then elected, and were as follows:—President: Prof. F. Guthrie, F.R.S.; Vice-Presidents: Profs. R. B. Clifton, F.R.S., W. E. Ayrton, F.R.S., W. Chandler Roberts, F.R.S., Dr. J. Hopkinson, F.R.S., Lord Rayleigh, F.R.S.; Secretaries: Prof. A. W. Reinold, M.A., Mr. W. Baily, M.A.; Treasurer: Dr. E. Atkinson; Demonstrator: Prof. F. Guthrie; other Members of Council: Mr. Shelford Bidwell, M.A., LL.B., Mr. C. W. Cooke, Prof. F. Fuller, Mr. R. T. Glazebrooke, F.R.S., Mr. R. J. Lecky, F.R.A.S., Prof. H. McLeod, F.R.S., Dr. Hugo Müller, F.R.S., Prof. J. Perry, Prof. S. P. Thompson. Honorary Member, Prof. H. A. Rowland. Prof. Clifton then resigned the chair to Prof. Guthrie, whose zeal for the Society he warmly praised. Prof. Guthrie expressed his high appreciation of the courtesy and kindness of the retiring President while in the chair. Mr. W. Lant Carpenter proposed a vote of thanks to the Lords of the Committee of Council on Education; Mr. Whipple moved the cordial thanks of the meeting to Prof. Clifton; Mr. Griffith and Prof. Adams proposed a vote of thanks to the secretaries, demonstrator, and treasurer; Prof. G. C. Foster proposed a vote of thanks to the auditors.—The meeting was then resolved into an ordinary one, and the Secretary read a paper by Dr. O. J. Lodge and J. W. Clark on the phenomena exhibited by dusty air in the neighbourhood of strongly-illuminated bodies, which we hope to print next week.

Mineralogical Society, February 12.—Rev. Prof. Bonney, F.R.S., president, in the chair.—Messrs. T. Vaughan Hughes and W. Semmons were elected members, and the Grand Duke of Leuchtenberg, M. E. Bertrand, and Prof. von Lang, corresponding members.—The following papers were read:—Note on a case of replacement of the quartz constituent of a granite by fluor spar, by the President.—On an arsenical copper ore, "garbyite," from Montana, U.S.A., by Mr. W. Semmons.—On an altered siderite from Alston Moor, by Dr. C. O. Trechmann.—Notes on a picrite (Palæopicrite) and other rocks from Gipps Land, and a serpentine from Tasmania, by the President.—Prof. Judd, on invitation by the President, submitted some slides of dust from the volcano of Krakatoa, which were exhibited under the microscope, and explained the principal features noticeable in these deposits —The President exhibited some slides of dust from Cotopaxi, which had fallen on Chimborazo at the time that Mr. Edward Whymper was ascending the latter mountain.

SYDNEY

Royal Society of New South Wales, December 5, 1883.—Hon. Prof. Smith, C.M.G., president, in the chair.—Three new members were elected and seventy-eight donations received.—A paper on additions to the census of the genera of plants hitherto known as indigenous to Australia, by Baron Ferd. von Müller, K.C.M.G., F.R.S., was read.—Prof. Smith exhibited Stroh's apparatus for producing attraction and repulsion by vibrations of air.—The following specimens from the Solomon Islands, collected by Dr. H. B. Guppy of H.M.S. *Lark*, were exhibited and described by Prof. Liversidge, F.R.S.:—1. White flint from Ulana or Contrariété Island. 2. Flints, including chips and cores, from Ugi, also a large flint tomahawk weighing about four pounds. The flints possess all the characteristics of those from the chalk of Europe, and cannot by mere inspection be distinguished from them. Prof. Liversidge remarked that some years ago Mr. Brown, the Wesleyan missionary, brought from New Britain a soft white limestone which was quite undistinguishable from chalk, not only physically but chemically, and pointed out that this discovery of flints afforded another very strong proof of the probable presence of true chalk of Cretaceous age in the South Sea Islands. 3. Samples of water from the fresh-water lake of Wailava in the Island of Santa Anna. 4. Water from the boiling spring in the Island of Simbo; temperature 212°. 5. Water condensed from one of the fumaroles in the Solfatara on the south-west point of Simbo, at an elevation of about 300 feet above the sea. 6. Water condensed from one of the fumaroles on the summit of the South Hill in the Island of Simbo, elevated about 1100 feet above the sea. 7. Two kinds of fruits ejected from the crops of pigeons shot on a small island off the south coast of St. Christoval.

BERLIN

Physical Society, January 25.—Dr. Kayser spoke on the results of an investigation, recently published by Prof. Bunsen of Heidelberg, into the condensation of carbonic acid on smooth glass surfaces, results which did not coincide with those of other physicists, the speaker among the rest. Prof. Bunsen had found that the condensation of carbonic acid was a continuous process which could not be regarded as finished even after a period of three years. According to the views hitherto entertained, the process referred to came to a conclusion in a very short time. Dr. Kayser was of opinion that the diverging result of Prof. Bunsen's examination was to be explained on the ground that in his experiments he made use of an absorbing vessel stoppered by a greased glass cock. Carbonic acid appeared, however, to diffuse itself thoroughly through fat, as had been proved by an experiment set in operation some weeks ago. Two cruciform glass vessels were set up, one arm of which, directed downwards, passed into a capillary tube dipped in quicksilver, while the three other arms were closed up in one vessel by greased glass plates and hermetically sealed in the other. Both were filled with carbonic acid. In the grease-stoppered vessel the volume of carbonic acid showed a slow progressive diminution, but in the other vessel it continued unaffected. Anything like condensation of the carbonic acid was here quite out of the question, though on the other hand there was clearly a case of osmose through the grease, a subject which Dr. Kayser would further prosecute.—Prof. Vogel exhibited instantaneous photographs of various animals in motion—horses, cows, dogs, and stags—which had been executed by Mr. Muybridge in San Francisco. Prof. Vogel having explained the mode of their production, directed attention to particular pictures completely at variance with the representations of animals in motion hitherto customary among artists. When, however, whole series of these figures, which were occasionally very curious, were viewed through the stroboscope, it was recognised how true to nature these representations were.—Prof. Neesen laid before the Society two new apparatus—one a call-apparatus for telegraphic purposes, constructed by Herr Abakanowicz, which, from the small number of its vibrations, would exercise no disturbing influence on neighbouring conductors; the other an electro-magnetic tuning-fork constructed by Herr König, in which the quicksilver contact common in other instruments of the kind was replaced by a metallic contact.—Dr. Aron communicated a practical experiment he had made on an old frictional electrical machine. By the application of cacao-butter as grease for the amalgam, he elicited from an old machine, which was no longer able to be charged, beautiful sparks of four inches long, and he recommended this fat for trial, particularly in the case of old electrical machines.

VIENNA

Imperial Academy of Sciences, December 20, 1883.—F. von Hoehnel, on the mode of occurrence of some vegetable raw materials in stem plants.—F. Strohmer, on quantitative determination of pure aqueous solutions of glycerine by means of their refractive index.—E. Lippmann, on the action of organic hyperoxides on organic compounds (sealed packet).—V. Hilber, on a recent land-snail found in the loess from China (second paper).—C. Auer von Welsbach, on the earths of the gadolinite of Ytterby (on a modification of spectral analysis).—A. Arche, on cerite and its breaking up to cerium, lanthan, and didymium compounds.—E. Stefan, on the calculation of the coefficient of induction of wire coils.

January 3, 1884.—R. Andreasch, contribution to a knowledge of allyl urea.—R. Rumpf, on the andesin in the lignite of Trifail (Styria).—A. Wassmutt, on the heat produced by magnetism.—L. Fodor-Mayerhofer, contribution to the theory of the varying vertical sun-dial.—H. Zukal, studies on lichens.—M. Kretschy, researches on kynurinic acid.—S. von Wroblewski, on the use of boiling oxygen as a freezing mixture, on the temperature obtained thereby, and on the solidification of nitrogen.

January 10.—F. Hoehnel, on wood-tissue with a story-like structure.—T. Wolfberger and F. Strohmer, on a generally applicable method of analytical determination of acidity by weight (sealed packet).

NATURE

THURSDAY, FEBRUARY 28, 1884

THE GERMAN CHOLERA COMMISSION

DR. KOCH, as chief of the German Cholera Commission, has just issued his fifth report. When we commented on his first report, which was transmitted from Alexandria on September 17, 1883, we drew special attention to the discovery by that expert of certain bacilli which were found to swarm in the discharges and coatings of the intestines of cholera patients, which were certainly not due to post-mortem changes, and which were absent from the intestines of bodies dead from diseases other than cholera. Dr. Koch believed that these bacilli, which much resembled those found in cases of glanders, stood in some special relation to the operation of cholera, but he was not prepared to say whether invasion of the bacteria was the primary cause of cholera, or whether it was merely an effect of the cholera infection. At that time the epidemic in Egypt had reached its decline, the period which of all others is the least satisfactory for etiological investigation; and hence, apart from some further record confirming the existence of the same bacilli in other cholera bodies which had since been examined, the reports which Dr. Koch has transmitted to his Government between his first one and the one now under consideration have not dealt with any scientific discovery. But since November last the Commission have pursued their investigations in India, the city of Calcutta having been decided on as the head-quarters of their mission of inquiry; and it is to the results there obtained that Dr. Koch's last report relates. In the meantime, however, Dr. Straus had reported on behalf of the French Commission, and had expressed his belief that the bacilli discovered by Dr. Koch did not bear the relation to cholera which the German Commission attributed to them; and that, unlike Dr. Koch, who had found nothing noteworthy in the blood of cholera patients, he had discovered in that fluid a definite micro-organism, which he believed he had succeeded in cultivating in the laboratory.

At this stage the subject is again taken up by Dr. Koch, who now gives an account of the further labours of his Commission. Under conditions of the most favourable sort, experiments have been renewed in Calcutta with an unbroken series of cholera patients and cholera bodies, and at the outset it is stated that microscopical examination has in all cases confirmed the existence, both in the choleraic discharges and in the cholera intestines, of the same bacilli as those which had been found in Egypt. And further, that which had not been possible in Alexandria, namely, the isolation and cultivation in pure media of these special bacilli, is stated to have been successful in Calcutta, with the result that they have been found to exhibit under cultivation certain characteristic peculiarities as to shape and mode of growth which enable the Commission to distinguish them with certainty from other bacilli. The Commission, too, have sought, as far as possible, to exclude sources of error, and hence they have subjected the bodies of patients dying from diseases other than cholera to careful micro-pathological examination, with the result that they are able to say that it has not been possible to find bacilli similar to the cholera bacilli in any of the bodies of persons who had died of pneumonia, dysentery, phthisis, and kidney disease. Nor has it been possible to detect these bacilli in the intestinal contents of animals and in other substances commonly abounding with bacteria.

The inoculation of the lower animals with cholera discharges and other cholera material had, in Egypt, led only to negative results; and even if nothing further had been adduced as to this, we should in no way have reregarded failure in this respect as invalidating any inferences that may be drawn by Dr. Koch and his fellow-workers as to the speciality of this bacillus, because it has been found impossible to transmit many of the specific infectious diseases of man to any other animal. We now learn, however, that several experiments made on animals have given results which allow of the hope of further success. Reviewing their more recent work, in this and other respects, the Commission are evidently hopeful of establishing an etiological relation between the bacilli in question and the cholera process, and this quite irrespective of success being attained in the reproduction of the disease in the lower animals. A telegram of more recent date than the report itself announces that Drs. Koch, Fischer, and Gaffky have discovered the same bacillus in a water-tank. If this be confirmed, it will be of value as proving that water, which, when polluted with excreta, has so often been alleged to be one of the principal means of conveying the cholera poison, is a medium favourable to the transmission of the "germ" from person to person, and the announcement comes aptly in connection with a report in which the German Commission announce that a diminution in the annual mortality from cholera in Calcutta from 10·1 per 1000 inhabitants before 1870, to 3 per 1000 since that date, is regarded by nearly all the physicians in that city as being solely due to the introduction of a water-supply of excellent quality.

Referring to the report of the French Commission, Dr. Koch declines to accept the conclusions of Dr. Straus as to the existence in the blood of organisms which are peculiar to cholera, and he expresses the belief that the alleged organisms are nothing but certain small, roundish blood-plates, which, not absent even in health, undergo a peculiar increase in the case of cholera patients, and which were referred to as far back as 1872 by Dr. D. Cunningham in his "Microscopical and Physiological Researches into the Nature of the Agents producing Cholera."

Whilst desiring to follow in the steps of Dr. Koch in observing an attitude of caution as to the meaning of the researches of the German Commission, we cannot but feel that the tendency of the reports as yet issued is favourable to the doctrine that cholera is associated with a specific organic contagion. A connection has already been established between specific disease on the one hand, and the staff-shaped bacilli of splenic fever, the spirillum of relapsing fever, and the microzymes of vaccinia and of sheep-pox on the other; and though it may still be doubtful whether these bodies should be regarded as actual generators of the diseases with which they are associated, or as mere carriers of infection, yet the advance which is being made is in the direction of the doctrine of the particulate nature of contagion. We may have to wait before there is sufficient evidence to warrant the application of this doctrine to the case of cholera, but we can congratulate Dr. Koch on the result of his labours so far, and at the same time trust that the example set us in this instance by the German nation may not be thrown away upon the people of this country, who, whilst having a higher interest than any other in ascertaining the real nature of cholera, allowed the opportunity of the Egyptian epidemic to pass by without attempting any scientific investigation as to its causes.

SCHOPENHAUER

The World as Will and Idea. By Arthur Schopenhauer. Translated from the German by R. B. Haldane, M.A., and J. Kemp, M.A. Vol. I. (London: Trübner and Co., 1883.)

As the Kantian leaven works, philosophy shows less and less of an inclination to quit what Kant described as the fruitful bathos of experience. No doubt many a structure is still reared around us, "pinnacled dim in the intense inane," but that is simply because philosophy, more than any special department of knowledge, is exposed to the inroads of the uninstructed. But here, as elsewhere, the honest inquirer will find a consensus of competent opinion which estimates these piles at their true value. Serious workers pass by on the other side without controversy, lest perchance they should be as those on whom the tower of Siloam fell On the other hand, only confusion of thought can lead people to *identify* philosophy with science, and to suppose that, when they have reckoned over the list of the sciences, they may erect a stone to the great god Terminus. For, though the matter of philosophy is the same as that of the sciences (and not, according to the current myth, a spider-like product of intestinal origin), yet the point of view from which the common material is regarded is *ab initio* different. Science, in its whole extent (including psychology), deals with the world of objects, whereas the first task of philosophy is to remind scientific men of the abstraction which they have been making—and for their own purposes rightly making—by showing them that the world of objects is unintelligible without a subject to which it is referred. Having rectified this fundamental abstraction, philosophy proceeds, as theory of knowledge, to a critical analysis of the conceptions on which, as ultimate presuppositions or working hypotheses, the different sciences are based. The notion of the atom and of infinite space may be mentioned as two of the earliest cases where such criticism is required. The result of such a criticism is to show that no science can say of its "facts" that they are absolutely true, because they cannot be stated except in terms of the conceptions or hypotheses which are assumed by the particular science. But conceptions such as those of space or atom are found to dissolve in self-contradiction when taken as a statement of the ultimate nature of the real. It follows, therefore, that they must be regarded as only a provisional or partial account of things. The account they give is one which may require to be superseded by—or rather, which inevitably merges itself in—a less abstract statement of the same facts. In the new statement, the same "facts" appear differently, because no longer separated from other aspects that belong to the full reality of the known world. For the philosopher is essentially what Plato in a happy moment styled him, συνοπτικός, the man who insists on seeing things together; and philosophy, in her office as critic of the sciences, aims at harmonising the notions on which they respectively rest, and thereby reaching a statement of the nature of the real which may claim to overcome the abstractness of the several provisional stages represented by the different sciences.

Judged by this standard, it is to be feared, Schopenhauer's philosophy will be found wanting. Its interest is undoubtedly, in the main, more literary than scientific; and in his central dogma of a metempirical or transphenomenal Will, Schopenhauer shows himself quite the traditional "metaphysician." Taken as literature, high praise must be awarded to the style of his productions, which is very different from that of his heavy-footed countrymen generally. Pessimism was lately much in fashion, and Buddhism is still highly esteemed. The philosophic father of these things is tolerably sure, therefore, of an interested audience; and "the general reader" will find rich pasture in the aphoristic wisdom of the man of the world, his keen and often cynical psychological analysis, and his genuine appreciation of art, especially of music, which was almost the one redeeming feature in an otherwise ignoble character. Mr. Haldane and Mr. Kemp have done their work so well, that those who are drawn to the book by the literary reputation of the original will not have their enjoyment marred by the intrusion of foreign idioms, clumsy constructions, and the general lameness of the translation style. All praise must also be given to the clearness and accuracy with which they have rendered the philosophical terminology of the work.

But the translators would probably hardly have undertaken the task, had they not believed that there was more of value in Schopenhauer than what has just been allowed him. And, in point of fact, it is perfectly possible to divide Schopenhauer's work into two parts. The world presents itself to him under the twofold aspect of "Will and Idea." "The world as Idea" is the phenomenal world, the world of science, while Will—one mighty unconscious desire or force—is the inner or noumenal reality of which the phenomenal world is the outward expression. I appear to others, and to myself, as an organised body—that is, as an object or complex of ideas; but I also know myself, Schopenhauer says, on the inner side as Will. He next denudes this Will of the characteristics which belong to it in the conscious life, ignoring at the same time the other features which, equally with Will, go to constitute that life, and then, with a superb sweep of anthropomorphism, declares that Will, as an impersonal force, is the essence of all phenomena—the steam that drives the world. In support of this thesis, he fastens on obscure facts like those of instinct; and, though he scouts at the "Bridgewater Treatises," he argues from teleology in an exactly similar sense. But as no scientific reader is likely to be led away by Schopenhauer's reasoning here, it is needless to enter into any formal refutation of his positions. It is more to the purpose to draw attention to the side of the book which, though not so distinctly Schopenhauerian, and probably not so attractive reading as the collection of brilliant analogies on which his system is built, contains an acute and, so far as it goes, a sound, criticism of certain false or inadequate views of the world. Schopenhauer claimed to be the true follower of Kant, and when he is speaking of "the world as Idea," we find ourselves on the general ground of the modern philosophical criticism which dates from Kant. Schopenhauer certainly neglects much that is valuable in Kant, and presents other elements superficially; but, perhaps for that very reason, he may be useful as a populariser of thoughts which, in one shape or another, it is essential for the modern world to master. We need only note here his insistence on the complete relativity of subject and object—a relativity which, of course, excludes the possibility of any causal relation between them—and his criticism of the ideas of space, time, and matter, leading him to the conclusion that the world of objects exists as a system of complete relativity, in which no individual objects can claim any reality except what consists in their necessary relation to one another. Any one reading these and similar passages must acknowledge that, where his doctrines are otherwise sound, Schopenhauer's clear and incisive style makes him an admirable interpreter. ANDREW SETH

OUR BOOK SHELF

Cours de Minéralogie. A. De Lapparent. (Paris: Savy, 1883.)

MINERALOGY was the father of Geology; but the son has for many years in this country shown great want of respect to his parent. A very large proportion of our geologists are extraordinarily ignorant of mineralogy. To them as well as to those who have not so seriously neglected that branch of science we recommend a perusal of the work before us. The object of its distinguished author (who has already rescued French Geology from the charge of possessing no modern text-book of native origin) is in the first place to simplify as much as possible the teaching of rational crystallography, as established by the works of Bravais and completed by Mallard, so as to bring it within the comprehension of all earnest students of minerals and rocks; and in the second place to put geologists in possession of the knowledge which they must acquire if they would apply themselves with any satisfaction and profit to the study of the microscopic structure of rocks.

The volume is divided into three parts. In the first of these, entitled *Geometric Crystallography*, M. De Lapparent states the laws of crystalline symmetry and shows in detail the forms of which each system is composed, these forms being rigorously classed and deduced from each other according to the method of Bravais. Tables and stereographic perspective diagrams are added.

The second part, or *Physical Crystallography*, is devoted to the explanation of the physical, and especially the optical, properties of crystallised matter. It concludes with an analysis of the different crystalline groups, with which, following Mallard, the author connects the phenomena of isomorphism and dimorphism.

The object of the third part is the *Description of the Principal Mineral Species*. The author adopts a system of classification which is entirely new, and which might be called the geological system of mineralogy, because it is based upon the part which each species plays in the composition of the earth's crust. From this point of view minerals are divided into four great classes:—(1) silicates or elements of the fundamental rocks. (2) Elements of mineral veins. (3) Metallic minerals. (4) Combustible minerals.

The work consists of 550 pages, with 519 figures inserted in the text, a chromolithographed plate, and an index comprising 3500 names, from which a knowledge can be obtained of all terms employed in mineralogy.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

The Remarkable Sunsets

THE remarkable and beautiful atmospheric phenomena which within the last four or five months have so powerfully attracted attention in all parts of the world, made their appearance here about the same time that they did in England and on the continent of Europe. It is true that as early as October 14, 1883, something similar was noticed at Santa Barbara, about 280 miles south-east of this place; but the characteristic phenomena were not observed here and at other positions on the coast of California until after the middle of November, 1883. I first observed it on the evening of November 24, when it presented a very striking appearance. That afternoon the sky had been overcast with dark clouds, and the south-east wind had brought a slight rainfall. Towards sunset a bright portion of sky appeared at the western horizon, extending to an altitude of about 10°, while the dark hood of clouds enveloped the remainder of the celestial vault. At 6 p.m. the lurid redness (almost angry) of the western horizon attracted universal attention; it had the appearance of a sky illuminated by an immense conflagration. Doubtless the effect was heightened by the contrast with the dark canopy of clouds. Similar appearances, more or less conspicuous, presented themselves during the remaining days of November, and in a less striking manner (when the weather was favourable) during the month of December, both after sunset and before sunrise. At a quarter past six on the morning of November 29 the eastern sky emitted such a brilliant ruddy light as to arrest my attention by the peculiar red illumination of the window-curtain of my bedroom. On looking out, the whole eastern sky was seen to be drenched in gorgeous red. During the month of January, 1884, the "upper-glows" (as Miss Ley appropriately designates them) became much less conspicuous.

At the period when the phenomena were most conspicuous, the atmosphere during the day was not perfectly clear, although the sunlight was not obscured to any considerable extent:—there was always observed a thin veil of fleecy clouds covering the heavens, and a *whitish glare* manifested itself about the sun, extending to a distance of about 20° or 25° from his centre. It is evident that the suspended matter producing these phenomena must have been above the region of the loftiest cirri, for ordinary changes of weather and disturbances in the atmosphere did not modify the appearances.

But the manifestations presented by the sky seem to have been so nearly identical in all parts of the globe, that detailed descriptions of them, as exhibited here, are unnecessary. It was, however, evident that the phenomena were less pronounced on this coast than they were in many other countries. This was indicated by the fact that, wherever the phenomena were sufficiently developed, the sun during the day was encircled by more or less distinct coloured halos or coronæ; whereas at this place it amounted to nothing more than a *whitish* glare about that luminary. The Rev. S. E. Bishop writes me from Honolulu, that these chromatic circles around the sun were constantly observed in all of the Hawaiian Islands from September 5 to December 15, 1883; and I notice that they were observed in England as frequent accompaniments of the upper-glows.

While the large size of these coloured circles might (as I have indicated in a letter to *Science*) seem to connect them with the well-known ice-crystal halos of 22° radius, yet I am disposed to regard this chromatic feature of the phenomenon as mainly due to the diffractive action of the impalpable dust-particles suspended in the lofty supra-cirri regions of the atmosphere. Nevertheless, inasmuch as the experiments of M. Coulier and Mr. John Aitken show that the presence of dust-particles in the air as nuclei is essential to the condensation of aqueous vapour, it is by no means improbable that *ice* may be associated with these phenomena. For, as these lofty regions must, even within the tropics, be far above the plane constituting the lower boundary of the term of perpetual congelation, the condensed vapour must necessarily assume the form of aggregations of ice around these nuclei. Hence the diffractive coronæ may be associated with imperfectly developed ice-crystal halos.

It seems to me scarcely necessary to invoke—as Mr. Rowell has done (NATURE, vol. xxix. p. 251)—the repulsive agency of electricity to account for the persistent suspension of the volcanic dust, even in these regions of rarefied air. If the attenuation be sufficiently great, there will be no sensible subsidence of the dust-particles. Faraday found that even metallic gold, when minutely divided, required months to subside when suspended in water; and some forms of insoluble mineral matter remain suspended in water for an almost indefinite period. Now, the dust-particles constituting the nuclei of condensation for fogs and clouds are absolutely *ultra-microscopic* in smallness; hence their suspension, even in rarefied air, may be prolonged almost indefinitely. Moreover, it is possible that air may possess some degree of *viscosity;* in which case the indefinitely attenuated dust-particles might have no tendency to subside, and could only be removed from the atmosphere by those meteorological agencies,—such as the condensation of vapour,—which tend to augment their size.

Mr. D. Wetterhan (NATURE, vol. xxix. p. 250) refers to Mr. Kesselmeyer's hypothesis of the atmospheric origin of meteorites put forth some twenty years ago, which ascribes them to the condensation of metallic and other vapours issued from volcanoes. If I am not mistaken this hypothesis was advanced by Biot near the beginning of the present century. The *high velocities* of meteorites is overwhelmingly *fatal* to their *terrestrial* origin.

JOHN LE CONTE

Berkeley, California, February 1

THE recent sunsets were nearly or quite as remarkable in the Rocky Mountain region as they were in Europe, and the phenomena were very similar. There was the same peculiar fire-red after-glow continuing for two hours after sunset, &c. These unusual appearances began to attract attention soon after the middle of November. They were most brilliant during the last week of November, but continued at intervals until early in January. The carefully kept meteorological record of Prof. F. H. Loud, of Colorado College, shows that the atmospheric pressure varied considerably during the latter part of November, but there was no apparent accompanying change in the after-glow. The sunrises were also quite brilliant, but less so than the sunsets. Late in November I began to observe the wide chromatic belt which surrounded the sun, and at midday usually reached from near the sun to the horizon. Somewhat similar appearances and chromatic halos are not uncommon here, and it was not until after several weeks of comparison of colours that I became convinced that the tints seen around the sun during the time of the remarkable sunsets were somewhat different from those ordinarily seen. By degrees the brick, or fire-red, and other abnormal tints of the twilight hours have given place to the ordinary prismatic colours, and a similar but less marked change could be seen in the colours observed near the sun during the daytime. These day colours were brightest when the sky was overcast with thin clouds or filmy cirri, though plainly visible when there was no cloud to be seen. The prevailing day tint is usually a peculiar dull purple, but during the time of the red after-glow the common colour was duller, more like a yellowish brick-dust.

Colorado College, February 8 G. H. STONE

"Probable Nature of the Internal Symmetry of Crystals"

IN reply to the important criticisms offered by Herr L. Sohncke on my new theory published in NATURE of December 20 and 27, 1883 (pp. 186 and 205)—

Taking first those relating to the geometry of the subject; the following explains why only the five symmetrical arrangements of points in space described in my paper are taken as the basis of the theory.

If it is the case that, prior to the act of crystallisation, the chemical atoms of a body fall into some symmetrical arrangement, it is natural to suppose that they do so through some influence they exert on one another—such, for example, as mutual repulsion—and that a similar influence is exerted by each atom of the same kind on atoms around it. And if this be so, there will be no *stable equilibrium* of the forces thus exerted *until the atoms are very evenly distributed throughout the space allotted to them.*

Now although, as Herr Sohncke has shown, there is a large variety of symmetrical arrangements of points in space in which the points are disposed around every one point of the system in precisely the same manner as around every other, it would appear that only four of these regular systems, the first four described in my paper, signally fulfil the requirement of even distribution, these four systems being distinguished from all the rest by the property that, *if the nearest points grouped around any point of either of these four systems are joined, the solid thus outlined has its edges all equal.*

And further, although the fifth system described in my paper is not one of Herr Sohncke's *regular* systems, its points are more evenly distributed through space than those of any of these systems except the four just referred to. In this system the property is found that either lines joining the nearest points around any point of the system, or lines joining the next nearest, in all cases outline a solid whose edges are all equal.

As the five systems I have in my paper too vaguely distinguished as "very symmetrical" thus stand alone, and moreover, if my views are adopted, they appear to be adequate to all cases of crystallisation, I still incline to think that the chemical atoms of bodies about to crystallise always have one or other of these five kinds of symmetrical arrangement. If I am wrong in this, and some other symmetrical arrangements are admissible, the general lines of the new theory will not however be affected.

Next, as to the bearing of the theory on chemical valency and the usual conception of a chemical molecule, it may be remarked that, while there is no clear knowledge of the nature of the union between the different sorts of atoms in a compound by which to test the new theory, this theory appears to receive support from the phenomenon of electrolysis. For the fact that one *ion* is liberated at one pole, the other at the other, while *no apparent alteration takes place in the fluid between the poles,* goes to show that any particular atom can change its partners without dissolving the chemical ties subsisting between the several atoms of the compound, and thus favours the view that similar atoms equally near to a particular atom are similarly related to it.

As to my supposition that the expansion, or contraction, occurring in the act of crystallisation, is due to the increased or diminished repulsion exerted by *some only* of the atoms of a body on surrounding atoms, it is, perhaps, interesting to notice that if this conception could be extended to the gaseous state, and the expansion to the state of gas of any compound attributed to the agency of certain atoms in each molecule, or ideal unit, to the exclusion of the rest, the simple relations found subsisting between the volumes of compounds and the volumes of their uncombined constituents might in this way be accounted for:—Thus the fact that aqueous vapour has a volume two-thirds that of the added volumes of the hydrogen and oxygen of which it is composed would be explained if all the gaseous expansion of this compound is due to the hydrogen atoms only.

Muswell Hill WM. BARLOW

"Mental Evolution in Animals"

MR. FARADAY does not seem to have quite understood one point in my comment on his letter. I said that whether the action of the skate was accidental or designed, "in either case, under the conditions, and more especially the 'attitude' described, seizure of the food at the proper moment can only be ascribed to the sense of smell." When we remember the form of a skate, it is certain that, under the conditions described, the animal could not *see* the approaching food, and therefore Mr. Faraday's illustration from the cricketer would only hold if the cricketer continued to hit the ball after he had been blindfolded.

I do not care to continue this discussion; but I may say that as the glass wall of a tank is not an object upon the solidity of which a skate would be likely to calculate, and as the sense of smell in this animal is so highly developed that it might easily give rise to "the appearance of co-ordination" described, I still think that the incident was probably accidental. Any other piece of food happening to approach the mouth would no doubt have been seized in just the same way.

GEORGE J. ROMANES

Instinct

WERE it merely for the sake of reiterating my views, I should not feel justified in commenting upon Mr. Romanes' letter on instinct in last week's NATURE (p. 379). He seems, however, to have understood my "subjective verification" in a sense somewhat different to that which I intended to convey by that expression. I venture, therefore, to beg a little space in these columns for explanation.

There is but one method in human psychology—that of introspection. By this method I obtain certain results. These results I communicate to my neighbour, and he by introspection verifies them for himself. This I call "submitting the results to the test of subjective verification." In this way and in no other can a science of human psychology be constituted.

I remember once seeing a schoolfellow caned. He did not flinch, but grew deadly pale. "Did it hurt much?" I asked afterwards, in schoolboy fashion. "Hurt! Who cares for pain? I was caned for a lie that I never told." I can remember to this day the indignation that his words roused within me. I could verify to some extent the true nature of his feelings. How can I verify the feelings of my dog? The feeling that I infer may be as wide of the mark as the mere pain I fancied my schoolfellow smarted under. Without myself becoming a dog, I can never know the true nature of my dog's feelings.

Mr. Romanes contends that "the involuntary groan of pain, the pallor of fear, and a thousand other unintended expressions of emotions, as well as a thousand other unintended expressions of thought, are, as it is proverbially said, 'more eloquent than words.'" In this I cannot agree. The groan, the pallor, tell plainly of some intense feeling; of its nature they can tell us little. So do the actions of animals testify to some corresponding mental states; of their nature we can form but a dim conception. Out of such dim conceptions no science of comparative psychology can, as it seems to me, be constituted.

Whether this is common sense (for which, by the way, in these matters I have not quite so much reverence as Mr. Romanes) or "an ingeniously constructed argument of scepticism," I must leave others to judge.

In conclusion let me thank Mr. Romanes for his letter, and assure him that I shall give to his objections to my physiological theory of instinct that weight which I feel to be due to the opinions of one from whose writings I have learnt much and hope to learn more. C. LLOYD MORGAN

University College, Bristol, February 25

Protection by Mimicry—A Problem in Mathematical Zoology

UNDER the above heading in the *Japan Weekly Mail* of February 3, 1883, we drew attention to what appeared to us an error made by Mr. Alfred R. Wallace in a letter to NATURE regarding the protection gained by two distinct species of insects of distasteful nature assimilating in appearance when subject to the attacks of young and inexperienced birds. The article was sent to Mr. Wallace, who by letter, and in an article in NATURE, vol. xxvii. p. 481, without hesitation, acknowledged the correction, saying that he had misstated Dr. Müller's proposition. He then gives Dr. Müller's own words, which are:—"If both species are equally common, then both will derive the same benefit from their resemblance—each will save half the number of victims which it has to furnish to the inexperience of its foes. But if one species is commoner than the other, then the benefit is unequally divided, and the *proportional advantage* for each of the two species which arises from their resemblance is *as the square* of their relative numbers." This alters the question altogether. Mr. Wallace had stated it, through an oversight, quite otherwise. He said:—"The number of individuals sacrificed is divided between them in the proportion of the square of their respective numbers." Such was what we took objection to; and we showed that it was not according to the squares, but to the simple numbers.

Mr. Wallace carries out his article, which is accompanied by one by Mr. Meldola (p. 482), to show by examples how it is that, notwithstanding the *loss* is in direct ratio to the numbers of each species, the proportional *saving* through resemblance is inversely as the squares; and he further says:—"The advantage will be measured solely by the fraction of *its own numbers* saved from destruction, not by the proportion this saving bears to that of the other species." On this Mr. Meldola remarks:—"The fact that these numbers stand to one another in the ratio of" the squares, "is a mathematical necessity from which I do not see how we can escape." Now even if this latter statement were strictly correct, we fail to see how it affects Mr. Wallace's statement. We shall show, however, that it is not correct but only an approximation when the number eaten by the birds is a small percentage, for as this becomes greater the ratio of proportional advantages increases considerably above that of the squares.

The proportional advantage that either species has after imitation over its former state (before imitation), appears to be according to the fraction of its original number remaining. Because while in its former state, should it lose one half its number, it would have one-half left, while if it after imitation lost only one-fourth, it would have three-fourths remaining; a clear advantage of one-fourth over one-half, or 50 per cent. This, however, is not a simple case for an example when we come to consider the relative numbers of the two species; we will therefore put it thus:—A has double the number of B. Supposing that when dissimilar A loses 30 per cent. then B loses 60 per cent. But after assimilation both lose in the same proportion, namely, 20 per cent. A has consequently an advantage, over its former state, of 10, and similarly B of 40. But in the former state the remainder of A not lost was 70 per cent., while that of B was 40 per cent., so that A's real advantage is 10 on 70 or 14·2857 per cent., and B's 40 on 40, or 100 per cent. These two numbers do not bear Dr. Müller's ratio of 1 to 4 (the squares of the numbers) but a greater, namely, 1 to 7 = $1^2 \times 40$ to $2^2 \times 70$.

The following examples will illustrate the increasing ratio:—

1. A to B as 2 to 1.

If when dissimilar A loses 20 per cent. then B loses 40 per cent., the remains being for A, 80 per cent.; for B, 60 per cent. When similar each loses 13⅓ per cent., leaving remains of 86⅔ per cent.

The advantage to A therefore is the excess of 86⅔ over 80 on 80 = 8·33 per cent., and the advantage to B is the excess of 86⅔ over 60 on 60 = 44·44 per cent. These advantages compared to each other are as 1 to 5·33 (according to Dr. Müller 1 to 4).

2. A to B as 3 to 1.

Dissimilar A loses 20 per cent.; B, 60 per cent. Remains 80—40.

Similar A loses 15 per cent.; B, 15 per cent. Remains 85—85.

Advantage to A excess of 85 over 80 on 80 = 6·25 per cent.

Advantage to B excess of 85 over 40 on 40 = 112·5 per cent.

Ratio 1 to 18 (Müller 1 to 9).

3. A to B as 4 to 1.

Dissimilar A loses 20 per cent.; B, 80 per cent. Remains 80—20.

Similar A loses 16 per cent.; B, 16 per cent. Remains 84—84.

Advantage to A excess of 84 over 80 on 80 = 5 per cent.

Advantage to B excess of 84 over 20 on 20 = 320 per cent.

Ratio 1 to 64 (Müller 1 to 16).

Dr. Müller's squares require to be multiplied by the remains per cent. (taken also inversely) of the two species when dissimilar, to bring out the proper ratios. Thus: 1 to 4 (the squares) in the first example, multiplied by 60 and 80 respectively, give 60 to 320 or 1 to 5·33. In the second 1 × 40 to 9 × 80 = 40 to 720 or 1 to 18. And in the third, 1 × 20 to 16 × 80 = 20 to 1280 or 1 to 64.

It will be understood therefore that, whether we reckon the proportionate advantage that each species obtains over its previous state of existence by the mimic, or calculate the ratio of proportionate advantage of mimicry between the two, the comparison has to be made with the state each would have been in had not mimicry taken place, indicated by the proportion of survivors each would then have had. If we ignore this, the comparison is untrue. What we want is the advantage a species which adopts mimicry has over one which fails to do so. So that if we speak of one numerous species A, and two equal non-numerous species B and B′; if B mimics A, while B′ mimics no species, B receives protection, and thus has an advantage over B′, which in particular cases may amount to so much that, while B survives, B′ may become exterminated. This is perhaps the simplest way of putting it.

It must be remembered, however, that B does no harm to A by mimicking it; on the contrary, the act of mimicry is of advantage to A over its former state of existence as well as to B; but A being the more numerous the advantage is less. Still after the assimilation neither has an advantage *over the other*.

Proportionally they suffer from the ravages of the birds equally; the percentage of losses is the same; they are on equal terms. No matter how long they continue the association, neither gains nor loses on the other; though through one being more numerous it loses more individuals, yet equally in proportion with the other. So that, if one is twice as numerous as the other at the time of assimilation, it must always—other conditions being eqnal—remain twice as numerous.

We now give the mathematical reduction:—

Designation of species … …	A		B
(1) Original number … … …	a	$>$	b
(2) No. lost without imitation …	e	$=$	e
(3) Remains without imitation …	$(a - e)$		$(b - e)$
(4) No. lost with imitation …	$\frac{a}{a + b}e$		$\frac{b}{a + b}e$
(5) Remains with imitation	$a\left(1 - \frac{e}{a + b}\right)$		$b\left(1 - \frac{e}{a + b}\right)$
(6) Excess of remains due to imitation, or *absolute advantage* (3)–(5) … … …	$\frac{be}{a + b}$		$\frac{ae}{a + b}$
(8) Ratio of excess to remains without imitation (6) : (3), or *proportional advantage*	$\frac{e}{a + b} \cdot \frac{b}{a - e}$		$\frac{e}{a + b} \cdot \frac{a}{b - e}$
(9) Ratio of proportional advantage of B to proportional advantage of A … …	$\frac{a(a - e)}{b(b - e)}$ or $\frac{a^2}{b^2}\frac{1 - \frac{e}{a}}{1 - \frac{e}{b}}$.		

From (8) we see that, if $e < b < a$, there is a proportional advantage to both, the mimicry "is twice blessed," but the proportional advantage to B is greater. If e is zero, there is no advantage to either. If $e = b < a$, the prop. advantage to B is infinite, while that to A is still finite; this is as it ought to be, seeing that to B it is a case of "to be or not to be," of existence with mimicry or extinction without. And in this extreme case it must be evident to every one that the ratio of $a^2 : b^2$, both terms finite, cannot be the ratio of the infinite advantage of B to the finite advantage of A. The greater e the greater are both advantages.

From (9) we see that, if e is small compared to b and a, the ratio is nearly $a^2 : b^2$ (Müller's law), but the larger e is the further it deviates from that law, the ratio becoming rapidly greater than $a^2 : b^2$, and approaching infinity as e approaches b.

To conclude, we may point out that Müller's law, as given in his own words and quoted above, is incompletely enunciated, and but for the numerical examples, it might lead any one astray as to what the law is. It ought to have *the ratio of* interpolated between "and" and "the *proportional*"; then "*advantage*" and "*square*" ought both to be plural; "relative" ought to be respective; and, lastly, the fact that the ratio is inverse should be explicitly stated.

Finally we enunciate our law. Let there be two species of insects equally distasteful to young birds, and let it be supposed that the birds would destroy the same number of individuals of each before they were educated to avoid them. Then if these insects are thoroughly mixed and become undistinguishable to the birds, a *proportionate advantage* accrues to each over its former state of existence. These *proportionate advantages* are inversely in the duplicate ratio of their respective original numbers compounded with the ratio of the respective percentages that would have survived without the mimicry.

This last "ratio compounded" corrects Müller's law, but we still think with Mr. Wallace that the law, even when corrected, has not much bearing on the question that the individual absolute advantages (6) above, together with the probable value of e and the ratio $a : b$ indicated by relative frequency of capture, solve the whole question. In our first paper above mentioned we established formulæ for calculating these last-named items, although in a different manner from and quite independent of Müller's law, which we had not then seen.

Christian Conrad Sprengel

I BECAME acquainted with Christian Conrad Sprengel's work, "Das entdeckte Geheimniss der Natur im Bau und in der Befruchtung der Blumen" (Berlin, 1793) in 1850 at the University of Berlin through Prof. C. H. Schultz-Schulzenstein, who brought it forward in one of his lectures on botany, praising Sprengel's good observations and illustrations, but making his teleological views appear so irksome as to dispose his hearers rather to depreciate and reject the book than be attracted to it by respect. The value of Sprengel's treatise in its bearing on the theory of selection was first recognised by Charles Darwin, whose writings recalled the remarkable book to my mind, and induced me to buy it, which I did at a very cheap rate at an old book-shop.

K. MÖBIUS

Kiel, February 18

Circular Cloud Bows

I FANCY that the phenomenon described by Mr. Fleming in your issue of January 31 (p. 310) is not a very uncommon one. It has twice fallen to my lot, when in Switzerland, to be a witness of these spectral shadows.

On the first occasion I was with a party of three on the mountains to the north-east of Montreux, almost opposite the Cape de Moine. It was midwinter, and the day was very cloudy, even in the valleys, while the high ground on which we stood, and all the surrounding peaks, were completely swathed in mist. Suddenly, and under the impulse apparently of a blast of wind from below, the mists around us were almost entirely dissipated, and a few sickly gleams of sunshine filtered through the fog. At that moment we saw gigantic images of ourselves projected on to the wall of vapour enshrouding the Cape de Moine, immediately opposite the point where the sunbeams had permeated. The effect was very transitory, and, so far as I remember, there were no prismatic colours.

The circumstances under which I saw the second appearance were as follows:—

In August last I was standing, just before sunset, on the summit of the Niesen, in company with a friend. The day had been very hot, and we were just remarking on the extraordinary difference in temperature between our elevated position there and our situation a few hours before on the Lake of Thun, when we saw some scattered wisps of cloud rising out of the depths below. These increased rapidly, both in size and number, uniting as they rose, till the whole abyss presented the appearance of a seething cauldron, from which was escaping a dense cloud of steam. The prospect towards the east was quickly blotted out, while the sky in the opposite quarter remained as clear as before.

We then saw dim and fragmentary signs of prismatic colours in the curtain of cloud, and these became more defined and vivid as the thickness of the cloud increased. Finally there appeared a very distinct circle of rainbow hues, with our own figures looming, weird and awful, in its centre. Both images were visible to myself and my companion, though each could see the other's reflection more distinctly than his own.

Mr. Whymper, in his "Ascent of the Matterhorn," mentions an instance in which the prismatic colours assumed the shape of crosses. This effect, occurring as it did soon after the fatal accident which marked the conquest of the mountain, filled the minds of the guides with superstitious horror. From my own experience on the Niesen I can well imagine that, as Mr. Whymper suggests, this form could be accounted for by the supposition that there were several circles interlaced, and that only segments of them were visible from the point at which he and his companions stood.

Perhaps some of your readers may be able to explain the exact atmospheric conditions under which these appearances become possible.

E. H. L. FIRMSTONE

Bewdley, February 21

On the Absence of Earthworms from the Prairies of the Canadian North-West

In NATURE of Jan. 3 (p. 213) Mr. Robert M. Christy writes on the absence of earthworms from the prairies of the North-West. I can confirm his statements, and extend them to cover the prairies of Kansas, the Indian Territory, Idaho, and Washington Territory. In all the above-mentioned territory of the United States the soil is more or less alkaline, and it seems to me that to this cause the absence of earthworms may be attributed. Ants and burrowing beetles, or the larvæ of the latter, are, however, common, and no doubt do much service in the manufacture of plant-food, as well as in the destruction of decaying material. At Boise City, Idaho, some enthusiastic disciples of Izaak Walton imported and successfully reared the coveted bait for their fish-hooks in soil suited to the habitat of the Lumbricidæ. TIMOTHY E. WILCOX

Vancouver Barracks, Washington Territory,
January 30

P.S.—Are earthworms found in Arabia and Egypt?

ZOOLOGICAL RESULTS OF THE WORK OF THE UNITED STATES FISH COMMISSION IN 1883

IN the summer of 1880 the United States Fish Commission steamer *Fish-Hawk* began her first work in dredging upon the Gulf-Stream slope seventy miles south of Rhode Island, working in from 75 to 600 fathoms of water. Upon this steep submarine bank several hundred species of Invertebrates were found which proved to be new to the American coast. Many were entirely new, others had been described from the Mediterranean and the deep waters off the west coast of Europe, and some were identical with fossils from the Italian Tertiary and Quaternary deposits, this being true of the shells more particularly. These species have long since been described in American scientific publications, and two subsequent summers of work in this region have brought to light numerous new and additional species, and at the same time very nearly exhausted the region. The *Fish-Hawk*, built for the purpose of serving as a floating shad-hatching station to work in the shallow inlets of Chesapeake Bay, was, during the summer, when she could not carry on her intended work, made use of for dredging purposes, work for which she was not well suited, for her shallow draft and round bottom rendered her unsafe when far from land and liable to encounter rough weather. She could make trips only when pleasant weather was assured for at least twenty-four hours, thereby losing much valuable time which could have been saved if a perfectly seaworthy vessel had been at the command of the Commission.

Accordingly in 1882 an appropriation was obtained, and early in 1883 the *Albatross* was launched, and made her first trip shortly afterwards. So much has been written about the *Albatross* that a mere passing notice will suffice. She is a 1000-ton iron vessel, 234 feet long, and drawing 12 feet of water. On the port side, near the bows, the sounding-machine is placed. Just forward of the pilot-house is the dredging-machine, and here, in a clear space left for the purpose, the rougher work, picking out the specimens from the mud, &c., is done. Aft of the pilot-house, with a chart-room intervening, are the two laboratories and a store-room,—an upper and lower laboratory, and the store-room beneath. The finer sorting and microscopic work is done in the upper laboratory, this being lighted by a skylight and four deck-windows. The library is in this room. In the laboratory beneath are cases of bottles ready for use and for those containing specimens, and a bench is placed on two ends of the room, where rough sorting can be done. In the room below this, bottles, jars, tanks, dredges, nets, and all apparatus used in the work are contained. Alcohol is carried in a large copper tank. In the upper laboratory are two copper tanks each of 32 gallons capacity, one containing fresh water, the other 95 per cent. alcohol. By means of faucets each can be drawn from its respective tank. The rest of the ship, with the exception of a few state-rooms reserved for naturalists, is given over to machinery and quarters for officers and crew. She is manned from the navy, and is under the command of Lieut. G. L. Tanner, U.S.N. Electricity is used for lighting, Brush incandescent lights being used for ordinary purposes, while an arc lamp suspended from the rigging lights the deck so well that work can go on as well by night as by day. Engineer Baird, U.S.N., chief engineer of the vessel, has succeeded in making an incandescent light that when lowered to 100 fathoms will neither be crushed nor extinguished. Used in connection with some deep-sea trap, this will undoubtedly give good results in capturing such quick-motioned fish as would avoid the trawl but would be attracted by brilliant light. The apparatus in use is the best which the past experience of the Fish Commission, U.S. Coast Survey, and European dredging expeditions could suggest. The vessel is so constructed that she can go backward as easily as forward. When the sounding-wire is running out, she can go completely around it without causing it to depart from its perpendicular. That the *Albatross* is perfectly seaworthy and that the machinery and apparatus and the vessel itself are in the best condition has been proved by the numerous trips made during the year just passed, and by the rough weather encountered. Starting early in 1883 upon her trial trip, she went into water as deep as 1200 fathoms. Afterwards numerous trips were made in the deeper waters off the southern coast of New England, some lasting a month. The principal work was done in from 1000 to 2000 fathoms, the deepest work done on the United States coast by an American expedition. Several successful hauls were made in 2400 fathoms, and one in 2950 fathoms. This latter is the deepest successful recorded haul made with a trawl as far we can find out. Soundings were taken in 3000 fathoms. The naturalist in charge is Mr. James E. Benedict. The *Albatross* has just started on a cruise to the West Indies, where work will be done both on the shores and in the deeper outer waters.

The previous explorations of the *Challenger*, *Blake*, Norwegian, and French deep-sea dredging expeditions, investigating similar regions in the North Atlantic, have rendered the results obtained by the *Albatross* much less remarkable than they would otherwise have been. Notwithstanding this, and the fact that some worked very near the field chosen by the *Albatross*, many new species—some of them of a very remarkable character—were taken, often in great numbers. The bottom in all the hauls deeper than 1000 fathoms was of globigerina ooze, the absence of pebbles and sand being a well-marked and universal fact. Whenever mud was obtained from any locality, it was thrown into a tub of water, stirred, and allowed to settle, and by repeating this several times a perfectly pure deposit of Foraminifera was obtained. Each sounding and mud from each station was treated in a similar manner, so that samples, and often large quantities, were obtained in this manner, so that material was furnished for a complete monograph of the group. Over fifty species have been found in a partial examination of a few hauls. Every variety, both in form and in colour, is represented in these shells. Numerous new species of Gorgonians and Pennatulids were found in many localities. In these soft bottoms, where no stones are to be found, such animals or colonies of animals as must have some firm basis of attachment are almost entirely wanting. Sponges, barnacles, and hydroids are very rare, occurring at times upon the bare stalks of Lepidisis or upon some dead shell. Frequently, barnacles and Actinians are attached to these stalks, fastened in a cramped manner, the base completely surrounding the stem. The barnacles found here are very remarkable, usually being stalked, but one was taken which was sessile. A common mode of fixation among the Pennatulids is by means of a bulb-like process which projects into the mud. Acanella, Lepidisis, and their allies fix themselves by branching, root-like projections. A number of specimens of an undetermined species of Umbellifera were taken. Three new species of Epizoanthus, or, more probably, new genera allied to Epizoanthus, were obtained, each with a new hermit crab. Other genera of Actinians were rare, owing to the few opportunities for attachment. The most abundant starfish was a new species of Zoroaster named *Z. diomediæ*, found in 1200 fathoms. An Archaster-like species was the most interesting, on account of its immense madreporic plate. Several other species of Archaster, and at least one of Solaster, were also taken. Starfishes from these depths belong to the two very opposite genera Asterias and Archaster, or their near allies. *Ophiomusium lymani* and *armigerum* formed the greater bulk of Ophiurians, but we dredged, in smaller quantities, *Ophioglypha convexa*, several species of Ophiocantha, and a number of other species not yet determined. One species of soft, flat sea-urchin was quite abundant, and another much larger one was taken in smaller numbers. *Echinus norvegicus*, previously found only rarely in the dredgings of the Commission, was obtained in great quantities in 1000 fathoms. Several other species of Echinus and a number of Spatangoids formed the best part of the collection of Echini. Holothurians were represented by many forms. One, resembling Leptosynapta in form and in its anchor hooks, another similar to Molpadia, and several others having the form of the typical Holothurian, will undoubtedly prove to be new. The most peculiar species of Holothurian were two new forms taken in great numbers from several localities. They are new species belonging to genera described from the *Challenger* Expedition; one will be called *Benthodites gigantea*, the other *Euphronides cornuta*. We can describe them no better than by giving the names applied by the sailors, Benthodites being called the "lump of pork," and "animated boxing-gloves," while Euphronides was christened "Old Boot," and its resemblance to an old, unblacked, low shoe was certainly remarkable. As the specimens of Benthodites tumbled from the trawl-net, they looked very much like pork, and reminded one of boxing-gloves, on account of their size and apparently useless bulk. In the 2950-fathom haul, a specimen of a Tunicate, allied to Boltenia, was taken, and a number of shrimps.

Several new and remarkable Cephalopods were dredged during the summer. Pleurostoma, Bela, and allied genera were taken in great variety and abundance. One species of Pleurotomella was very large. A Dentalium, differing in no respect from *D. striolatum*, excepting in size, it being often nearly two inches long, was very abundant in from 1000 to 1500 fathoms. *Nucula reticulata*, *Cryptodon ferruginosus*, and several other species had their range extended as deep as 1500 fathoms. *Dolium bairdii* was obtained, and several specimens of a species which differs from Dolium only in the fact that it has an operculum, which would lead to the inference that it is a Buccinum. The Mollusca probably have more new species than any other group.

In several of the 200 to 400 fathom hauls, *Calliostoma bairdii* was taken. This species is remarkable from the fact that it is one of the few animals which, when taken from the cold bottom waters, will survive and flourish when placed in the aquarium. It is one of the few shells found in our deep water which has a truly tropical appearance. Many Annelids, mostly very minute, were taken at nearly every locality. It is probable that many will prove to be new. *Hyalinœcia artifex*, a worm which secretes a horny quill-like tube, was encountered in some of the shallowest dredgings.

Crustacea were represented by many new and interesting forms, especially of shrimps, including many very curious types. In 2300 fathoms we dredged a shrimp nearly a foot in length, and an Amphipod 3 inches long. Some very odd species of crabs, and hermits furnishing types for entirely new genera, were taken on several occasions. Collossendes, that gigantic Pycnogonid, was dredged many times, and several other large species were also taken. One specimen measured over 2 feet from the end of one leg to the opposite extremity of the other. Notwithstanding this remarkable length of legs, the body was less than an inch long, and an eighth of an inch in breadth. To support this great length of legs, a branch of the stomach extends into the base of each leg. The fish were perhaps the most remarkable, in point of curious structure, aberrant forms, and marked specialisation. One, *Gastrostomus bairdii*, forms the basis of a new order, and is one of the most remarkable recently-described types of primitive anatomical structure, and, especially as regards the skull and branchial apparatus, it presents a remarkable phase of specialisation. Its nearest ally is a Eurypharynx, described by M. Vaillant. It is at present in the hands of Mr. John Ryder and Prof. Theodore Gill, the former studying the anatomy, the latter working out its systematic position. Together they propose to publish a complete monograph of the species. Another remarkable fish has no external traces of eyes. Most animals from the bottom have well developed eyes, although their use is unknown, for, unless some such light as phosphorescence is common, they must live in nearly absolute darkness. Some shrimps and a few other species have no eyes whatever. There are as many as fifteen new species of fish described from the *Albatross* summer collection, most of them belonging to new genera, while one or two families have been added. The field of deep-sea research is as yet just begun, and with what remarkable results. Hundreds of new animals, belonging to entirely new types, have helped to fill up gaps in the animal kingdom which had been left unfilled after a thorough examination of all the shallow waters. Such groups as Crinoids, for a long time supposed to be extinct, are now found quite abundantly and in considerable variety in certain localities. And when the whole ocean bottom has been examined as thoroughly as some portions of the North Atlantic, who can tell what curious forms may be found?

The collections obtained have been placed in the hands of the best American naturalists. Prof. L. A. Lee, of Bodoin College, Maine, has the Foraminifera, Mr. Jas. E. Benedict and Prof. H. E. Webster the Annelids, Prof. S. I. Smith the Crustacea, who will work up the greater bulk, but will turn a few groups over to other naturalists. Mr. Sanderson Smith and Prof. H. E. Verrill will work up the Mollusca, Alexander Agassiz the more important Echini, and the rest of the Invertebrates will be studied by Prof. Verrill. It is not yet determined who will study the Sponges. The fishes are being worked up systematically by Prof. Theo. Gill, and Mr. Ryder is studying the anatomy of the more interesting forms.

RALPH S. TARR

AFRICAN SPIDERS[1]

THE paper above noted forms Part III. of an important and interesting series upon the Arachnida of Africa, and was first published in *Annali del Museo Civico di Storia Naturali di Genova*, vol. xx. pp. 5-105. Its subject-matter comprises the collection of Arachnids formed by Count Orazio Antinori in the kingdom of Scioa in the years 1877-1882. Before entering upon the details of this paper it will be well to notice briefly the two preceding ones of the same series. Part I. (published in the same *Journal* in 1880) states that the object of the series is to bring together all the existing materials in the shape of papers and other works on African Arachnida and present them on one plan and method in accordance with the following five zoological provinces:—(1) *Mediterranean* (extending nearly to the Tropic of Cancer, and including the Azores, Madeira, Canaries, and Cape de Verde Islands); (2) *Oriental*, or, rather, *Central and Oriental African*; (3) *Western African* (from the Gambia to the Congo); (4) *Southern* (included by a line drawn from Kalabini to Limpopo, and comprising a portion of the eastern coast to the Mozambique); (5) *Malagasic* (*i.e.* the Lemur country with Madagascar). Various expeditions and other means by which materials have been obtained are mentioned, and a bibliographical list is given, in the introduction, of the numerous published works and papers on African Arachnida from the days of Linnæus to the present time. The Arachnida described and recorded in this first part are from Tunis, while the second part (published *loc. cit.* vol. xvi. 1881) simply contains an account of a collection of Arachnids from Inhambane (in the southern region), with some considerations on the Arachno-fauna of the Mozambique, of which a list of species is also added.

---

[1] *Memoire della Società Geographica Italiana*, vol. ii. parte quarta, pp. 1-103 (Roma, 1883). Spedizione Italiana nell'Africa Equatoriale. Risultati Zoologici. IV. Aracnidi di Scioa, e considerazioni sull' Aracnofauna d'Abissinia, per il Prof. P. Pavesi.

The Tunisian collection described in Part I. numbers 115 species of six orders: *Scorpionidea*, 6 species (Scorpiones, 5; Pseudoscorpiones, 1); *Solpugidea* (Solifugæ), 4; *Phalangiidea* (Opiliones), 4; *Araneidea* (Araneæ), 96; *Acaridea* (Acari), 5. Of the above, two new genera, and eleven new species (all but one of the latter—a pseudo-scorpion of a new genus) belong to the Araneidea. As might be supposed, the essential character of the Tunisian collection is South European or Mediterranean. Very different from these are the arachnids described and recorded in Part II. from Inhambane and the Mozambique. Here we have, though the number of species is very scanty, the true tropical character. Only 54 species are recorded, comprised in 43 genera, 20 families, and 5 orders. The larger part (35 species) belong to the *Araneidea*, of which 1 genus and 4 species are new. Coming now to the Arachnida recorded and described in Part III. from Scioa (in the eastern zoological province) we have 71 species belonging to 49 genera, 18 families, and 4 orders. A general catalogue is also added of Abyssinian Arachnida, which, including those from Scioa, number 124 species. It is noted as remarkable that no scorpions were contained in the collection from Scioa, and that 30 of the Arachnids recorded are new to science; also that only 12 of the Scioan species are common to the rest of Abyssinia.

The author enters into some other considerations on the distribution of the Arachnids of Abyssinia; but the researches and materials on which his observations are based appear as yet to be too scanty to sustain any very general conclusions. At the same time it must be acknowledged that the plan on which the author has worked, of bringing the materials of so large and varied a region as the African peninsula under the geographical divisions announced in the introduction to Part I. is a most useful one, and the work he has done so far is undoubtedly a valuable contribution to arachnological science.

O. P. C.

MR. BURNHAM'S DOUBLE-STAR MEASURES

THE recently published volume of the *Memoirs of the Royal Astronomical Society* contains a further series of measures of double stars by Mr. S. W. Burnham, made with the 18-inch refractor of the Observatory at Chicago. This series comprises measures of 151 double stars discovered by this eminent observer, which brings up the number of such objects discovered by him during the last ten years to no fewer than 1013, amongst which are included some of the most interesting stars of this class; also measures of a selected list of double stars, 770 in number, made chiefly in the years 1879 and 1880, with an appendix, the results of observations of several objects, as late as the middle of the past year. Every one who is interested in this branch of astronomical science will read with much regret one remark in Mr. Burnham's introduction: he writes:—"The present catalogue will conclude my astronomical work, at least so far as any regular or systematic observations are concerned." He expresses himself modestly respecting his own labours—"In a field so infinitely large, one can accomplish but little at the most, and how much, or how little, the astronomers of a few centuries hence can perhaps best decide. . . . At this time I may venture to claim that my work in this field has been prosecuted with some enthusiasm, and for its own sake only, and that my interest has not been divided among several specialities."

But a higher estimate of Mr. Burnham's work in this particular line of observational astronomy to which he has devoted himself may be justly taken. To read of the discovery of upwards of a thousand double stars within a limited period by one observer, we might almost suppose we were living in the days of Sir William Herschel, when the heavens were comparatively an open field, and had not undergone the wide and close exploration which they had done when Mr. Burnham commenced his work. He has had, it is true, the advantage of instruments of the finest class, and we may believe an unusually acute vision; but he must have exercised an extraordinary and most meritorious amount of patience, perseverance, and care in the discovery and accurate measurement of such a list of double stars, and it will be gratifying to the astronomical world that such well-directed exertions have met with so exceptional a success.

Among the more noteworthy stars included in Mr. Burnham's new Catalogue (the fourteenth), which may be considered a continuation of that published in vol. xliv. of the same *Memoirs*, the following may be mentioned:—

1. 126 Tauri (β 1007), "a most remarkably close and difficult pair, one of the closest known"; magnitudes 6·0 and 6·2. With a power of 1400 there was only a slight elongation.

2. B.A.C. 346; Mr. Burnham thinks the principal star may be variable, and he is certainly correct in his surmise. Heis gives it as a naked-eye star 6·7 m., Gould 7·0 m., and it has been several times noted 8 m.; while the writer has recorded it as low as 9 m.

3. β 117; a star with a proper motion, according to Argelander, of 0″·438; measures in 1883 show a common motion of the components; their distance is 2″·2.

4. ζ Sagittarii; detected by Winlock, probably a retrograde motion of 225° in less than fourteen years; and evidently a change of 48° in less than three years, by Mr. Burnham's measures alone. It is an object for large instruments in the other hemisphere.

5. β Delphini (β 151).—A very rapid binary; since its detection by Mr. Burnham in 1873, there has been an increase in the angle of about 180°, and a diminution in distance from 0″·6 to 0″·25. He thinks "it may prove to have, with the single exception of δ Equulei, the shortest period known."

Mr. Burnham collects the measures of δ Equulei, and infers a period of revolution of about 10·8 years. Measures should be easy again in 1885.

6. 85 Pegasi (β 733).—The close pair was not measurable in 1882; the angle was about 323° at the epoch 1883·75. The mean annual motion is about 12°·5, at which rate the period would be less than thirty years.

In the introduction to the Catalogue will be found references to the publications where the thirteen previous ones are to be found.

MEASURING THE AURORA BOREALIS

THE study of the height of the aurora borealis above the earth's surface is, it will be easily conceived, of the greatest importance in understanding the nature of this phenomenon. Unfortunately the height of the aurora has always been, and is to some extent still, a moot point in natural science. There are, of course, not wanting estimates and observations relating to this question, but the general results of these, particularly of the earlier ones, are very contradictory. There seems, however, to be every probability of this problem being very soon solved.

As a basis for the measurements of the aurora we have generally selected the arcs or the more pronounced solitary streamers, when they have been clearly and simultaneously observed from two points situated some distance from each other, the apparent height or position in each place having been determined by comparisons with, and measurements of, stars. In consequence, however, of the rapid shifting both of appearance and position of the auroræ, this method is difficult and unsatisfactory, and these drawbacks may to a great extent explain the very divergent results which have been obtained by the same.

In order to give an idea of the manner and principle of measuring the auroræ in their simplest form I venture to describe the method I have been in the habit of following.

On March 17, 1880, a great aurora was observed at the 145 stations which I had established over the southern part of Norway, the west coast of Southern Sweden, and in Denmark. One of the characteristics of this phenomenon was a large broad arc, or, perhaps more correctly, band, which for a long time spanned the sky from east to west. In Bergen (Norway), where my own observatory was established, it remained for some time in the zenith, then moving a little to the south, but at the stations lying further north it was seen in the south, while at those south of Bergen it was seen in the north.

By its characteristic internal repose and slow motion this remarkable band was especially suited to establish the identity of this aurora at the various stations and to serve as a basis for its measurement. It had apparently, when in its most southern position, no connection with the types which appeared simultaneously in the north, the latter being streamers which it was impossible, from their rapid change of form and appearance to observe connectedly at the various stations.

If the various reports of this auroral phenomenon be examined, not the slightest doubt will remain of the object seen being the same, *i.e.* that the same arc was observed at the most southern as well as the most northern stations. The further we move southwards however—away from the same—the more the apparently observed height diminishes, until we find that at the most southern points it was seen merely as an ordinary low-lying arc. In Bergen no trace of an auroral phenomenon was seen south of the band in question, and the reports from the stations south of this place all agree that neither was any seen there. From this we may conclude with certainty that the auroral arc observed in the zenith of the horizon of Bergen was the identical one seen at all the southern stations, and that the line of demarcation of the phenomenon seen from that place was the absolute southern extension of the band.

Before it is possible, however, from the observations before us to measure the height of the arc, it is necessary to ascertain its direction and its position in space relatively to the localities on the surface of the earth from which it was seen. In the main the point of culmination of ordinary auroral arcs is in the direction of the magnetic north of the place of observation, and the arcs themselves follow approximately the magnetic parallels. I found, however, from careful calculations that the apex of this arc deviated some 10° west from the magnetic meridian, and that its course or strike was at an angle of about 25° with the geographical parallel circles.

The calculation of the height of the arc rests on the following principle. If in Fig. 1 S and S′ denote points of observation, C the centrum of the earth, and P two points in the aurora borealis situated in the same perpendicular plane through S and S′, whose angles above the horizon h and h' have been determined at each station, and the longitude and latitude of each place is known, it is possible (by a well-known trigonometrical formula, viz. $\cos d = \cos (l - l') \cos b \cos b' + \sin b \sin l'$, where l and l' indicate the longitude and b and b' the latitude of the two places, and d the distance or great circle between the two) to find the arc S S′, which is equal to S C S′. From this again S S′ ($\frac{1}{2}$ S S′ = sin $\frac{1}{2}$ S C S′) is found. Further, $\angle\, x = x' = \frac{1}{2}$ S C S′. One knows, therefore, in the triangle S P S′, the side S S′ and the angles P S S′ and P S′ S, so that its other parts, as for instance P S, may be ascertained by means of some simple trigonometrical calculations. If P S is known, we further obtain, in the triangle P S C, S C, which is equal to the radius of the earth, and the angle P S C = $90° + h$. From this P C is found, and, subtracting S C, the perpendicular height of P above the earth's surface is determined. Finally, if ∠ P C S is ascertained, the point on the earth above which P is situated perpendicularly is found.

In practice the matter is, however, not quite so simple. The method presupposes thus that P lies in the same vertical plane as both points of observation, which would rarely occur, but still it retains its adaptability, even if P only indicates a point in the upper or lower edge of the auroral arc, the culminating point of which has been determined in both places, provided that these lie in the same plane perpendicularly in the longitudinal axis of the circle, or may at all events be referred to such a common plane.

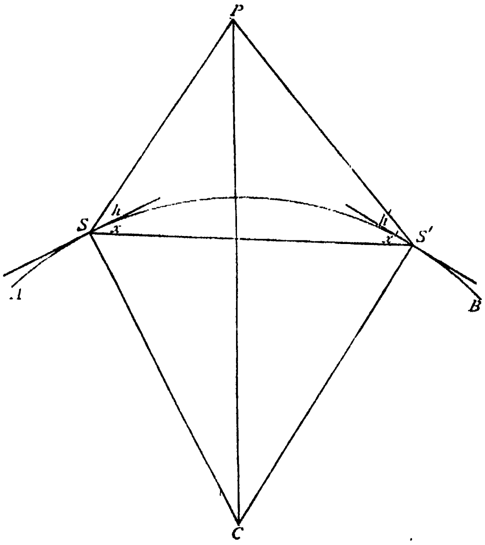

FIG. 1.

It is, however, far more difficult to overcome another drawback. Provided that the arc has a perceptible thickness in relation to its horizontal breadth, those parts of the upper or lower edge of the arc which present themselves to the various observers cannot always be referred to the same parts of the arc, in consequence of the circumstance that the apparent breadth, particularly with the lower arcs, is due to a combination of both the real breadth and thickness of the arc.

If a, b, c, d in Fig. 2 represent the circumference of a circle observed from the points A, B, C, assuming that the line of demarcation of the arc north and south is parallel with the inclination needle, the point a will denote the upper (southern) edge for A and B, for C on the other hand b; and, in a similar manner, the lower (northern) edge is determined by the point d for A and B, c for C, &c.

Now if the determination of the apparent height of the upper edge for A and C is taken as a basis for calculation, the height of the same cannot be ascertained therefrom, but from the crossing point of the lines A *a* and C *b*, and so forth. A great many other variations may also be met with according to the dimension and position of the arc. Generally, however, when the arc lies on one side of both places of observation, the edges observed in the respective places are identical.

In the following simple manner I have succeeded in referring the various places of observation to the vertical plane of Bergen, where my own observatory is situated, in order to find the arc S S′ in Fig. 1. The direction of the arc I have, in accordance with observations, let form an angle with the circles of latitude of 25°. I have constructed a globe with the circles on a large scale in Mercator's projection, on which the various stations have been denoted. Through the place "Bergen" a straight line is drawn under an angle of 25° with the circles of latitude, while the perpendicular distance of the various stations from this line has been determined in the construction and by direct measurements. The stations whose observations are so complete that the angle of the arc above the horizon has been determined have been combined with Bergen. I have succeeded in forming nineteen such combinations. The heights of the arc calculated at these stations vary somewhat, but not very much, and if an average is taken we find that the value of the height of this arc above the earth's surface was most probably 146·95 km.

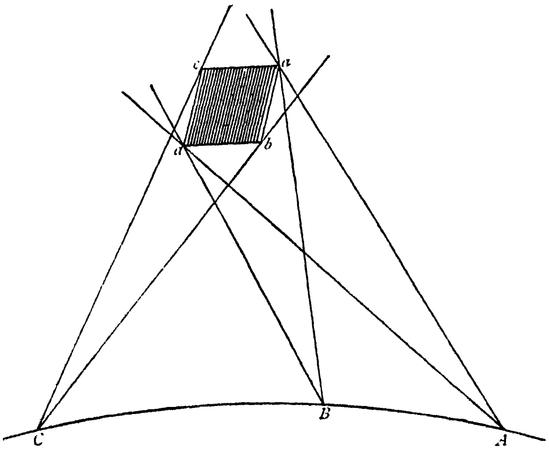

FIG. 2

It further appears that the observations were not exact enough to obtain an estimate of the thickness of the arc, so that we can only accept the figure given above as an average one, *i.e.* an average of the distance of the uppermost and lowest layers from the surface of the earth.

If we compare the height arrived at in this case with those obtained through previous researches, we shall find that it agrees to some extent with the value of the arcs measured in recent times. They differ, however, greatly from old ones. Thus Prof. Fearnley finds, through observing sixteen auroral arcs from *one* spot, in Christiania, by an ingenious theoretical method, that the average height in these cases was 27·15 geographical miles, or 201·5 km. Newton found, by the same method, that the average height was 130 English miles, or 209·3 km., while Nordenskjöld, by a similar method, has come to the conclusion that it is 190 km. The French expedition established at Bossekop during 1838-39 obtained no reliable statistics on this point, owing to the small distance between the two points of observation, viz. 15·6 km. But from the results obtained it seems that the height must be sought between 100 and 200 km.

In opposition to this Bergman fixes the height at 753 km., Boscovich at 1328 km., and Mairan at 780 km. More in correspondence with our result Dalton found the height of the auroral arc to be 241 km., and Backhouse found the three measured by him to lie between 81 and 160 km. On the other hand, Franklin found at Cumberland House (North America) that several auroræ which he measured had a height only of 11·3 km. In fact, the *savants* who have studied the aurora borealis in the Arctic regions appear to agree that it does not attain the height given above as the results of researches further south.

I have here only mentioned a few of the very divergent values obtained in measuring the aurora borealis, but I do not believe it will be of any service to append more, as the values range from 0 to 2000 km.

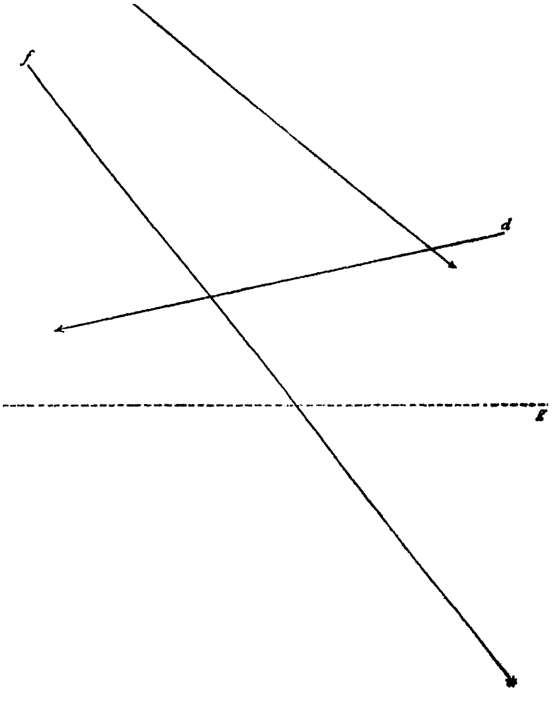

FIG. 3.

In Fig. 3 I have attempted to illustrate the height of the aurora referred to by me by comparing it with other well-known heights. The scale is 1 mm. = 1 km. Below is drawn a profile of Norway from Bergen in a direction E. 25° N. The heights here range to upwards of 5000 feet. Above *n n* indicates the arc of the aurora in its height of 146·95 km. The thickness given is wholly approximate, and probably too small. For comparison is inserted, *a*, the highest mountain in the world (Mount Everest, 8839 m.); *b*, the greatest height reached by man (Glaisher and Coxwell in their balloon on September 5, 1862, 31,800 feet); *c*, the estimated height of the cirrus clouds (25,000 feet); *d*, the plane of the August meteors—beginning and ending (155 and 98 km.); *f*, the point of appearance and disappearance of the large meteor which was seen on March 4, 1863, in England, Holland, Belgium, and Germany (134 and 26 km.); and finally *g*, the hypothetical height of the atmosphere (10 geographical miles = 74 km.).

With regard to the results of the measurements of the aurora which I effected during last winter at Kautokeino, in conjunction with the stations at Bossekop and Sodankylä, I may be brief, from the circumstance that the observations made at the latter station are not to hand, while the material at my disposal requires a more careful analysis than I have as yet been able to bestow upon it.

I must, however, state that a preliminary examination of the observations made in the plane Kautokeino-Bossekop has led to the important discovery that the aurora borealis, at all events in this locality, lies in a plane at least 100 km. above the earth. I have examined all the observations made simultaneously at the two stations, and have not found the slightest indication of the aurora descending to a level in which it would only be visible at one of them, while there seems to be no reason for assuming that the types observed were not identical, when due regard is paid to the difference in the height above the horizon of the two stations.[1] The distance between Kautokeino and Bossekop is about 107 km.

I have, on the principle indicated in Fig. 1, made a series of preliminary measurements of the lower edge of auroræ observed at both stations, having selected only those where there cannot be the least doubt as to identity, from which I have obtained the following values in kilometres:—76·0, 79·9, 84·6, 93·6, 97·7, 98·2, 99·0, 100·0, 100·6, 107·0, 116·6, 124·1, 124·9, 131·9, 141·6, 144·9, 149·0, 163·6.

If the average of these eighteen measurements is taken, the average height of the lower edge will be 113 km., *i.e.* a result which is in perfect harmony with the later observations referred to above.

To give any definite results of the studies of the thickness of the arcs, the length of the streamers, &c., is, of course, impossible, until the material has been carefully sifted. I may here in passing observe that we must in all estimates of the height of the aurora borealis be content with approximate figures; this lies in the nature of the case, apart from inaccuracies in the measurements which it is impossible to avoid. The aurora borealis has, in common with clouds, no absolutely defined and fixed line of extension, either downwards nor upwards. We must therefore rest content with ascertaining only approximately the height of the plane in which the aurora borealis appears.

That the aurora generally appears at a height of 100 km. or more above the earth's surface does certainly not preclude the possibility of its appearance on some occasions much nearer the earth. In fact there are a considerable number of reports in our hands which imply that this is really the case. Thus observers aver that they have seen auroræ below the clouds, in front of mountains and icebergs and coasts, and even on the very ground. These assertions have been greatly doubted as being the result of the imagination, or optical illusions, but with what justice I will not venture to say. For my own part I can only say that during my long stay at Kautokeino I had unfortunately often enough occasion to observe auroræ and clouds simultaneously, but although always paying the closest attention to this particular point I have never seen even a fragment of an aurora in front of or below the clouds. Even the most intense development of light, colour, and motion occurred always above what seemed to be the very highest-lying clouds.

When the entire material relating to the study of the aurora borealis has been collected from the various international circumpolar stations, sifted and carefully analysed, the question of the height of the aurora borealis will not, I believe, long remain one of the unsolved problems of nature. Until then the reader must remain content with the discoveries I have indicated in this paper.

SOPHUS TROMHOLT

COUNT DU MONCEL

COUNT THEODORE DU MONCEL, whose death we briefly announced last week, was born at Paris on March 6, 1821. His father had been a General of Engineers under Louis Philippe, and the son was at one time destined also for the army. When but eighteen years of age he showed a predilection for scientific pursuits, and published two treatises on perspective, treated mathematically and artistically. He was also at this time an enthusiastic archæologist and traveller. In 1847 he published a volume entitled: "De Venise à Constantinople à travers la Grèce," illustrated with lithographic plates drawn by himself. His family objected to his democratic pursuits, and became estranged from him. In consequence he determined to adopt science as a profession. But not having studied at the Ecole Polytechnique, nor at the Ecole Centrale, he lacked those scholastic recommendations without which, in France, promotion is so difficult. A professorship being absolutely closed to him, he became a scientific writer, and devoted his attention chiefly to electricity. In the years which followed he zealously sought to acquaint himself with every new discovery and invention which was made; and his industry in collecting and disseminating information on electric science was immense. During the years 1854-1878 he published at intervals in five volumes, his well-known "Exposé des Applications de l'Electricité," a work which, though it relates chiefly to inventions and instruments now superseded by newer forms so abundantly poured forth during the past few years, nevertheless maintains its place as a standard work of reference in electric technology. Since 1878 Count du Moncel published several volumes containing popular expositions of various branches of the science. His work on the Telephone and Microphone has been translated into English; so also has his work on Electric Lighting, and that on Electricity as a Motive Power. Thoroughly in his element as a writer for the scientific press, and more of a journalist than a man of science, Count du Moncel nevertheless distinguished himself by a series of valuable contributions to science, chiefly in the form of papers read before the Académie des Sciences. His researches on the properties of electromagnets and on the conductivity of badly-conducting bodies are worthy of mention. To du Moncel we owe the observation that the variation produced by pressure in resistance offered at the point of contact between two conducting bodies—a phenomenon well known before his time—is more marked in certain bodies than in others, wood-charcoal being one. In this observation he laid the foundation for the subsequent applications of this principle made by Clérac and by Edison. Du Moncel was also an inventor, and obtained a gold medal at the Exposition of 1855 for the collection of instruments exhibited by him, including an electric water-indicator, an electric anemograph, an electric recorder of improvised music, a recording galvanometer, and sundry telegraphic instruments. From 1860 to 1873 du Moncel was occupied as electrician to the administration of telegraphs; but he quitted the post somewhat abruptly in 1873 in consequence of disputes in the administration. In 1874 he was elected a member of the Académie des Sciences, in which body he was very active in bringing forward accounts of all discoveries in his favourite science. It was he who thus successively introduced to the Academy the Bell telephone, the Hughes microphone, and the Edison phonograph. He was very prominently connected with the Electrical Exhibition at Paris in 1881. From 1881 until his death he held the editorship of the journal entitled *La Lumière Électrique*, which was founded by him, and to which he was an unceasing contributor. Whether he was a great scientific genius may be doubted, and whether in some matters he did not assume the attitude of partisan rather than that of historian is also perhaps open to debate; but none can deny that he had by his diligence and talents won himself a very important place in the ranks of science. The *rôle* of scientific journalist may be said to have almost been created by him, and he was always anxious to maintain the dignity of science and to advance the interests of scientific workers. It would be difficult to fill up the void left by his sudden decease.

---

[1] The experiences of Prof. Lemström at Sodankylä (NATURE, vol. xxvii. p. 389), which seem to point in a different direction, I intend to discuss on another occasion.

NOTES

M. Faye read to the Academy of Sciences, on Monday, a report drawn up by the Academical Committee appointed to prepare for the election of the three French delegates to the Meridian Congress of Washington. The Committee, whose conclusions have been adopted by the Academy, declines to take any final step, and will ask the Minister to appoint a certain number of delegates of several public administrations in order to deliberate in common with them and give final advice.

The Committee appointed by the Academy of Sciences to report on the proposal to sell the Paris Observatory grounds, has held its first meeting. M. Wolff, Member of the Section of Astronomy, read a note, which will be printed, opposing the scheme. He said, *inter alia*, that the Government had constructed an Observatory at Meudon, which was almost complete, and that he was certain that M. Janssen, the present director, would lend his instruments and grounds to any astronomer wishing to execute special work which could not be executed in the interior of Paris. M. Janssen, who was present, said that he should be most happy to comply with any wish expressed by a competent observer, the Observatory not being his private property, but belonging to the Government.

The Meteorological Observatory of Sentis, in the Canton of Appenzell, Switzerland, at a height of 8094 feet was established in August 1882, and the regular observations began with September 1 of that year. This observatory, which, from its position and height, is *par excellence* the high-level meteorological station of Switzerland, is maintained at an annual cost of 6000 francs, raised jointly by the four neighbouring cantons, the learned societies, and the Alpine Club of Switzerland, and is further subsidised by 1000 francs from the national grant for meteorology. A brief *résumé* of the results of the first year has been received. The eye-observations are made five times daily; the results at these hours, however, are only given in full as regards the force of the wind. These are of some interest, as showing that, so far as regards the observing-hours, viz. 7 and 10 a.m. and 1, 4, and 9 p.m., the mean diurnal force of the wind, for each of the twelve months beginning with August 1882, is least at 1 p.m. We look forward with no small interest to a fuller report than the one now before us of the diurnal results for each month of the barometric, thermometric, hygrometric, and rain observations from this invaluable addition recently made to the high-level stations of Europe.

A curious tidal phenomenon took place on the morning of the 21st inst. on the west coast of England. The following communication (dated Feb. 21) to the Secretary, Meteorological Office, from Ellis Roberts, Trinity Buoy Keeper, Aberdovey, contains the leading circumstances connected with the occurrence:—"Afternoon of the 20th (civil time), it blew strong (6 to 7) from south-south-west and south-west, increasing towards midnight to very heavy gale (force in the squalls, 10 to 11) with heavy rain. I retired at 11. Barometer at 29·31, falling. I cannot say when it moderated, but at 6 a.m. the sky was beautifully clear, with moderate breeze about west (force 3 to 4). The time of high water for this bar, by the Liverpool almanacs, this morning tide would be 2h. 33m., but from some observations that I have made for eighteen months that I have been living here, the time of high water in the river off the village would be about 3h. 5m. to 3h. 10m. I wish to make this remark on account of the time; the phenomenon took place. About 6.30, or near half ebb, I noticed the barometer had risen to 29·34 or ·35, with beautiful, fine, clear sky; moderate breeze (about 3) from west-south-west, but the stream nearly slack when it ought to have been running *ebb* about two knots; very heavy sea on the bar. At 6.50 the vessels were fairly swung to the flood, which was running about 1 to 1½ knot, and the water was fast rising. At 8·15 water again nearly slack, with light breeze (about 2) from south to south-south-east; very fine, but clouds beginning to form in the south-west and west. At 8.30 the water was falling; at 9, water falling very fast, ebb running 2½ to 3 knots; at 10.45, water beginning to rise for the natural tide. As there is no gauge for the rise and fall at this place, I cannot give the *correct* rising and falling, but I will give them according to the best of my judgment. The afternoon tide of the 20th was noticed to be very low, much lower than could be expected from the state of the wind and weather. But this morning's tide rose fully *six* feet above the ordinary level, or nearly to the height of the tides at full and change, with the moon's parallax 59′ to 60′ (this tide had fallen as usual, or rather more rapidly, up to nearly half ebb). I cannot exactly say how much the water had risen before I noticed it, but the unnatural tide rose after I noticed it over 2 feet 6 inches; and from 8.30 to 10.15 the same had fallen over 6 feet, although the wind had shifted to the westward, with passing showers and hard squalls. Barometer all the time very steady at 29·34 or ·35. Now, 4 p.m., it is slack water, ships lying head to wind, but a lower tide than any that I recollect in this river with the wind as strong from the westward. I have heard it reported that there was heavy thunder and lightning in the neighbourhood, but I neither saw nor heard any." Similar occurrences are reported from the Dee, near Chester, and from the Mersey.

The Second Teyler Society of Haarlem offers a gold medal of the value of 400 florins for a critical study of all that has been said for and against spontaneous generation, especially during the last twenty-five years. The competition is international, and further details may be obtained by applying to "La Maison de la Fondation du feu M. P. Teyler van der Hulst, Haarlem."

We are asked to state that a society calling itself the "Society of Arts, Letters, and Science," has no connection whatever with the Society of Arts.

The old Sorbonne and Collège Louis-le-Grand in Paris will soon be demolished, to be reconstructed on a larger and more magnificent scale. The same measure is to be applied to the Collège de France. All this part of the Latin Quarter will be quite remodeled, and will in a few years be unrecognisable.

The Municipal Council of Paris has passed a resolution to exhibit, in each of the twenty town halls of that city, the meteorological notices issued every day by the French Office.

Professor Milne of Japan has just made a new move in the direction of investigating seismic phenomena. He has made preparations for the establishment at Takashima, near Nagasaki, of an underground or catachthonic observatory. The workings in the coal-mine at that place not only extend beneath the island of Takashima itself, but also beneath the sea, and have a total length of about seventy miles. About 2500 people are employed there, and the output of coal is about 1200 tons a day. Owing to chemical decomposition going on in the workings, which are on the "post and stall" system, the temperature is so high that spontaneous combustion is constantly occurring. Prof. Milne visited places having a temperature of 110° F. This, together with the escape of fire-damp, make the mine very dangerous. The experiments which have been commenced, and which are to be continued systematically, are: (1) the observation of earth-currents, which so far appear to be but feeble; (2) listening in a telephone to the sound produced by the movement of a microphone placed in the solid rock; (3) the observation by means of a tromometer, or tremor measure, of earth-tremors; (4) the observation of two delicate levels to see if the seasonal movements of the soil on the surface exist also underground; (5) attempts to measure the influence of the tide, which rises there about eight feet every twelve hours, in producing a bend, or crushing in the roof of the mine. Observations on atmospheric electricity may subsequently be added. All these will be carried on in conjunction with tidal, barometrical, and thermometrical observations, as well as with those on the escape of fire-damp and the entrance of water to the mine. One practical object of these series of observations is to ascertain whether any of these phenomena are connected with each other, and especially with the escape of fire-damp in the mine. At present it appears that the gas shows itself about eight hours before a fall in the barometer, and therefore the indications of the latter are useless as danger warnings. On the *surface* of the earth tremors increase with a barometrical fall, and perhaps before it. Earth-tremors and the escape of fire-damp may, therefore, Prof. Milne thinks, be connected; but, whether practical results be obtained or not, the experiments will enable a comparison to be made between surface phenomena and those which are subterranean. The native company which now owns the mine, as well as the resident engineer there, have afforded every assistance to Prof. Milne in his investigations, and that gentleman, we are informed, will be glad to receive suggestions for improved or additional observations, from any scientific men in this country interested in the subject. Any communications intended for him should be addressed to the Imperial College of Engineering, Tokio.

THE Russian *Izvestia* publishes the results of the researches of M. Brounoff into the variations of temperature in consequence of the cyclones in Europe. He has taken seventy-six cases in which the meteorological bulletins showed the presence of a cyclone in Europe, and prepared a meteorological map for each of these days, showing the deviation of temperature from the normal, and the route of the cyclone. The average deviations of temperature in the regions of the cyclones appear as follows for different months: January, 3·7° Cels.; February, 2·2°; March, 1·2°; April, 0·2°; May, 0·0°; June, −0·7°; July, −0·2°; August, −0·4°; September, −0·1°; October, 0·2°; November, 0·9°; December, 1·4°. It results from these figures that, as might have been foreseen, during the winter the cyclones bring warmer air, and colder air during the summer. If the region of the cyclone be divided into four parts by two perpendicular lines traced through its centre, the two right parts widely differ from the two left, the deviations being for the former: winter, 4·6°; spring, 1·9°; summer, 0·7°; and autumn, 1·7°, all positive; while for the two left parts the deviations are all negative as well during the summer as during the winter, namely: −0·9° for the winter, −1·1° for the spring, −1·7° for the summer, and −0·9° for the autumn.

IT appears from a notice published in the last issue of the *Isvestia* that stone-age implements were used by Russians in Siberia at a time very near to our own. Thus, owing to the difficulty of having iron implements, and even iron, the Cossacks who occupied the valley of the Irkut at Tunka availed themselves of the numberless stone implements they found scattered on the hills around Tunka, where large manufactures of stone implements have been discovered. There are still people who remember also that their grandfathers were compelled to follow the advice of the Mongols, and to make use of nephrite hatchets; the tradition says also that there were Cossacks who understood themselves the art of making jade implements. Any one who knows the difficulties of obtaining iron in Siberia some thirty years ago, and even now, will not doubt the trustworthiness of the tradition. We may add also that the late Prof. Schapoff has found the settlers at Turukhansk largely using stone pestles and hammers, some of which were exhibited at the Irkutsk Museum, before it was destroyed by fire.

IN the last number of *Naturen* Herr Geelmuyden of Christiania describes the so-called "Jættegryder" giant-bowls of Orholm, on the east side of Christiania fjord. These curious geological formations, of which good drawings are given, are not only the largest of their kind in Scandinavia, but are of greater size than those of the well-known glacier garden of Lucerne, which have hitherto been considered as the most extensive of such natural depressions. In two of the upper cavities at Orholm, all of which lie on the edge of a steep fjeld, a few pine and birch trees have taken root and grown in a tolerably normal manner till they reached the level of the surrounding rock, when the branches have invariably been bent and distorted by the force of the winds, and their growth has been arrested. The depth of the depressions has not been determined, but the perpendicular inclination of the inner walls would lead to the inference that it is considerable.

MESSRS. CROSSLEY BROTHERS, of Manchester, have recently added an important improvement to their "Otto" gas-engine. This consists of a self-starting apparatus by means of which the engine can be put in motion by simply opening a valve. The apparatus consists of a small receiver into which the engine exhausts for a very short portion of its strokes the burnt gases which result from the ignition of the charge in the cylinder. These gases fill the receiver, and in the course of half a minute raise a pressure in it nearly corresponding to the pressure in the cylinder during the moment of ignition. These stored burnt gases are admitted again to the cylinder at the moment of starting by a very simple piece of mechanism, and thus put the engine in motion in much the same way as steam moves a steam-engine, thus saving the trouble of pulling the wheel round to get in the first charges.

ON January 22, at 8.47 p.m., a meteor was observed in the province of Kalmar, Sweden. It appeared in the north as a fire-ball, without trail, gradually descending to the earth, so slowly that some observers, in order that it should not become hidden from view by intervening houses, ran about 300 m., and still beheld the object. The speed decreased by degrees, and finally the ball seemed to remain stationary and then went out. No whizzing noise or report was heard. The object was observed for a minute and a half. Its path was not regular but marked by great deviations. When first seen its size and lustre was like that of Jupiter, and its point of issue 50° above the horizon, while when disappearing it was 10° above the horizon. It seemed to increase in size as it descended. Its slow speed was particularly remarkable, as it differed so greatly from that of ordinary meteors.

THE Anthropological Society of Paris is constituted as follows for 1884:—President: Dr. Hamy; Vice-Presidents: Drs. Dureau and Letourneau; Secretary: Dr. P. Topinard; Assistant Secretaries: M. Girard de Rialle, Dr. Prat, and M. Issaurat; Committee of Publication: Drs. de Quatrefages, Matthias Duval, and Thulié.

THE death is announced of Dr. Gotthilf Heinr. Ludw. Hagen, with whose name for the last sixty years progress in the domain of hydrotechnics in Germany is closely associated. He died at Berlin on the 3rd inst., having nearly completed his eighty-seventh year.

THE death is announced of Dr. A. Bernstein, the well-known author of the "Naturwissenschaftliche Volksbücher." He was born at Danzig in 1812, and died at Berlin on the 12th inst.

ON February 18 an earthquake was felt in several parts of the Department of Algiers. Its duration was very short. The *Turkestan Gazette* states that as many as ninety distinct shocks of earthquake have been felt at Oosh since November 14. Other shocks have also recently occurred at Viernoe and Tashkend. A violent earthquake is also reported from the Birvari district (province of Bitlis, on Lake Van, in Asiatic Turkey) on February 10. Great damage was done, as many houses fell.

MR. W. WHITAKER desires us to point out in reference to the article on the "Geological Survey of the United Kingdom," printed in the last number of NATURE (p. 395), that some of the bulkiest publications of the Survey have appeared since 1855. He favours us with a list of these, in which we are glad to observe his own "London Basin, pp. xii. 620."

IN consequence of a generally expressed wish from many hundreds of intending participators at the forthcoming Ornithological Congress at Vienna, the Committee of the Congress has altered the date for the first meeting from April 16 to April 7. As the Ornithological Exhibition will be held from April 4 to April 14, the ornithologists present in Vienna at that time will have an opportunity of seeing the Exhibition, while at the same time attending the Congress. Numerous Belgian, Danish, French, German, Austrian, Italian, and Russian men of science will meet in Vienna upon that occasion.

THE German Government has issued an edict concerning the preservation of prehistoric burial-mounds which may be discovered henceforth upon German soil.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♂) from India, presented by Mr. W. Graeme; a Sambur Deer (*Cervus aristotelis* ♂) from Ceylon, a European Flamingo (*Phœnicopterus antiquorum*) from Southern Europe, presented by Mr. James McGregor; a Vulpine Phalanger (*Phalangista vulpina* ♂) from Australia, presented by Mr. A. H. Lowder; a Pine Marten (*Mustela martes*), British, presented by Mr. Edward de Stafford; a Common Hare (*Lepus europæus*), British, presented by Mr. G. Pottier; a Rhesus Monkey (*Macacus rhesus*) from India, presented by Master A. J. Neill; two Laughing Kingfishers (*Dacelo gigantea*) from Australia, presented by Dr. Evans; a Black-footed Penguin (*Spheniscus demersus*) from South Africa, presented by Mr. F. Bloor; a Greek Tortoise (*Testudo græca*), European, presented by Miss M. L. Fergusson; a Stump-tailed Lizard (*Trachydosaurus rugosus*) from New Holland, a Bearded Lizard (*Amphibolurus barbatus*) from Australia, presented by Mr. J. W. Bostock; a Pike (*Esox lucius*) from British fresh waters, presented by Mr. Charles D. Hoblyn, F.Z.S.; a Lesser White-nosed Monkey (*Cercopithecus petaurista* ♀), a Campbell's Monkey (*Cercopithecus campbelli* ♀) from West Africa, a Ruddy Ichneumon (*Herpestes smithi*) from India, a Bactrian Camel (*Camelus bactrinus* ♂) from Central Asia, three White-crowned Pigeons (*Columba leucocephalus*) from the West Indies, purchased.

OUR ASTRONOMICAL COLUMN

THE SOLAR ECLIPSE OF 1806, DECEMBER 10.—When Rümker was on the point of leaving England to undertake the direction of the observatory erected by Sir Thomas Brisbane at Paramatta, N.S.W., he came into possession of a letter addressed to Maskelyne by Admiral Bligh, Governor of the colony, containing observations of a solar eclipse on December 10, 1806, which was described as almost total; the observations were made at Government House, Sydney Cove, with a three-feet achromatic and two chronometers by Arnold; Rümker communicated the Admiral's letter to Zach, who published it in vol. v. of his "Correspondance Astronomique," with the places of the sun and moon from Delambre and Burckhardt, and the longitude of Sydney Cove, which he had deduced from Bligh's observations. Employing Burckhardt's Lunar Tables and the last Solar Tables of Carlini the elements of this eclipse will be found to be approximately as follows:—

G.M.T. of conjunction in R.A. 1806, Dec. 9 at 14h. 19m. 14s.

	°	′	″
R.A.	256	19	1
Moon's hourly motion in R.A.		35	3
Sun's ,, ,,		2	45
Moon's declination	23	1	8 S.
Sun's ,,	22	52	2 S.
Moon's hourly motion in decl.		0	5 S.
Sun's ,, ,,		0	14 S.
Moon's horizontal parallax		56	16
Sun's ,, ,,		0	9
Moon's semi-diameter		15	20
Sun's ,, ,,		16	15

The eclipse was therefore an annular one: it was central and annular with the sun on the meridian in longitude 143° 23′ E. and latitude 32° 23′ S. Admiral Bligh's position was not within the annular phase, but on making a direct calculation for it, we find the greatest eclipse at 0h. 41m. p.m. local mean time, magnitude 0·92. Perhaps this is the first eclipse that was astronomically observed at Sydney, and it may be noted in connection with Mr. Russell's historical account of the progress of astronomy at that place, of which we gave some account last week.

THE LATE PROF. KLINKERFUES.—Ernst Friedrich Wilhelm Klinkerfues was born at Hofgeismar in Hesse, on March 29, 1827. He was attached to the Observatory of Göttingen as assistant in 1851, under Gauss; he became provisional director of that establishment in 1859, and in 1868 was confirmed in that appointment. Since 1863 he was one of the professors in the Philosophical Faculty at Göttingen. He was an able practical and theoretical astronomer, and discovered the comets 1853 III., 1854 I., 1854 III., 1854 IV., 1855 II., and 1857 V.; the first of these, which bore his name very generally while under observation, was telescopically observed in full sunshine, and only a few degrees from the sun's place by Mr. Hartnup at Liverpool, and by Schmidt at Athens. In 1860 Klinkerfues proceeded to Cullera in Spain for the observation of the total solar eclipse in July. His work in theoretical astronomy included a method of determining the orbits of the binary stars, and he was the author of a valuable theoretical treatise on the science. When, on the occurrence of the great meteor shower of November 27, 1872, it was found that the meteors followed the track of Biela's comet, and the comet itself was supposed to be close to the earth on that day, Klinkerfues thought it might be found opposite the radiant of the meteors in Andromeda, and accordingly telegraphed to Mr. Pogson at Madras to this effect, "Biela touched earth November 27, search near θ Centauri." It will be remembered that, in consequence of this telegram from Klinkerfues, Mr. Pogson actually detected a comet in the vicinity, but was only able to obtain its place on two mornings; so that the orbit could not be determined. There was a divided opinion at the time as to its connection with Biela, and perhaps this may now be said to be more than doubtful, notwithstanding the singular circumstances attending its discovery. Klinkerfues died suddenly at the Observatory of Göttingen on January 28.

GEOGRAPHICAL NOTES

MR. H. H. JOHNSTON leaves London to-morrow for Zanzibar, to conduct an expedition to Mount Kilimanjaro. The expenses of the expedition are borne by the Royal Society and the British Association, the object being to form as large a collection as possible of the flora and fauna of the highest mountain in Africa.

ANOTHER attempt will be made this year to rescue the United States observing party in Lady Franklin Bay, under Lieut. Greeley. This party, twenty-five in all, went out in August 1881 and in 1882 and 1883 unsuccessful attempts were made to reach them. This year four vessels will be sent out, one of them H.M.S. *Alert*, which we are glad to know has been presented for the purpose of the search to the United States Government. It is to be expected that with such a formidable expedition the Greeley party will be reached, and we fervently hope brought home, though it is to be feared that some at least must have succumbed to the hardships of three winters in 81° N.

THE fourth German Geographical Congress will meet at Munich from April 17 to 19 next. The preparations are now being made. The main subjects for discussion are: the present state of Polar investigation; the innovations relating to the standard meridian; the Glacial epoch; and the mode of drawing large-sized maps for schools. Numerous travellers and investigators have promised to read papers.

DR. WILD of St. Petersburg, the President of the International Polar Commission, is now sending out invitations for the Polar Congress which is to meet at Vienna on April 22 next. All the leaders of the International Polar Expeditions of 1882 are expected to attend.

DR. ZINTGRAFF of Berlin is about to follow Dr. Chavanne to the Congo, by order of the Brussels National Geographical Institute. His special investigations are to be of an ethnological nature.

HERR L. STEINEGER informs *Naturen* that his fortnight's stay in Kamchatka in May, 1883, proved fairly satisfactory. The complete success of the expedition was, however, interfered with by the exceptionally late snowfalls, which had buried the whole district round Petropaulovski under a layer of six to nine feet of snow, the surface of which melted daily under the scorching sun only to be frozen again at night. Among other interesting points he has noted the presence of four distinct species of the sea-eagle in Kamchatka, while Europe and the whole of the North American continent had only one species of this magnificent bird. One of these four, which Herr Steineger has named *Haliæetus hypoleucus*, is distinguished from *H. leucocephalus*, *H. albicilla*, and the giant *Thalassætus pelagicus*, by the dazzling whiteness of some parts of the body and its generally lighter colour. Herr Steineger's collections, which have been sent on to Washington, include the bones of a complete skeleton of the sea-cow, seventeen sea-calves, three skins of the Kamchatkan Alpine sheep, a considerable number of crania of the Cetacea, of which three would appear to belong to new species. Besides these and some 700 skins of birds, with a large number of mammalian crania, he sends back a large and interesting collection of fish, crustaceans, land and freshwater mollusks, and numerous fossil and living plants.

AFTER having done so much in restoring to our maps the old bed of the Amu-daria, the Russian explorers seem to be inclined now to take a quite opposite view. Thus, Prince Hedroits, geologist of the Amu daria Expedition of 1880, after having explored the eastern part of the Uzboy, came to the conclusion that the total want of river-beds in the ravine and the presence of Aral-Caspian mollusks in it are a sufficient proof that the water of the Amu never ran on the stretch between the Sary-kamysh lakes and the Caspian. Now, M. Konshin—a mining engineer who has recently explored the western part of the Uzboy—arrives independently at the same conclusion with regard to the western part of the supposed old bed of the Amu. He considers that its passage between the Greater and the Smaller Balkhan Mountains is a recent strait of the Aral-Caspian Sea, and that the western part of the Uzboy is merely a remnant of the outflow towards the Caspian of the brackish water of the Sara-kamysh lakes. The ravine of the Uzboy would be thus one of the numerous *sors*, or elongated lakes, the likeness of which to beds of rivers had already struck Pallas in the Astrakhan steppes, where the Daban-gol has a length of sixty miles. The view of M. Konshin may be summed up as follows:—The immense Sara-kamysh depression, 4400 miles wide, and at some places 280 feet below the level of the Aral, formed at a geologically recent time a single basin with the Aral; the fossils found on its borders show that it was filled up with at least brackish water. This lake had an outflow into the Caspian; but for 130 miles west of Sara-kamysh there is nothing like a river-bed. The likeness begins only west of Balla-Ishem, where the Uzboy begins. This channel, however, was filled up, not with the sweet and muddy water of the Amu, but with a brackish and rather pure water of the Aral-Sara-kamysh Lake. In fact, in this channel, on its whole stretch from Balla-Ishem to the Caspian, one finds everywhere the typical Aral-Caspian *Cardita*, *Dreyssena*, *Neritina*, and *Hydrobia* in the most perfect state, whilst there are no traces at all of a fluviatile flora or fauna, nor any traces of human settlements. However opposite to current opinion, this view of the Uzboy surely has much to be said in its favour.

THE same geologist publishes in the *Izvestia* of the Russian Geographical Society an interesting account of his explorations in the Kara-kum desert, between Kyzyl-arvat and Khiva. He considers the bad reputation of this desert quite exaggerated. In the neighbourhood of the Caspian and Lake Aral the Kara-kum sands offer a great many difficulties to the traveller. Geologically speaking they have quite recently emerged from the sea, and the *barkhans*, or sandy hills, are devoid of vegetation and move freely before the wind; the same is true with regard to the neighbourhood of Sara-kamysh and the Uzboy. But farther in the steppe the sands are older, and the brushes which cover them render them quite stable, so that the Akhal-Tekkes like better to stay in the steppe, and return to the oasis only for the needs of agriculture. The routes are quite comfortable, with exclusion of steeper ascents and descents on the slopes of the *barkhans*; and the cisterns (*kaks*) when kept in order contain plenty of water; while the steppe yields throughout the year abundance of food for the horses and camels. The *barkhans* are often intermingled with *takyrs*, that is, with places covered with firm clay, on whose surface small canals collect rain-water and bring it to a common basin called *kak*. The *sors*, or elongated ravines, the sandy bottom of which is impregnated with brackish water, are most numerous, especially in certain parts of the steppe; in the neighbourhood of the Akhal-Tekke oasis they run in numerous parallel lines for several dozen miles in length. The Uzboy, which M. Konshin visited at Kurtysh, is a ravine, sometimes crossed by hills of sand, at the bottom of which one perceives a narrow serpentine of brackish water. The Tertiary beds are covered there with a fine dirty dust filled with remains of the Aral-Caspian *Dreyssena*, *Neritina*, and *Cardium*. Above Kurtysh the supposed old bed of the Amu can be distinguished only by these marine remains. Notwithstanding the most careful search, M. Konshin failed to discover any traces of fluviatile deposits at Shikh, where the Charjuy bed of the Amu is traced on our maps. The hills at Shikh are remarkable as a rich mine of very pure sulphur (62 per cent.) One of them would contain at least 160,000,000 cwt. of pure sulphur, and sulphur appears on the surface of very many of them.

DR. REGAL, travelling for the Geographical Society in Central Asia, has returned to Tashkend through Sarafshan and Samarcand, after visiting Hissar, the Mura Pass—never before explored—the town of Karatag, and Baldshan, Duway, Rushan, and Shignan. Dr. Regal intends to start again in a few weeks for Baldshan, and in the spring to continue his explorations as far as the Kashgar frontiers.

COLONEL PREJEVALSKY, with his Cossacks, must be now in Mongolia, on his way towards Thibet. The other well-known explorer of the Turcoman region of the Transcaspian, M. Lessar, is again on his way to the scene of his geographical triumphs along the Persian frontier to complete his work for the General Staff. He will probably be absent another year or a year and a half.

THE Director of the Russian Observatory at Peking, Dr. Fritsche, who made last winter a journey through Southern China, from Peking to Kai-fong-fu on the Huan-Lo, has determined on his route the positions and the magnetic elements of forty-six places. A few days after his return to Peking he left again and went, *viâ* Changhai-kuan, on the Gulf of Pe-che-li, to Tsitsigar Mergen, Aihun, and Blagoveschensk, on the Amur, determining the positions and magnetical elements of sixty three new points.

A CORRESPONDENT in *Naturen* draws attention to a curious narrative of an expedition to high northern latitudes, undertaken in 1266, at the instigation of priests belonging to the Monastery of Garde in Greenland. This narrative is derived from an Icelandic transcript of the so-called "Hauksbok," compiled about 1300 by the Norsk law-expounder, Hauk Erlandsön. It must be observed, however, that the particulars of the Garde Expedition are not to be found in the still extant parts of the original manuscript of the "Hauksbok," from which various pages have been lost. Notwithstanding the absence of this conclusive proof, northern scholars are inclined to accept the later transcript as a *bonâ fide* version of the original before the loss of its missing parts, and if this assumption can be maintained, we have evidence that the Northmen advanced four days' journey north of 76°. The object of the expedition, we are informed, was to discover what lands and people were to be found north of the Christian Station at Garde, and whether the much dreaded Skröllinger or native Esquimaux occupied those unknown regions in any formidable numbers. The seamen, we are told, saw many islands on which there were traces of the presence of these people, but they were unable to land, owing to the number of bears which, together with numerous seals and whales, frequented the coasts. In reference to the high latitude said to have been reached by these early explorers, and which is inferred from the description of the height of the sun on St. James's Day (July 25), it may be observed that a runic stone was found in 1824 in 72° 55′ N. lat., about twenty miles north-west of Upernivik, the northernmost existing Danish station. The inscription, which records that three men, whose names are given, erected the stone as a landmark, concludes with six runic characters, which have been variously interpreted to indicate the years 1135 and 1235.

FROM his scientific expedition to Anatolia, Syria, Egypt, India, Indo-China, China, and Japan during the years 1880-83, Dr. Emil Riebeck has lately returned to Europe laden with ethnological and archæological treasures of all sorts. This splendid collection, on which the enterprising explorer has expended no less than 30,000*l.*, has during the past few months formed a chief attraction to naturalists in Berlin, where it has been on exhibition at the Kunstgewerbe Museum. Here the available space was not sufficient to allow of a thoroughly systematic arrangement of the objects, which however have been roughly disposed in three main geographical groups:—(1) Western Asia and Africa; (2) India and Further India; (3) East Asia (China and Japan). Some idea of the immense variety of articles here brought together may be had from the detailed catalogue of Dr. Riebeck's "Asiatic Collection," recently issued by Messrs. Weidmann of Berlin. From Palestine and Syria we have objects of every description; while the articles from Somaliland, which are very numerous, illustrate almost every phase of the social life of the little known inhabitants of that region. Several specimens are shown of the masks used in Ceylon at the "devil dances" performed during illness. The masks represent divinities of the Hindu mythology, rakshasas or demons, nāgakanyās or snake masks, lions, tigers, crocodiles, negroes, Mussulmans, Malays, &c. India is largely represented. From Burmah, where the Irrawadi was ascended as far as Bhamo, were brought many costly articles, such as royal coronets and dresses, alabaster and gilt wooden statuettes of Buddha, masks of strolling minstrels and players, amber rosaries, richly carved consols, lacquer ware, ornamental drinking vessels, writing materials, &c. A visit to Bangkok yielded models of Siamese floating houses, fishing gear, agricultural and industrial implements, &c. Amongst the most characteristic objects from China are brightly painted clay models of popular types, bronze vases, chased, inlaid in silver, and studded with gems; shallow dishes of "imperial bronze" (yellow picked out in red), silver teapots, artistic articles in jade, rock crystal, and marble, &c. The rich and varied Japanese collection comprises specimens of all the most characteristic productions of the country, especially Satsuma porcelain and other ceramic ware, illustrating the development of Japanese porcelain from the sixteenth to the nineteenth century. During the first part of his journey Dr. Riebeck was accompanied by Dr. Moock, who, after escaping from many perils amongst the Bedouin tribes in the Moabite country, was drowned in crossing the Jordan, and now lies buried in Jericho. During the visit to Egypt he was attended as far as the Nubian frontier by Dr. Schweinfurth, who again accompanied him in March 1881 to the south coast of Arabia and the Island of Socotra. During the rest of his wanderings throughout the Far East Dr. Riebeck had for his associates M. C. B. Rosset, who joined him in Germany, and Dr. Mantei, whom he engaged in Egypt after the untimely death of Dr. Moock.

IN the March part of *Good Words* Mr. Edward Whymper gives some particulars of his journeys in Greenland which have not been heretofore published; and states that he found the height of the interior in the latitude of Umenak (about 70° 30′ N.) considerably exceeded 10,000 feet. Mr. Whymper says that from the various mountains he has ascended on the eastern sid of Davis Straits he has had continuous views of the glacier covered interior of Greenland between about 68° 30′ and 71° 15 N. lat., and that there is no break or depression within those limits, and that the country is everywhere so absolutely covered by snow and glacier that not a single rock or crag can be seen.

ON THE PHENOMENA EXHIBITED BY DUSTY AIR IN THE NEIGHBOURHOOD OF STRONGLY ILLUMINATED BODIES[1]

IN 1870 Dr. Tyndall described the dark or dust-free plane which rises from a hot body in illuminated dusty air, and gave two explanations of the dust-freeness of this dark space. Another explanation was suggested by Dr. Frankland. In 1881 Lord Rayleigh re-examined the phenomenon, and discovered that a cold body gave a similar down-streaming plane. He also suggested a totally different explanation. The writers discuss all these suggested explanations, and see reasons for rejecting them all. They have, moreover, observed that the dark plane rising from a hot body is only a prolongation of a well-defined dust-free *coat* of nearly uniform thickness under ordinary circumstances surrounding the body, and they point out that this dark coat is the thing really requiring explanation, the dark plane being merely due to the up-carrying of portions of this coat by convection currents.

The preliminary experiments were described in a letter to NATURE last July (vol. xxviii. p. 297).

The dark coat is found to increase in thickness with the temperature of the body, becoming very thick at high temperatures, say 1000° C., but being narrow for temperatures only a few degrees above the air. When the temperature of the body is the same as that of the air surrounding it, the dust-free coat is either non-existent or exceedingly thin. The thickening of the coat by a rise of temperature is interfered with by convection-currents, which sweep the outer portions off more rapidly than they can be renewed, and so make the coat thinner than it otherwise would be. By means of a blast of air the coat can be almost wholly or entirely blown away; but convection-currents are never able to sweep it off, for the same cause which increases the convection-currents also broadens and assists the formation of the coat. The coat can be seen on round rods of all materials, on flat plates, both horizontal and vertical, on hollow and irregularly shaped pieces, and in general on every substance whatever. Nevertheless the behaviour of certain bodies is peculiar, and is detailed in the paper; such bodies, for instance, as a stick of phosphorus, which itself gives off smoke, a volatile solid like camphor, moistened solids like soaked carbon, liquids like sulphuric acid water and ether, and thin films of glass or mica. Other substances examined are: copper, iron, zinc, electric-light carbon, charcoal, glass, mica, selenite, selenium, Iceland spar, tourmaline, potash, rock-salt, bismuth, silver, chalk, and all kinds of paper. In every case the method of examination was as follows:—A glass box was mounted in front of the nozzle of an electric lantern, and the body to be examined was supported in any convenient manner, so as to be about the middle of the box, and to be well illuminated. Smoke was introduced, the lamp turned on, and the effect examined by looking along the length of the body at right angles to the light. Sometimes a microscope was used, but it was not necessary except for measurements. A hand lens is useful. For smoke, tobacco was the most common, but ammonic chloride was used when a distinctly volatile smoke was desired, and magnesic oxide whenever a non-volatile and incombustible smoke was wanted. Any kind of smoke serves equally well. Hydrogen and carbonic acid and other gases have been used as well as air: in hydrogen the coat is much thicker, in carbonic acid a little thinner, than in air. The effect of pressure on the dark coat was examined, and it is found that the coat broadens as the pressure diminishes. An increase in pressure of 4½ atmospheres renders the coat very thin and sharp, and at the same time causes the convection-currents to be sluggish.

The writers considered that it would be very instructive to examine whether a dark coat and plane could be observed when a warm body was immersed in a dusty *liquid*; and they accordingly devoted a good deal of attention to this point. After failures with mastic and other substances, they succeeded in observing a very thin, dark coat on the surface of an iron wire immersed in water holding rouge in suspension, with a dark plane rising from it. It is not always easy to obtain the dark coat in liquids, however, and its thickness is enormously less than it is in air. Moreover, the results are less definite and satisfactory. In gases the thickness of the coat may be anything below the eighth of an inch, according to the circumstances of the case, but its commonest width is more comparable with the hundredth of an inch. On a carbon rod in an electric beam the coat is about half a millimetre thick, no other heat being applied. Glass shows a perfect coat and dark plane, but for some reason or other very thin films of glass (·0003 inch thick) behave differently, and it is sometimes by no means easy to see any coat at all. It may be that such thin films are unable to absorb enough radiation, or it may be that the cause is more deeply seated. It can hardly be that they give off their heat too rapidly, because the convection-currents set up by them are very sluggish. It is pretty certain that they fail to absorb radiation; for a plate of rock-salt in a perfectly dry atmosphere behaves in the same way. In ordinary air, a lump of rock-salt is able to absorb sufficient radiation to give a satisfactory dark plane. The behaviour of thin films is under further investigation. Covered with lampblack they act perfectly well. Incidentally it has been noticed that films of freshly-blown glass adhere together though cold, giving the black spot; but that when films are a day or two old they refuse to adhere, doubtless because of the condensed air-sheets with which they have coated themselves. The slow formation of these condensed sheets, as studied recently by Bunsen (*Wied. Ann.* February 1884) is of great interest.

---

[1] Abstract of a paper by *Oliver J. Lodge* and *J. W. Clark*, read at the Physical Society, February 9.

The effect of electrifying rods from which a dark plane is streaming is not marked except when the potential is high; 100 volts or so produce a little effect, positive potential broadening the coat, negative potential narrowing it. As soon as a brush discharge occurs, the effects are violent and the air is rapidly cleared of smoke, the particles being deposited on all the surfaces near. Various electrical phenomena can be conveniently examined by means of smoky air and a strong beam of light. Thus a flake of mica, on being examined for its coat one day, showed a curious phenomenon. The dust aggregated on its surface in little bushes or trees, and its edge became fringed with long aggregations of dust particles. Our first thought was that mica was photo-electric, but we now think that it had been perhaps electrified by casual pressure. This also is still under investigation. Tourmaline shows all its pyro-electric properties exceedingly well by being simply illuminated in dusty air. If mica be written on with a blunt point, a sheet of paper intervening, the writing becomes manifest when it is exposed to dust. We find, however, that a brass plate is capable of acting in a similar way, and we are not prepared to be content with a mere electrical explanation. We are probably here dealing with phenomena allied to those known as *Hauchbilder*, which are supposed to be connected with the condensed air-sheet on the surface of solids; though their explanation may also be associated with vapour-condensing nuclei on solid surfaces. The phenomena connected with the settling of dust on surfaces by gravitation have also been investigated, and it is found that so long as a body is warmer than the air it keeps itself free from dust; except that just at the top, where the air is stagnant, the excess of temperature being only small, a large particle or two may drop on. The dust-free coat is not an absolute barrier to dust: it marks the region into which dust is not carried *by convection-currents*; but other causes may drive dust into this region. Thus it may be blown into it either from outside or through a hole in the rod itself if it be hollow; or the rod may give off smoke, or the dust may, as stated, occasionally drop into the dark region by common gravitation. The persistence of the dust-free plane at a distance from the body which produced it is dependent on the motion of the dust particles *with* the air stream-lines; whatever drives dust across stream-lines interferes with and tends to obliterate detached dust-free regions. All dark streaks in smoky air are commonly the wiped-off coats of bodies.

We have been led to a fairly complete explanation of the whole phenomenon, and though it is impossible to attribute every case of dust-freeness to one single well-defined cause, we see reason to believe that the main causes in ordinary operation are two, viz.:—

1. Molecular bombardment.
2. Gravitative settling.

We were long under the impression that the sheets or films of condensed gases which are known to exist on the surface of all bodies were connected with the dark coats, and had some share in their production; and this view was pressed home by an observation of the surface of warm water in dusty air. The evaporation of the water drives back the dust and keeps a clear space of some thickness above the water; and if the water be linearly heated by a platinum wire stretched just beneath its surface and warmed by a current, the dark coat streams upward in a fine and well-defined dust-free plane. The up-streaming of the portion above the wire causes the remainder to become thinner, until there is an evident equilibrium between the rate at which the evaporation reproduces the dark coat and the rate at which the convection-current carries it off. That the dust is kept off a solid, say a warm copper wire, by an evaporation and continued renewal of its condensed air-sheet, we think decidedly improbable, but we are convinced that the dust particles are driven away from the solid by some form of molecular bombardment, possibly such as goes on from the vanes of a Crookes' radiometer. There is, however, a very great difference between the two phenomena; the Crookesian layer is supposed to correspond with the mean free path, and this is enormously less than the thickness of a dust-free coat. A possible suggestion is that the dust-free coat represents something more like the extreme free path of the molecules, the dust particles being so easily moved that they are driven away by the blows of even a few molecules. A simpler and more satisfactory mode of putting the matter is this. The temperature of the air near a warm solid decreases gradually as we recede from its surface. Consequently a dust particle in the neighbourhood of the solid has warmer air on one side of it than on the other; in other words, it receives heavier and more numerous blows on one side than on the other, and accordingly is driven away from the warm body. Whenever the temperature of air is steadily different in successive layers, there the dust particles must get driven in the direction of decreasing temperature at a rate depending on the temperature slope. This is not complete, however, because the extra temperature really shows itself as a diminution of density, not as an increase of pressure. The explanation is further elaborated in the paper, which will appear in the *Philosophical Magazine* for April. The conduction of heat across the air near a hot body is itself an interesting problem. So also is the distribution of up-streaming velocities. The maximum velocity of convection occurs at some distance from the body, being often distinctly outside the dust-free coat.

Some few cases of the dust-free coat and plane can hardly be explained in the manner now indicated. We point out, however, that gravitation is an effective cause certainly in operation, which of itself is competent to account for the formation of dust-free spaces when circumstances are favourable. Dust is always settling or falling downward relatively to the air in which it is. The velocity of relative fall depends on the size of the particle, on the density and viscosity of the gas, but not on the motion of the gas. Immediately below a solid body round which gentle currents are rising, there is a small region of nearly stagnant air; out of this dust slowly falls, leaving it free, and if then part of it is dragged round the body by the currents, it contributes to the dark coat and to the ascending dark plane. Underneath horizontal plates, also, this gravitation-settling of the dust assists and broadens the coat. But there is also a coat on the upper surface; and this coat gravitation, so far from producing, does its best to spoil. A few of the larger particles are in fact seen to fall occasionally through it on to the surface of the body, their weight being too great for the bombardment to sustain. In the case of a *cold* body the down-streaming currents deposit a good deal of dust on the upper surface of the body, and so that portion of air which has grazed the surface passes on dust-free. The tendency now is for the warmer air outside the dust to bombard it on to the cold surface. This goes on all over the upper half of the body, but over the lower half a coat is visible when the cold is not too great, but it is only fairly thick at the bottom of the body when it forms the base of the inverted dark plane. A smooth vertical surface of ice gives no dark coat, and the maximum velocity of the particles in the descending current is apparently little, if at all, distant from the actual surface. Finally the writers call attention to a paper just read at the Royal Society of Edinburgh by Mr. John Aitken. They have only seen an abstract of this paper at present, but it appears that Mr. Aitken has been travelling over much of the same ground as they have, and that he has arrived on the whole at fairly the same conclusions. The abstract of Mr. Aitken's interesting paper was printed in NATURE of January 31 (p. 322).

AGATES

THE following letter was addressed by the writer in 1871 to Mr. Joseph John Murphy, and though not originally intended for publication, is now published with the writer's consent:—

St. Andrews, November 4, 1871

DEAR SIR,—I have on my return found your note as to agates. Though I have been at work on the subject in different ways for many years, I have not found myself in a position yet to publish. In fact I cannot yet say that I *know* much as to how they have been formed, though I do know, or rather am able to show, that they have not been made in the manner usually supposed.

The late Principal Forbes conceived that they had been formed by concentric deposition round a central nucleus:—this I showed him to be untenable. Others conceive that siliceous matter in a state of fusion has been poured into cavities through an opening, such opening being called the "point of infiltration." I am able to show that this so-called point of infiltration is an orifice of escape or exit of something.

Fully to state how (from examination of their mode of occurrence, experiments upon the decomposibility of trap rocks under the action of carbonated water, section of agates in every conceivable direction, experiments upon their powers of absorbing liquids, and from microscopic examination) I conceive agates to be formed would call for indeed a long statement.

I will attempt briefly to put it thus:—

Igneous rocks are being poured forth from a volcanic vent, in perfectly fluid or at least plastic flow; some are dense, some scoriaceous, some frothing, and so when solidified are vesicular, or perchance even hold in suspension bubbles of included water, this latter holding in solution (red-hot solution) solids afterwards to separate as rheolites. Should the air-bubbles of the vesicular rocks arise through the plastic mass while it is motionless, these bubbles will be more or less rounded or pear-shaped. Should the solidifying rock, however, become crystalline or porphyritic, as generally is the case with amygdaloids, the separating crystals of labradorite, &c., will more or less roughen the sides, and so destroy the smooth and rounded figure of the cavity; while, if the lava-flow continues its motion while the bubbles are still rising, their shape will be more or less flattened or altered:—try bubbles in flowing treacle.

Stage the first.—An empty cavity of any shape.

Stage the second.—The rock, while solidifying, may contain an excess of a magnesian mineral, which is exuded into the cavity; or this excess of magnesian compound (magnesia not being, to any large extent, a *natural* constituent of the mass of a trap) may be held as vapour in the cavity, to be, on cooling, deposited on its sides. This forms in Scotland, Faroe, Iceland, &c., the layer of celadonite or delessite; at Giant's Causeway, of chlorophœite, which, on the extraction of the afterwards filled-up cavity, forms the "skin of the pebble."

Stage the third.—One of two processes, the first very doubtful. The cooling and shrinking rock holds in a state of *liquidity, from heat*, an excess of colloidal silica which is exuded into the cavity forming a chalcedonic druse. But, admitting the process, it must here stop, and a *solid* agate could not thus be formed. This seems to have been the view of Sir George Mackenzie.

The other process I pin my faith to. The thoroughly solidified—indeed the now *old*—rock is having its felspar (labradorite or other) decomposed by water holding carbonic acid in solution. I have proved that this process is rapid and continuous, and agate-holding traps are all rotten; the colloidal silica, with a certain quantity of *tridamyte* is taken up by this water, and transfuses into the cavity; the silica is there solidified—probably the layer of delessite is the coagulation. We have now a cavity slightly lined with chalcedonic matter, containing, within, water more or less pure, while without (that is outside of the now double skin, delessite and first layer) we have a strong solution of colloidal silica constantly supplied. Endosmose and exosmose are set up with all their resistless force. The *strong* solution finds its way through the two or any number of increasing skins: the *weak* water is forced out through the "point of infiltration," and so in its passage out thins all the successively deposited layers *at that place.* By this continuous flow of colloidal silica (held in solution by liquid) through the already coagulated or deposited layers, continuous coagulation of the silica in the yet hollow agate, and continuous extrusion of the residual water, we have the ultimate filling up of the cavity, and a solid agate formed.

The adhesion of agates to the containing rock is slight in most cases from the so-called "skin" being magnesian and soapy.

The "point of infiltration," instead of being at once filled up, as would result from the inflow of coagulable silica, is in reality the last point filled up, being truly the point of escape: indeed it frequently is not altogether filled up, *remaining an open tube.*

The microscope shows on a cross section the concentric layers of coagulated silica, soluble in alkalies; the crystals or fibres of *tridamyte* cross these layers at right angles, radiating like a rheolite from the skin, and it is always along the sides of these crystals that intruding and staining liquids find a way; probably, therefore, along their sides also did the ingress of chalcedonic fluid find entrance. I remain very truly yours,

M. FORSTER HEDDLE

THE ORIGIN OF THE SCENERY OF THE BRITISH ISLANDS[1]

THE Lakes of Britain present us with some of the most interesting problems in our topography. It is obvious that the existence of abundant lakes in the more northern and more rocky parts of the country points to the operation of some cause which, in producing them, acted independently of and even in some measure antagonistically to the present system of superficial erosion. It is likewise evident that as the lakes are everywhere being rapidly filled up by the daily action of wind, vegetation, rain, and streamlets, they must be of geologically recent origin, and that the lake-forming process, whatever it was, must have attained a remarkable maximum of activity at a comparatively recent geological epoch. Hardly any satisfactory trace is to be found of lakes older than the present series; perhaps Lough Neagh, which from its thick deposits and their fossils, has been referred back to Pliocene times, is the solitary exception. How then have our lakes arisen? Several processes have been concerned in their formation. Some have resulted from the solution of rock-salt or of calcareous rocks and a consequent depression of the surface. The "meres" of Cheshire, and many tarns or pools in limestone districts, are examples of this mode of origin. Others are a consequence of the irregular deposit of superficial accumulations. Thus, landslips have occasionally intercepted the drainage and formed lakes. Storm-beaches, thrown up by the waves along the sea-margin, have now and then ponded back the waters of an inland valley or recess. The various glacial deposits—boulder-clays, sands, gravels, and moraines—have been thrown down so confusedly on the surface that vast numbers of hollows have thereby been left which, on the exposure of the land to rain, at once became lakes. This has undoubtedly been the origin of a large proportion of the lakes in the lowlands of the north of England, Scotland, and Ireland, though they are rapidly being converted by natural causes into bogs and meadowland. Underground movements may have originated certain of our lakes, or at least may have fixed the direction in which they have otherwise been produced. A very large number of British lakes lie in basins of hard rock, and have been formed by the erosion and removal of the solid materials that once filled their sites. The only agent known to us by which such erosion could be effected is land-ice. It is a significant fact that our rock-basin lakes occur in districts which can be demonstrated to have been intensely glaciated. The Ice Age was a recent geological episode, and this so far confirms the conclusion already enforced, that the cause which produced the lakes must have been in operation recently, and has now ceased. We must bear in mind, however, that it is probably not necessary to suppose that land-ice excavated our deepest lake-basins out of solid rock. A terrestrial surface of crystalline rock, long exposed to the atmosphere, or covered with vegetation and humus, may be so deeply corroded as, for two or three hundred feet downward, to be converted into mere loose detritus, through which the harder undecomposed veins and ribs still run. Such is the case in Brazil, and such may have been also the case in some glaciated regions before the glaciers settled down upon them. This superficial corrosion, as shown by Pumpelly, may have been very unequal, so that when the decomposed material was removed, numerous hollows would be revealed. The ice may thus have had much of its work already done for it, and would be mainly employed in clearing out the corroded debris, though likewise finally deepening, widening, and smoothing the basins in the solid rock.

---

[1] Abstract of fourth lecture given at the Royal Institution, February 26, by Archibald Geikie, F.R.S., Director-General of the Geological Survey of the United Kingdom. Continued from p. 397.

The Hills and Hill-groups of Britain have all emerged during the gradual denudation of the country, and owe their prominence to the greater durability of their materials as compared with those of the surrounding lower grounds. They thus represent various stages in the general lowering of the surface. In many cases they consist of local masses of hard rock. Such is the structure of the prominent knobs of Pembrokeshire and of Central Scotland, where masses of eruptive rock, formerly deeply buried under superincumbent formations, have been laid bare by denudation. In connection with such eruptive bosses attention should be [illegible] to the "dykes" so plentiful in the north of England and [illegible] over most of Scotland. In numerous instances, the dykes run along the crests of hills and also cross wide and deep valleys.—Had the existing topography existed at the time of their protrusion, the molten basalt would have flowed down the hill-slopes and filled up the valleys. As this never occurs, and as there is good evidence that the dykes are not of higher antiquity than the older Tertiary periods, we may conclude that the present configuration of the country has, on the whole, been developed since older Tertiary time—a deduction in harmony with that already announced from other independent evidence.

Escarpments are the steep edges of hills in retreat. The British Islands abound in admirable examples of all ages from early Palæozoic rocks down to Tertiary deposits, and of every stage, from the almost unbroken line of cliff to scattered groups of islet-like fragments. The retreat of our escarpments can be well studied along the edge of the Jurassic belt from Dorsetshire to the headlands of Yorkshire, likewise in the course of the edge of the Chalk across the island. Not less suggestive are some of the escarpments of more ancient rocks, such as those of the older Palæozoic limestones, the Old Red Sandstone of Wales, the Carboniferous Limestone and Millstone Grit of Yorkshire, and the Coal Measures of the Irish plain. Our volcanic escarpments are likewise full of interest—those of the Lower Old Red Sandstone along both sides of the Tay, of the Carboniferous system in Stirlingshire, Ayrshire, Bute, and Roxburghshire, and of the Tertiary series in Antrim and the Inner Hebrides.

SUN-GLOWS AND VOLCANIC ERUPTIONS IN ICELAND

IN reply to the inquiry despatched to me by NATURE with last mail, whether any remarkable sun-glow had been observed recently in Iceland, and which, I learn, has been observed in nearly all parts of the world, and whether any volcanic eruption had lately taken place in the island to which the same might be attributable, I beg to relate, as regards the first of these points, that on November 23, between 5 and 6 p.m., I noticed for the first time an unusual and striking purple intensity of the sky, a phenomenon which was also observed on the subsequent mornings and nights. I did not attach much importance to this phenomenon at the time, through the circumstance that I was told that sunrises and sunsets were generally attended by very intense auroræ here, and since then I have had so few opportunities of seeing the sky free from clouds that I have not observed any similar phenomenon. I learn, however, on inquiry here, that the same glow was observed once or twice before Christmas by several persons. On one occasion, January 30, the sky was perfectly clear several hours after sunset, but there was no unusual glow.

With regard to the second point, as to recent volcanic eruptions in the island, I have not much new information to transmit (NATURE, vol. xxix. p. 343). The only thing we know as to this is that a man has written a letter to an Iceland paper stating that on October 8 and 9 last year he was at a farm about three geographical miles east-north-east inland from the well-known fishing village Seydisfjord, on the east coast, when he saw, on the first-mentioned day, in the direction of the unexplored gigantic volcanic mountain, the Vatnajökull, about 130 geographical miles in extent, in the south-eastern corner of the island, two columns of fire, and on the following morning, in the same direction, two columns of smoke. He adds that a similar phenomenon was observed on the farm two days previously. It is also reported to us here that ashes have fallen in Seydisfjord.

It is most probable that these eruptions have occurred in the same place where similar phenomena have been observed several times in recent years, viz. in the neighbourhood of the Kverk Mountains on the north side of the Vatnajökull, and that there are, in all probability, several volcanoes in activity in this district, which is utterly unapproachable to explorers.

There is, however, no reason to assume that eruptions of any magnitude have recently taken place in any other part of the island, as such an occurrence would soon have been reported by some means or another to us here.

If, therefore, the remarkable sun-glows of which I read are attributed to terrific volcanic eruptions, the latter must be sought in other localities than Iceland.

SOPHUS TROMHOLT

Reykjavik, Iceland, February 1 (by mail February 8)

COMPOSITE PORTRAITURE ADAPTED TO THE REDUCTION OF METEOROLOGICAL AND OTHER SIMILAR OBSERVATIONS[1]

IT has often been remarked that one of the main, if not the chief, of the difficulties the meteorologist has to contend with, is the enormous amount of preliminary labour which has to be expended in the not very pleasing task of forming the observations he may wish to discuss into tables, casting the columns of figures so obtained, and then computing the means. Should, as in many cases nowadays, his original material be in the shape of curves, *e.g.* barograms, thermograms, or anemograms, he has first to reduce these to figures by tabulation, before he can attempt any step towards their reduction.

The deterrent nature of these preliminary operations not unfrequently forms a complete bar to the entering upon most interesting investigations with a view to the advancement of the science, in the case of persons unable to devote sufficient time to such labour, which may almost be termed drudgery. To cite examples, a glance at the recently published papers in the *Proceedings of the Royal Society*, by Prof. Balfour Stewart (vol. xxv. p. 577) and by Mr. C. Chambers (vol. xxxiv. p. 231), in which they endeavour to trace a possible intimate connection between solar and terrestrial phenomena, will show the immense amount of calculation they had to perform in order to arrive at their results—how, for instance, preliminary means had to be taken of three days' observations and the result assumed to be a corrected value for the middle day of the three, then, after the whole series had been so treated, a second or even a third set of averages computed. The author has also a lively recollection of the excessively tedious calculations required to eliminate in a somewhat similar manner the effect of disturbances in the discussion of the Kew magnetic observations for the late Sir E. Sabine. With the view of arriving at results by a shorter cut, the author has been led to consider the possibility of employing a method suggested by an examination of the highly ingenious system of composite portraiture invented by Mr. Francis Galton, F.R.S., and utilised in his anthropological studies.

Mr. Galton's method of experiment is based upon the fact that certain groups of people possess certain physiognomical features in common. This agreement of feature is usually characterised by the term "family likeness." In order, therefore, to select this particular element from the others, and to obtain a picture in which it is most strongly defined; or, in other words, to form a characteristic portrait of the group of individuals, Mr. Galton employs a series of photographs. These, representing a large number of men or women, are first reduced to the same scale, and then projected successively upon a sensitised photographic plate, having been previously so arranged that the eyes or other salient feature shall always fall on the same portion of the plate.

In this manner a negative is eventually obtained which gives a print depicting a countenance which, although resembling but partially any one of the component portraits, gives a fair typical picture of the group of individuals. Among other results Mr. Galton has detected the likeness existing in various classes of criminals, and also in patients suffering from the same disease, as well as the more marked features transmitted through the different members of a family.

Since in meteorological investigations the desire is to select and to identify the one particular variable running through a group of phenomena, it has appeared to the author, arguing by analogy, feasible to perform this operation by a method somewhat resembling that just described. Supposing, for example, it is desired to determine the true curve of diurnal variation of the wind velocity at any given station. In the case of proceeding by the ordinary routine of hourly sums and means, it will be found that the occurrence of a high wind or gale on a single day will vitiate the results for a considerable period of time.

---

[1] By G. M. Whipple, B.Sc., F.R.Met.Soc., F.R.A.S., Superintendent of the Kew Observatory, Richmond (from the *Quarterly Journal of the Meteorological Society*, vol. ix. No. 48).

If, on the other hand, instead of doing this, a drawing or photograph be made on one sheet of the daily curves for a few weeks, it will be found that the traces for the days free from storms will lie so fairly close together or upon one another, that little difficulty will be found in selecting or drawing through them a curve representing the general run of the group. Several sets of curves having been so treated, the typical curves must be in turn themselves superimposed, and through them another curve drawn, which will be still less affected by abnormal movements; so eventually the true curve of diurnal variation would be arrived at.

In the case of subjecting photographic traces, *e.g.* barograms, thermograms, electrograms, magnetograms, &c., to this treatment, it would be advisable to employ secondary impressions or prints from the original curves, in order that the composite produced might consist of dark lines on a white background; not the reverse, which would be comparatively useless for the purpose.

For the reduction of anemograms, rain, and sunshine curves by this method, it will be necessary to make drawings or tracings first from the curves, giving the hourly values separated, as is done in the diagrams published in the *Quarterly Weather Reports* of the Meteorological Office and in the Kew *Times* curves.

Another application of the method of composite drawing will serve to facilitate the acquisition of a knowledge of the general distribution of weather systems over large tracts of the earth's surface. To do this, a series of weather charts should be taken, and selecting certain prominent features, such as the centres of cyclonic and anticyclonic disturbances, day by day their positions should be marked off upon one chart. This being done in a sufficient number of cases and combined, a repetition of the process would enable a determination to be made of the average distribution of these systems for a given season.

The author illustrated his proposed applications of the method of composite portraiture by three examples, which were exhibited to the meeting of the Society. The data treated in every case were chosen at random, and therefore may be considered as indicating the applicability of the process to meteorological work in general.

In the first example the mean diurnal variation in the wind velocity at the Kew Observatory, Richmond, was determined for three months—August to October, 1879. Taking the hourly values of the rate at which the wind was blowing from the Meteorological Office publications, they were plotted down on a conveniently open scale, a fortnight's superimposed curves being on a sheet. Through the fourteen curves so drawn in pencil a mean curve was traced in red. This roughly represented the average daily variation during the fortnight.

The pair of fourteen-day curves being superimposed on a third sheet, a third trace drawn between them was assumed to be the mean trace for the month, and finally combining the three so derived months' traces, it became easy to draw the final curve showing the mean diurnal variation of wind velocity during the quarter in question.[1]

The second experiment was an attempt to obtain a monthly mean of the barometer directly by the graphic method. Taking advantage of a self-registering aneroid being on trial, its traces were utilised for the month January 8 to February 7, 1883. These were copied off on a sheet of tracing paper, ruled so as to comprise one day's curve only. The tracing paper was then folded vertically, so as to compress the curves, and the mean positions of the traces were drawn on the folds. After four foldings a point was readily fixed upon as the position of the mean of the month, and the value of this point referred to the scale of the instrument. The resulting value for the mean barometric pressure of the month very satisfactorily agreed with the value determined by calculation from the barometer readings taken daily at the Observatory.

The third series of illustrations represented the general positions of the centres and the contours of the areas of maximum and minimum barometric pressure over the Atlantic during January, February, and March, 1881. A number of blank charts were worked off by the chromograph, on tracing paper, to the scale of the international synchronous charts of the U.S. War Department Signal Service. Tracings were made on one sheet in blue pencil of the cyclonic centre for each day of the month, and then on another a similar set of tracings in red of the anticyclonic centres. Having from these drawn the prevailing positions and areas of the systems for the month, it was easy to draw another chart with the general distribution for the quarter. The diagrams were seen, on comparison, to differ materially from those drawn for the monthly means of the observations. In suggesting the composite method of treatment of meteorological data, the author is fully aware that a somewhat similar process has been already applied in the determination of the radiant points of shooting stars, and would also desire to state that the process is not by him considered as equalling or even approximating in accuracy that of employing the harmonic analyser in computing the periodical variations of the elements. As, however, that instrument is not at the command of many investigators, he is of opinion that the labour of reduction may in many cases be saved by making use of the graphic or composite, instead of the purely numerical, method.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Dr. Hans Gadow, Strickland Curator, has been approved as a Teacher of Comparative Anatomy; Mr. L. Humphry, M.B., as a Teacher of Pathology; and Mr. F. H. Neville as a Teacher of Practical Chemistry.

Messrs. J. W. Hicks, R. D. Roberts, and A. S. Lea are appointed Examiners in Natural Science in the Special Examinations for the ordinary B.A. degree.

The Examiners' Report on the Special Examinations in Natural Science states that there was no improvement in the book work, but the practical work was more intelligently done. The few candidates in Geology did well. Botany was ill done. In Zoology the candidates did well.

Mr. J. A. Lyon (Clare College) has been appointed to the new office of Superintendent of the Mechanical Workshops.

SCIENTIFIC SERIALS

Bulletin de l'Académie Royale de Belgique, November 3, 1883. On the anatomy and histology of a new species of derostoma (*D. benedenii*), by M. Francotte.—Report on the work still required to complete the geodesic survey of Belgium, by Capt. Delporte.—Observations on the periodic shooting stars made at Louvain in 1882-83, by M. Terby.—Influence of magnetic disturbances on the scintillation of the stars, by M. Charles Montigny. The paper is accompanied by various comparative tables showing the intensity of scintillation before, during, and after the magnetic disturbances in dry and wet weather.—Summary report on the researches undertaken at the Ostend biological station during the summer of 1883, by Edouard van Beneden. Amongst the remarkable objects fished up near this station were a torpedo of unusual size (*Torpedo marmorata*), a fine specimen of *Labrus maculatus*, an *Amphioxus lanceolatus*, and an unknown species of Scopelidæ, referred by Günther of the British Museum to the Odontostomus, or some allied genus. —On the observation of very rapid movements, especially when occurring periodically, by M. J. Plateau.—Analytical study of the volcanic ashes which fell at Batavia during the eruption of Krakatoa on August 27, 1883, by M. Renard. The author concludes that these ashes are formed by the pulverisation of a fluid igneous mass, whose particles, projected by the expansion of the gases, are subjected to rapid cooling during their passage through the atmosphere. Nothing was detected to indicate the direct action of vapour of water in volcanic disturbances.—On the perfect elasticity of solid bodies chemically defined. New analogy between solids, fluids, and gases, by W. Spring. Here are embodied some of the results of the researches conducted by the author for several years on the action of pressure on solids reduced to a powder. The main object of these researches was to ascertain by experiment whether it be possible by means of pressure permanently to diminish the volume occupied by a given weight of a solid body chemically defined. As a general result, a slight increase of density was obtained under a pressure of 20,000 atmospheres. But, this once realised, most bodies resisted all further permanent diminution of volume. Some even retained their specific weight intact under extreme pressure.—Observations on M. van Beneden's last note respecting the discovery of fossil iguanodons at Bernissart, by E. Dupont. This communication closes the controversy.—Note on the literature of international law before the publication of Grotius's "Jus belli et pacis" (1625), part ii., by Alph. Rivier.—A literary study on the position of words in the Latin sentence, by J. Gantrelle.

---

[1] It must be remarked that a due proportion should be preserved between the scales of the ordinates and abscissæ, for unless this is done the combined traces may appear merely as a mass of confused lines. Such was the case in some experiments made by the author, when he attempted to derive mean curves directly from the zinc templates engraved at the Meteorological Office for the Quarterly Weather Reports, kindly placed at his disposal by Mr. Scott.

Journal of the Russian Chemical and Physical Society, vol. xv. fasc. 8.—On dipropylacrylic acid, by A. Albitsky.—On the action of iodide of allyl and zinc on epichlorhydrine, by M. Lopatkin.—On an accessory product obtained during the preparation of diallyl carbinol, by W. Shestakoff.—On the action of iodide of allyl and of isobutyl on acetone, by A. Shatsky.—On the hydrocarbon C_8H_{14}, by S. Reformatsky.—On the refracting power of $C_{12}H_{20}$, by A. Albitzky.—Attempt of a theory of dissolutions, by W. Alexeyeff.—On $C_{21}H_{20}$ and the products of its oxidation, by W. Hemilian.—Analysis of a phosphorite from Nijni-Novgorod, by N. Lubavin.—On some phenomena of remanant magnetism, by P. Bakhmetieff.—On the changes in the galvanic resistance of selenium under the influence of light, by N. Hesehus. It depends chiefly upon allotropic dissociation of the molecules.—On the characters of the intramolecular force, by M. Bardsky, being a mathematical discussion of its dependence upon temperature.

Bulletin de l'Académie Impériale des Sciences de St. Pétersbourg, vol. xxviii. No. 4.—Demonstration of several propositions relative to the numerical function E(x), second paper, by V. Bouniakovsky.—Contributions towards palæontology, by M. Schmalhausen (with two plates); being a description of fossil plants of the Jura coal-basin of Kuznetsk, in the Altay (*Thyrsopteris prisca* and *Rhiptozamites gœpperti*), from North-West Mongolia, at the sources of the Yenisei, on the high plateau of the Ulu-khem (*Bornia radiata*, *Neuropteris cardiopteroides*, *Lepidodendron veltheimianum*, *Rhiptozamites gœpperti*, *Czekanowskia rigida*, and *Phœnicopsis angustifolia*), and from the Djün-khair-khan Mountains (*Asplenium argutulum* and *spectabile*, and *Czekanowskia rigida*).—On the sympathetic nervous system of the *Petromyzon*, by Ph. Owsiannikow.—On the camphor of the *Ledum palustre*, by M. Rizza.—Analyses of samples of water from thermal sources of Southern Altay (Byelukha-Rakhmanovka), and from a number of lakes and wells in the same region, by Prof. Carl Schmidt. Compared with thirty other thermal waters of Europe, Asia, New Zealand, &c. (the composition of which is given in a table), the Altay water shows a minimum of mineral substance.—Letter on natural history phenomena observed at the Lena Polar station, by Dr. Bunge.

Rendiconti of the Sessions of the Accademia delle Scienze di Bologna, March 14, 1883.—On a remarkable anatomical peculiarity observed in the eye of the swordfish (*Xiphias gladius*, L.) (one illustration), by Prof. G. V. Ciaccio.—Some observations on the *Mucor racemosus*, Fresenius, by Dr. F. Morini.

April 8.—A century of premature artificial births at the Lying-in Hospital of Bologna, by Dr. C. Belluzzi.—Chemical analysis of the meteorite which fell at Alfianello on February 16, 1883.—Researches on the *Phellandrium aquaticum*, by Dr. Leone Pesci.—Thermal and galvanometrical researches on the internal discharges of condensers, by Prof. E. Villari.—New studies on the polygenesis of crystallised minerals, by Prof. L. Bombicci.—Researches on the action of the magnet and of the thermal agents in hysterical hypnosis.—Observation on the series of functions, by Prof. C. Arzelà.—On the infinite products by analytical functions, by Prof. S. Pincherle.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 17.—"On the Electrolysis of Dilute Sulphuric Acid and other Hydrated Salts." By J. H. Gladstone and Alfred Tribe.

On March 1 last a communication was presented to the Royal Society by Prof. Frankland in which, among other things, the reactions the authors had described as taking place in the charging and discharging of secondary batteries were confirmed. Prof. Frankland expressed these reactions, however, by formulæ founded on the electrolysis, not of H_2SO_4, but of hexabasic sulphuric acid, H_6SO_6, in accordance with the views of Bourgoin.

The French chemist employed a divided cell, analysing the liquid in each compartment at the close of the experiment. He calls the increase of the acid in the positive compartment *a*, and concludes that 2*a* represents the amount of sulphuric acid electrolysed. This conclusion rests on the well-known theoretical views of Grotthuss, and, did his theory express all that goes on in the electrolytic processs, the method would readily discriminate between the actions represented by the following formulæ:—

Before electrolysis		After electrolysis Positive pole	 Negative pole
(1.) SO_3H_2O	=	$SO_3 + O$	H_2
(2.) SO_33H_2O	=	$SO_3 + O_3$	H_6
(3.) SO_3nH_2O	=	$SO_3 + O_n$	H_{2n}

But it was pointed out by Reuss, as far back as 1807, that, when electrolytic action occurs across a permeable diaphragm, a portion of the liquid may travel from the positive to the negative compartment of the compound cell by what is now called electrical endosmose. Daniell and Miller in 1844 pointed out that in electrolytic action there was also an unequal transference of the ions. Moreover, Daniell investigated the electrolysis of sulphuric acid of very different strengths by a similar method, and concluded that, for each equivalent of hydrogen liberated, the acid which passed across the diaphragm was not more than one-fourth nor less than one-fifth of an equivalent. Most of his experiments incline to the former. Did 2*a*, therefore, represent the amount of sulphuric acid electrolysed, it would appear from his results that *tetra-*, rather than *hexa-*, basic sulphuric acid was decomposed by the current. These discrepancies, both of observation and deduction, led the authors to make some experiments on the subject.

The apparatus employed consisted of a U-shaped tube of about 70 c.c. capacity, having a stop-cock in the centre of the horizontal part. The vertical parts of the apparatus were divided into millimetres, and the hole in the stop-cock packed with asbestos. The authors found that the closeness of the packing could be so nicely adjusted as to allow very little mechanical admixture of the fluids or electrical endosmose. In their experiments the current density was varied, and, unlike Bourgoin, they found that the increase of sulphuric acid in the positive compartment per equivalent of hydrogen set free decreased along with the decrease in the current density. The results are set out in the annexed table.

Current in milli-amperes	Time in hours	Increase of sulphuric acid in positive compartment for one part of hydrogen set free
32·8	20	9·17
33·4	6	9·5
72·3	2·5	10·3
72·7	2	9·4
106	2	11·0
117	2·5	10·5
215	1·5	12·05
220	1	12·04
229	2	12·31

It is necessary also to bear in mind the remarkable phenomenon called by the Germans "Wanderung der Ionen." Daniell long ago described an experiment in which he placed dilute sulphuric acid in the positive compartment and a solution of sulphate of copper in the negative. He found that when 15·5 grs. of copper had been deposited on the negative electrode there were 23 grs. of sulphuric acid in the same compartment. Now, as 15·5 grs. of copper are equivalent to 24 grs. of sulphuric acid, and as Bourgoin's formula allows for the formation of only half an equivalent of sulphuric acid, that is, 12 grs., it is evident that there was a considerable accumulation of that substance unaccounted for. In two similar experiments the authors obtained for 0·147 and 0·125 grm. of deposited copper 0·209 and 0·180 grm. of free sulphuric acid. The half equivalents would be 0·114 and 0·097 grm. respectively. If both compartments had been filled with sulphuric acid, some similar transference would doubtless have taken place, in addition to what is expressed in Grotthuss' chain of decomposition.

The authors conclude, therefore, that the method employed is incapable of determining whether it is H_2SO_4 or some hydrate which yields to the current.

Copper Sulphate

An examination of the chemical changes which accompany the electrolysis of a solution of copper sulphate appeared, however, capable of throwing additional light on the value of this electrolytic method. It is well known that water forms with $CuSO_4$ a definite hydrate, $CuSO_45H_2O$. Now, if in the electrolytic process the water of hydration suffers decomposition along with the $CuSO_4$, the primary chemical changes might be expected to be—

$$\text{(A.)}\quad CuSO_45H_2O = \overbrace{SO_3 + O_6}^{\text{Positive pole}} \quad \overbrace{Cu + 5H_2}^{\text{Negative pole}}.$$

But, if the water of hydration takes no more part in the electrolysis than the water of solution does, then the chemical changes would manifestly be—

$$\text{(B.)}\quad CuSO_4 = \overset{\text{Positive pole}}{SO_3 + O} \quad \overset{\text{Negative pole}}{Cu.}$$

Of course the collateral action—

$$H_2O = \overset{\text{Positive pole}}{O} \quad \overset{\text{Negative pole}}{H_2}$$

might also take place, but this would occur only with currents of considerable density. The method is obviously capable of discriminating between these two actions, even supposing a considerable quantity of the electrolyte travelled unchanged from one compartment of the apparatus to the other. For, in the first case, either free hydrogen would be liberated at the negative pole, or free acid formed in the negative compartment, equal to five-sixths of the total copper deposited; the free acid, and the five-sixths of the total copper, to which it is equivalent, being produced by the chemical action $5H_2 + 5CuSO_4 = Cu_5 + 5H_2SO_4$; equation A becoming—

$$CuSO_4, 5H_2O + 5CuSO_4 = \overbrace{SO_3 + O_6}^{\text{Positive pole}} \quad \overbrace{Cu_6 + 5H_2SO_4}^{\text{Negative pole}}.$$

On the other hand, if the action was in accordance with B there would be only a deposition of copper on the negative electrode, and no formation of free acid in the negative compartment. In the annexed table the results and particulars of the authors' experiments are set out:—

Experiment	Time in Hours	Free sulphuric acid	
		Pos. Compart.	Neg. Compart.
I.	1½	·0766	nil.
II.	2	·0936	nil.
III.	3	·1868	·0191
IV.	3	·1501	·0204
V.	3	·2442	·0237
VI.	3	·2546	·0372

In none of these experiments was there any trace of hydrogen visibly escaping from the negative electrode, while, as will be seen from the table, there was no free acid formed in the negative compartment till two hours or more had elapsed. By that time some admixture in the horizontal part of the apparatus might reasonably be expected, but even in the greatest instance it is small as compared with the amount of salt decomposed.

Similar experiments were made with the sulphate of zinc, with similar results, no hydrogen being evolved, and little or no sulphuric acid appearing in the negative compartment.

We conclude, therefore, that it is not possible to determine the composition, or even to show the presence of a hydrated salt in aqueous solution by means of this electrolytic method.

Zoological Society, February 5.—Prof. W. H. Flower, F.R.S., president, in the chair.—Mr. F. Day, F.Z.S., exhibited and made remarks on a specimen of a Dog-fish, of which the entire interior had been eaten out by Isopod Crustaceans of the genus Conilera.—Mr. G. F. Butt, F.Z.S., exhibited two specimens of a singular variety of the Red Grouse, shot in Westmoreland.—A communication was read from Mr. W. Leche, of the University of Stockholm, in which he gave an account of a collection of bats from Australia. Two new species were described and named respectively *Nyctinomus petersi* and *N. albidus*.—Mr. Sclater read some notes on the Lesser Koodoo (*Strepsiceros imberbis* of Blyth), with a view of confirming the distinctness of this Antelope from its larger relative, *Strepsiceros kudu*.—A communication was read from Mr. R. Bowdler Sharpe, containing the description of a new species of Bush-Shrike of the genus Laniarius, based on a specimen obtained in Ashantee by Mr. Godfrey Lagden, which he proposed to call *L. lagdeni*, after its discoverer.—Prof. Flower made some remarks on the chief points of interest exhibited by the Burmese Elephant now in the Society's Gardens.

Geological Society, February 6.—J. W. Hulke, F.R.S., president, in the chair.—Edward John Dunn was elected a Fellow, and Dr. Joseph Szabó, of Buda-Pest, a Foreign Member of the Society.—A delta in miniature—twenty-seven years' work, by T. Mellard Reade, F.G.S. The author described a delta deposit, which, during a period of twenty-seven years, had formed in the Rake reservoir (Rivington Waterworks) from materials brought down by a stream of that name. The reservoir at this part was divided by a road, water communication being maintained by a culvert, once eight feet high, now almost silted up. The author described the stratification of these deltas: that near the influx of the Rake consisted of peaty matter, gritty sand, gravel, shingle, and boulders of Millstone-grit up to about one foot diameter; the other chiefly of fine sand with some peaty matter. The former covered an area of 2508 yards, with an average thickness of 2 yards; the latter, an area of 430 yards, with an average thickness of 3 yards. These materials had come from the drainage-area of the Rake. This is estimated as 1·176 square mile, and the delta being estimated at 6306 cubic yards, and the time being 27 years, gives, as the annual rate of denudation over the whole area, 1/432 inch per annum, or 1 foot in 5184 years. The mean rainfall of the Rake Brook watershed for the last ten years was 49·57 inches per annum. In this calculation no account is taken of the finer materials which have doubtless been distributed over the rest of the bed of the reservoir. The author pointed out that this rate of denudation was rather more rapid than that of the Mississippi (1 foot in 6000 years), and that the arrangement of the materials under the varying condition of the stream illustrated the phenomena of larger deltas.—On the nature and relations of the Jurassic deposits which underlie London, by Prof. John W. Judd, F.R.S., Sec.G.S., with an introductory note on a deep boring at Richmond, Surrey, by Collett Homersham, A.M.Inst.C.E., F.G.S. An account of this appeared in NATURE, vol. xxix. p. 329.

SYDNEY

Linnean Society of New South Wales, December 27, 1883.—C. S. Wilkinson, F.G.S., F.L.S., president, in the chair.—The following papers were read:—On the localities of some plants from the southern parts of New South Wales, by Baron von Müller, K.C.M.G., F.R.S., &c.—Descriptions of Australian Microlepidoptera, No. 10, by E. Meyrick, B.A. This is a continuation of the Œccophoridæ of Australia, and deals with the genera *Philobota*, *Leistomorpha*, *Compsotropha*, and *Eriodyta*. About seventy new species are described.—Notes on the geology of the southern portion of the Clarence River basin, by Prof. Stephens. This was an account of the sugar lands of the Clarence, explaining the mode of their formation, and their relation to the Coal-measures which underlie them unconformably. The period of deposition of these latter rocks was also considered, and their immediate superposition upon the vertical Siluro-Devonian slates and quartzites described. The existence of a great north and south fault at the present outcrop of these rocks was demonstrated, and the probable existence of others near the present coast-line supported by various considerations.

PARIS

Academy of Sciences, February 11.—M. Rolland in the chair.—Note on Faraday's law (continued), by M. Ad. Wurtz.—Remarks on the slight horizontal and vertical vibrations of the ground observed at Abbadia, near Hendaye, for several years past, by M. d'Abbadie.—Note on the meteorite which fell at Grossliebenthal, near Odessa, on November 7/19, 1881, by M. Daubrée. In its outward appearance and microscopic structure it presents all the characters of the typical meteorite which fell at Lucé, Sarthe, on September 13, 1768, and which is already represented in the collection of the Natural History Museum, Paris, by fifty-four other identical specimens.—Description of an absolute calculating actinometer invented by M. G. A. Hirn. This delicate instrument is based on the principle of steam condensers, that a saturated vapour contained in a closed vessel acquires a tension corresponding with the minimum temperature of the walls of the receptacle. So far it acts with perfect satisfaction, and the inventor will report the numerical results as soon as he feels that they are absolutely trustworthy.—Report on the thunderstorms observed in France during the first six months of the year 1883, with complete and detailed tables of all the accidents caused by lightning in every part of the country during that period, communicated by the Minister of the Postal and Telegraph Department. The fatalities amounted altogether to nine persons and seventy-eight animals killed and about fifty persons and seven animals injured, by lightning.—Report on the solar spots and faculæ observed at Rome during the year 1883, by M. P. Tacchini. The paper is accompanied by a table of dates, relative size, frequency, and number of the spots.—Observations on the Pons-Brooks comet at the Observatory of Nice, one illustration, by M. Perrotin.—Note on the appearance of the same comet on January 13 and 19, 1884, by M. Perrotin.—On the sudden modifications of form (wings, egrets, &c.), presented by the same comet during its passage through perihelion, by M. G. Rayet.—On the barometric disturbances caused by the Krakatoa eruption, as recorded by the Rédier barometer of the Observatory of Toulouse, by M. Baillaud.—On linear substitutions (mathematical analysis), by M. H. Poincaré.—Generalisation of Jacobi's theorem on the Hamilton equations, by M. J. Farkas.—On curves of the fourth order, by M. C. Le Paige.—On the propagation of light in a crystallised medium, by Madame Sophie Kowalevski.—On the distribution of potential in a liquid mass having the form of an indefinite rectangular prism, by MM. Appell and Chervet.—On Joule's electric law, by M. P. Garbe.—On the electric conductibility of greatly diluted saline solutions, by M. E. Bouty.—Note on several unsuccessful attempts recently made to liquefy hydrogen, by M. K. Olszewski. These experiments are reported in consequence of M. Wroblewski's statement that he has succeeded in liquefying hydrogen by expansion at a temperature of − 186° C. by means of boiling hydrogen.—On a gas-burner yielding a white light by the incandescence of magnesia, by M. Ch. Clamond.—On the law of the thermic constants of substitution (thermo-chemistry), by M. D. Tommasi.—On the formation of the iodide of methyl and of the iodide of methylene by means of iodoform, by M. P. Cazeneuve.—Note on the monobromic methylchloroform $CCl_3 - CH_2Br$, by M. L. Henry.—On the albuminoid substances contained in milk, especially caseine, by M. E. Duclaux.—Fresh observations on the morphology, anatomy, and development of the parasites of the onion and other bulbous plants (*Tylenchus hyacinthi*, *Tylenchus putrefaciens*, &c.), by M. Joannès Chatin.—Remarks on the preparation of farmyard manure, by M. P. P. Dehérain.—On the presence of pegmatite in the diamantiferous sands of South Africa; observations in connection with M. Chaper's recent communication on the subject, by M. Stan. Meunier.—On some freshwater formations during the old and recent Quaternary periods, by M. Ph. Thomas.—On the arched waterspouts of the Indian Ocean (two illustrations), by M. Le Goarant de Tromelin.—Note on the particles of dust found in the snow that fell at Stockholm last December, by M. E. Yung.—Actinometric observations made at Montpellier during the year 1883, by M. A. Crova.

February 18.—M. Rolland in the chair.—Observations of the small planets made with the large meridian at the Observatory of Paris during the third and fourth quarters of the year 1883, communicated by M. Mouchez.—On the reciprocal displacements between fluorhydric and the other acids, by MM. Berthelot and Guntz.—On the law of modules or thermic constants of substitution, by M. Berthelot.—Remarks on a note by M. J. Luvini in connection with the controversies carried on in the eighteenth century on the subject of waterspouts and whirlwinds, by M. Faye.—Determination of the difference of longitude between Paris and the Observatory of Bordeaux, by MM. G. Rayet and Salats. The longitude of t[illegible]meridian of the Bordeaux Observatory, as here rectified, is fixed at 11m. 26·444s. ± 0·008s.—Remarks in connection with the recent researches made on the propagation of the atmospheric currents caused by the eruptions of Krakatoa, by M. Foerster. The author disclaims priority for the observations made by him on this phenomenon, a priority which he awards to General Strachey, whose paper on the subject appeared in a recent number of NATURE (p. 181).—On the divisors of certain polynomes, and on the existence of certain primary numbers, by M. A. Genocchi.—On the composition of such polynomes as admit only of primary divisors of a determined form, by M. Lefébure.—On certain linear substitutions (mathematical analysis), by M. E. Picard.—On an equation of the *m* degree, which has never more than two real roots, by M. D. André.—On a differential equation of the third order, by M. E. Goursat.—On M. Levy's elastic curve, expressing the equilibrium of an elastic circular rod subjected to normal and uniform pressure throughout its whole length, by M. Halphen.—On the adiabatic expansion of the vapour of water, by M. Paul Charpentier.—Researches on the fluorhydrate of fluoride of potassium, and on its states of equilibrium in various solutions, by M. Guntz.—On the nitrous derivatives of hydride of ethylene, by M. A. Villiers.—On the probable number of homologous and isomerous rosanilines, by MM. A. Rosenstiehl and M. Gerber.—On a new compound arising from the preparation of the hexachloride of benzine, having the same centesimal composition as that substance, by M. J. Meunier.—On the constitution of milk, by M. E. Duclaux. The author reduces milk by a new method of analysis to the following elements:—

	In suspension	In solution
Fatty substance	3·32 ...	—
Sugar of milk	— ...	4·98
Caseine	3·31 ...	0·84
Phosphate of lime	0·22 ...	0·14
Soluble salts	— ...	0·39
	6·75	6·35

—On the pigmentary function in the Hirudineæ (common leech, Nephelis, *Aulostoma vorax*, &c.), by M. Rémy Saint-Loup.—On the physiological development of the adult Comatule, by M. Edm. Perrier.—On a placentoid organ in the embryo of birds, by M. Mathias Duval.—Origin and mode of formation of the Belgian Devonian and Carboniferous limestones, by M. E. Dupont. The author explains the formation of the older marine rocks of organic origin by causes still in operation, and from this deduces a fresh proof of the value of the comparative method applied to the study of the past geological history of the globe.—On the variability of the composition and concentration of mineral waters, by M. A. Inostranzeff.

THURSDAY, MARCH 6, 1884

RECENT TEXT-BOOKS ON TECHNOLOGY

1. *Steel and Iron.* By William Henry Greenwood. (London: Cassell and Co., 1884.)
2. *Bleaching, Dyeing, and Calico Printing.* Edited by John Gardner. (London: Churchills, 1884.)
3. *The Art of Soap-Making.* By Alex. Watt. (London: Crosby Lockwood and Co., 1884.)

ALTHOUGH the comprehensive system of technological examinations established under the direction of the City and Guilds of London Institute has been at work only a comparatively short time, it has already called into existence a considerable number of manuals and text-books designed to meet the special requirements of teachers and students in connection with those examinations. No doubt excellent works in certain branches of technology already exist, but many of these are scarcely suited to the purpose of the teacher, and most of them are in price beyond the means of the class which the Institute seeks to benefit. The action of many of our leading publishing houses in thus vying with each other in the production of series of low-priced handbooks of technology to meet a demand primarily created by the policy of the Institute is calculated not only to serve the interests of those preparing for examinations but also to react beneficently upon the general intelligence of our workmen. Numbers of these smaller works find their way into the hands of the better class of our mechanics, foremen, and apprentices, to whom the larger and more elaborate works, even when present in our free libraries, are as sealed books. On the whole, it may be said that the handbooks which have already appeared have been prepared with a rational appreciation of the needs of intelligent practical men. The majority of them are written or compiled by specialists, or by men who are well acquainted with the industries to which their works relate, and their descriptions and statements are made with the authority and discrimination which result from a practical knowledge of the manufactures of which they treat. The first and third of the works before us are excellent illustrations of this fact. In Mr. Greenwood's manual we have not only a comprehensive account of the present condition of our iron and steel manufacture, full of sound, practical information, but a very clear and accurate exposition of the scientific principles upon which the manufacture depends. The information is fully up to date; the illustrations are not mere pictures, but diagrams based upon original drawings, the majority of which have been reduced from scale plans of existing plant, and so arranged as to be readily understood by those who have only a slight experience of mechanical drawings. The chemical portion of the work makes no pretensions to be exhaustive, but it is accurate and sufficiently full. On p. 63, however, we notice that the composition of spiegeleisen is represented by the formula $FeMn_4C$, probably a misprint for $(FeMn)_4C$, although the evidence in support of the existence of any such definite carbide is very weak. A characteristic feature of the work is seen in the prominence given to such Continental processes as may possibly react upon English methods, as for example the Perrot revolving puddling furnace, and the various reheating furnaces of Bicheroux, Casson, and Ponsard. The chapters on steel are remarkably concise and complete. The author meets the well-known difficulty of definition by assuming that any compound of iron and carbon which is delivered from a vessel in a state of fusion and at once cast into malleable ingots may be considered as steel. This definition is perhaps not very rational or precise; it seeks to exclude cast iron on the ground of its immalleability, and wrought iron from the circumstance that in practice it is never obtained wholly fused; however, it is at least more accurate than that based upon the quality of hardening and tempering, which the so-called mild steels do not possess to any sensible extent.

The volume on "Bleaching, Dyeing, and Calico Printing" is a production of a very different character. It has not the slightest claim to originality, but is mainly a compilation, of some 200 pages, from the standard works of Crookes, Stenhouse, and Groves and Ure, and consists very largely of receipts and formulæ. The chapter on bleaching is fairly well done, especially the portion relating to linen bleaching; and the section on mordants is good so far as it goes. What there is of chemistry in the book is generally accurate, but the author would in nowise have diminished the air of practicality about his work if he had removed or replaced some of the barbarisms in chemical nomenclature affected by dyers. It is quite possible to be precise without being pedantic. The book is poorly illustrated and somewhat loosely put together.

Mr. Watt's book on "Soap-Making" is a thoroughly practical treatise on an art which has almost no literature in our language. The author is the son of the late Mr. Chas. Watt, the inventor of the well-known process of bleaching palm-oil for soap-makers, and he has been connected with that industry for many years. Soap seems to have been made in England only since the middle of the seventeenth century, but the manufacture made very little progress until the invention of the Leblanc process for converting common salt into carbonate of soda. The art received its second great impetus from the labours of the venerable Chevreul in the early part of this century, who, with Liebig, elucidated the theoretical principles upon which the manufacture depends. Mr. Watt's book shows what influence these researches have had upon the development of the art, not only directly, but as demonstrating to the soap manufacturer the importance of a knowledge of chemistry in its applications to his processes. The general theory of saponification is first explained, and is followed by a chapter on the arrangement of a soap factory and a description of the materials used in soap-making. The various methods of making hard soaps and cheapened soaps are then fully described, both by the old processes and by those of Hawes and Bennett and Gibbs, Rogers, and Berghart. The processes for manufacturing potash soaps and soaps for printed goods and silks are next explained, and there are special chapters on toilet and medicated soaps, alkalimetry and the methods of soap-analysis, and on the recovery of glycerine from spent lyes. We congratulate Mr. Watt on the success of his endeavour to fill a void in English technical literature.

T. E. THORPE

MARINE ENGINEERING

Die Schiffsmaschine: ihre Construction, Wirkungsweise und Bedienung. Bearbeitet von Carl Busley, &c. (Kiel, 1883.)

THIS is designed to be a manual and book of reference on marine engineering, for the use of engineers, naval officers, students, and others interested in steamships. The author is a marine engineer in the Imperial German service, and a professor at the Naval Academy of Kiel. He has laid down a most comprehensive scheme for the work, and the first and second divisions already published contain good evidence that the book when completed will become the standard German work on the subject.

Marine engineering has made great strides in recent years, and is now much more largely regulated by scientific methods than it was formerly. The earlier textbooks have become obsolete to a great extent, and a demand has arisen for new works in which modern principles and practice should be represented. In response to this demand two or three excellent books have recently been published in this country; and Mr. Busley has determined to do a similar service for Germany. It is but right to say that his book will bear very favourable comparison with any book of the class yet published, and it surpasses all of them in the fulness and beauty of the illustrations, which are contained in separate atlases and printed in colours, on a scale which makes many of them virtually working drawings.

Theoretical investigation and practical information on the details of the construction and management of marine engines and boilers both find a place in this book. Its arrangement is admirable. First, there is a clear and succinct description of the principles of the mechanical theory of heat, followed by a discussion of the properties of steam. Next comes a chapter on combustion, including a summary of the conditions essential to good boilers, and a statement of the steam-producing powers of various kinds of coal. If there is not much novelty in this section of the book, it is full of useful information. In the fourth chapter there is a long discussion of the various matters affecting the performance and economy of marine engines; details as to coal-consumption in various types of engines, with methods for estimating the expenditure of steam and coal in ships of new design; definitions of horse-power, nominal, effective, and indicated; together with remarks on various systems of condensing steam, &c.

Following these introductory chapters, three others are devoted to marine boilers, their construction and management, including the best means of preserving them. These chapters are chiefly of a practical character, and will repay careful study, as they contain a most valuable summary of information and good rules for guidance. The eighth chapter is also of a practical nature, containing detailed examples of the auxiliary engines used for a vast variety of purposes in steamships. Amongst these may be mentioned the turret-turning and air-compressing engines of modern war-ships; steam-steering engines of various types; engines employed for heaving-up anchors and cables; others used in the production of the electric lights now generally carried by war-ships or large passenger steamers; pumping engines; steam-winches; ventilating machinery; appliances for condensing fresh water, &c. All of these and many others are described and illustrated in a manner which makes this portion of the book most valuable for reference. No similar summary of information on these important, if subordinate, portions in the equipment of a steamship has been previously published; and Mr. Busley deserves great credit for his perception of the necessity for and value of the information herein collected.

The ninth, tenth, and eleventh chapters relate to the construction and theory of the various types of marine engines which are or have been in use. Full descriptions and drawings are given of different systems—including some which are, as yet, only in the experimental stage; screw-steamers, paddle-steamers, and vessels driven by water-jets all come under review; and very valuable tables are given of the dimensions and particulars of the machinery in a large number of German, English, and French ships. Mr. Busley throughout displays a cosmopolitan spirit in his massing of facts, and this makes his book all the more valuable. The theoretical investigations include rules for estimating the engine-power required to attain the assigned speed of a ship; examples of the analysis of indicator diagrams for simple and compound engines; graphic processes for dealing with the slide-valves; and detailed investigations or descriptions of slide-valve gear, steering gear, &c.

This completes the contents of the first half of this book; the other half has yet to be published, we believe. If it maintains the high character of the part already given to the world, the book will be certain to achieve success. It has been produced in excellent style, both as regards letterpress and illustrations. Its chief value consists no doubt in the large amount of information respecting modern practice which has been brought together; but the treatment of the scientific branches of the subject will assist to secure its favourable reception by the classes of readers for whom it is especially designed.

OUR BOOK SHELF

Guide to the Calcutta Zoological Gardens. By John Anderson, M.D., F.R.S., Honorary Secretary and Treasurer. (Printed by order of the Honorary Committee of Management, Calcutta, 1883.)

ALTHOUGH the meritorious idea of starting a zoological garden at Calcutta was put forward by the well-known naturalist MacClelland as long ago as 1842, and several attempts were subsequently made to carry out the plan, it was not until 1875, chiefly, we believe, owing to the exertions of the late Mr. Schwendler, the telegraph engineer, that an appropriate site was obtained, and the present gardens were founded. After eight years of development the Zoological Gardens of Calcutta, under the energetic rule of the present Honorary Director, have attained a degree of arrangement sufficiently stable to allow of a "Guide" being prepared. Dr. Anderson's able pen has accordingly been employed in describing the institution which he has so well organised.

For a "Guide" Dr. Anderson's volume is perhaps rather bulky, and the type employed unnecessarily large. It is also, we may add, in our opinion a little too learned for a popular handbook. But the information contained in it, compiled as it is by one of the leading zoologists of India, may be generally depended upon, and so much can scarcely be said for some similar publications. At the same time we may remind Dr. Anderson that the statement that the sternum in *all* Picarian birds has a "double notch behind" (p. 94) is not quite correct, and that he has overrated the number of African rhinoceroses.

Judging from the "Guide," the series of animals now exhibited in the Zoological Gardens of Calcutta must be considerable, although no actual statistics are furnished to us on the subject. Several animals of special rarity are mentioned as in the collection, such as a specimen of Grant's Gazelle (*Gazelle granti*) from East Africa, and the *second* known example of the Hairy-eared Rhinoceros of Chittagong. It is also of great importance to learn that the phenomenon of incubation of one of the large Pythons has been witnessed in Calcutta as well as in European Gardens. On the whole, the naturalist will find many things to interest him throughout the present volume, though, as already said, some of the disquisitions are not perhaps quite suitable to a popular work.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Earthquakes and Air-Waves

IN the *Comptes Rendus* of the French Academy of Sciences for February 18, 1884, there appears a communication from Prof. Förster of Berlin relative to a statement previously made in the *Comptes Rendus*, to the effect that it was from observations taken at Berlin that he had arrived at certain conclusions as to the propagation of the atmospheric disturbance caused by the last great explosion in the eruption of Krakatoa in August last.

Prof. Förster explains that the statement referred to was a mistake, and that he had in fact only reproduced, after verifying them by reference to the Berlin observations, the conclusions come to by me, as explained in a paper read before the Royal Society on December 17, 1883, the principal part of which was published in NATURE of December 20 last (p. 181).

He adds that in his original note on the subject he had not mentioned my name as the author of the conclusions referred to, in consequence of the manner in which I had spoken of them myself.

Prof. Förster, while putting himself right on this point, has interpreted my own intention with great sagacity. For the light I may have been able to throw on the facts was in truth consequent on information put before me by the intelligent officers of our Meteorological Office, aided by a suggestion from Prof. Stokes, who like myself is a member of the Meteorological Council.

Such credit, however, as is due for bringing to notice the curious phenomenon in question may be fairly claimed for our Meteorological Office, as there is little reason to doubt that it would have remained unnoticed had it not been for the comparison of the several records of the continuously self-registering instruments which the organisation provided from the public grant we receive has placed at our command, and which no individual effort could have supplied.

February 26 RICHARD STRACHEY

IN the Jamaica Weather Report, No. 35, for November last year, I was unable to explain how it was that the Krakatoa air-wave had affected our barometer so strongly: the explanation is that Jamaica is very near the antipodes of Krakatoa (NATURE, vol. xxix. p. 181).

The general effect of the disturbance at Jamaica was to produce a barometric depression, preceded and followed by small barometric elevations, according to the following table, which gives for local time the pressure of the atmosphere at the sea-level, expressed in inches of mercury at 32°, and corrected for diurnal variation:—

Kingston, Jamaica, 1883

	in.
August 26, 3 p.m.	29·972
26, 11 p.m.	·975
27, 7 a.m.	·982
27, 3 p.m.	·944
27, 11 p.m.	·983
28, 7 a.m.	·994
28, 3 p.m.	29·975

Now the impulse at Krakatoa occurred at 9.24 a.m. local time, and it reached Jamaica about 3 p.m. local time, or eighteen hours afterwards; consequently the average velocity of the wave was about 690 miles an hour—which is wholly in accordance with the velocity deduced by General Strachey from places in Europe and elsewhere.

But there was no great explosion at Krakatoa at 9.24 a.m., and it seems possible that this great air-wave was similar to the air-waves we always experience in Jamaica whenever there is a shock in Kingston sufficiently strong to be distinctly felt.

In August 1881 I published a Report on Earthquakes in Jamaica, No. 4, in order to call attention to the following facts:—

1. The atmospheric pressure oscillates for some hours before and after a shock, the lowest depression generally occurring at the time of the shock.
2. The wind generally lulls, so that "the weather" is hot and oppressive.
3. Clouds (stratus) gather over the sky after the shock.
4. The temperature of the air, if we allow for the cooling effect of (3), remains unchanged.
5. The rainfall is unaffected.

These facts have been fully confirmed by subsequent shocks. As an example let us consider the last shock which occurred on January 14 this year, and which was felt over nearly the whole of the island.

At Kingston it was felt as a sharp double-shock at 1.15 p.m.; the first shock lasted about three seconds, then there was an interval of about two seconds, which was followed by the second shock, lasting about five seconds. There was a strong sea-breeze blowing during the day, but a temporary lull occurred just before the earthquake.

The following table gives the pressure of the atmosphere at the sea-level, expressed in inches of mercury at 32°, and corrected for diurnal variation:—

Kingston, January 14, 1884

	in.
24 hours before the shock	30·061
16 " "	·047
8 " "	·043
At the time of the shock	·016
8 hours after	·024
16 "	·063
24 "	30·056

On January 13 the average amount of cloud was 7 per cent. of the whole sky, on the 14th it was 10, and on the 15th it was 43!

Further particulars will be found in the Jamaica Weather Report, No. 37, for January 1884, and it will here be sufficient to remark that the depression at the time of the shock was quite as strongly marked at the cinchona plantation, thirteen miles from Kingston, but 4850 feet above the sea-level.

It is needless to say that I am at a loss to account for the connection which most undoubtedly exists in Jamaica between earthquakes and air-waves; but it is evident that the latter may be connected with the former without any, the slightest, approach to volcanic explosion; and the Krakatoa air-wave was probably similar in all respects, except magnitude, to the waves we continually experience in Jamaica at the time of earthquake shocks.

Jamaica, February 7 MAXWELL HALL

The Remarkable Sunsets

AT 8.45 a.m. to-day the sun seen from here through a light mist was of a slightly metallic and very pale sea-green colour. The mist was not dense enough to render objects at a distance of twelve yards indistinct, but beyond that distance they rapidly became invisible. There was no wind, and the mist seemed free from smoke. I could form no opinion as to its height. Half an hour later, in Manchester, the sun glowed with the ordinary coppery-red hue it assumes when seen through a thin fog.

Moor End, Kersal, near Manchester, February 26

Instinct

I DO not think that the difference between Mr. Lloyd Morgan and myself on the point to which he returns in his last letter is so great as it at first appeared. For he now admits that "the actions of animals testify to some corresponding mental states," and therefore that from such actions we are entitled to infer something as to these states. His objection to comparative psychology as a science is thus reduced to the observation that our inference from bodily actions to mental states cannot be so clear or certain in the case of animals as in the case of men, where intentional sign-making, or language, comes to our assistance. Now this is precisely what I argued in my own communication to NATURE (p. 379), and also in my books. Therefore I do not consider that this is "an ingeniously constructed argument of scepticism"; I applied that phrase to the argument which denies the possibility of all or any ejective knowledge, both of men and animals.

Thus the only point of dispute between us is whether such conceptions as we can form of the mental life of animals are sufficient to constitute this mental life the subject-matter of a science—*i.e.* whether this mental life admits of investigation. And, so far as I am aware, Mr. Morgan is the only individual who has ever said that such is not the case.

GEORGE J. ROMANES

THERE is a remarkable instance of instinct displayed by the common magpie which I have not seen noticed in NATURE or anywhere else, although it has long attracted my attention and is well known to farmers in the west of Scotland. This bird may be seen each year, on the first Sunday of March (old style), very busily employed carrying small twigs of branches to renew its old nest or form a new one for the approaching breeding season. This particular day appears to be appointed for taking formal possession of the premises, as no more work whatever is done for some weeks after. The instinct which enables a bird to take the sun's altitude on a particular day in March is certainly a very rare gift, but any person who wishes to satisfy himself of its truth, and who lives in a locality where these birds breed, has only to rise early on Sunday, March 16, this year, to see them at work for himself. It would be interesting to know within what degrees of latitude this particular day is observed by these birds.

WM. BROWN

"Mental Evolution in Animals"

I AM as unwilling as Mr. Romanes to continue this discussion needlessly, but inaccuracy calls for correction. Mr. Romanes says that "the glass wall of a tank is not an object upon the solidity of which a skate would be likely to calculate." If he will read my original account of the incident again, he will find that the skate made himself absolutely sure of the solidity of the glass wall of the tank; he tried hard to seize the food, and failed because he could not get his head through the glass, and therefore his mouth could not touch the food. As for his being unable to see the food when the current lifted it, that is precisely my case. But he saw it clearly enough, and had tangible experience of the conditions, before he adopted the successful device. If the matter is worth noticing, it may as well be described correctly.

F. J. FARADAY

Manchester, February 29

I WILLINGLY apologise for making the remark about the glass wall without having first consulted Mr. Faraday's original account; but as, in "noticing" the matter in "Animal Intelligence," I quoted that account *verbatim*, I cannot allow that on the only occasion when I "described" the circumstances, I failed to do so "correctly."

G. J. ROMANES

Natural Snowballs

IT is nearly a year since I inclosed to you an account of the natural snowballs or snow-rollers which were to be seen in great numbers for many square miles in this vicinity on February 21, 1883. A friend has called my attention to a brief newspaper report of a recurrence of the same remarkable phenomenon on a larger scale in Oneida and Herkimer counties, in the State of New York. The rollers were formed by the wind on the night of Tuesday, January 22, and are said to have been "innumerable," hundreds being seen on an acre of ground. The measurements of the largest are the same as those which I made of the largest that I saw last year, 18 inches in length and 12 in diameter. But, whereas all of last year's were extremely delicate, so as to yield to the touch, it is reported that some of those seen in January were "solid and so firm that they could be handled quite roughly without breaking." I send these memoranda to you, thinking that you may deem them worthy of preservation in the columns of your journal.

SAMUEL HART

Common Domestic Duck Diving for Food

WHEN at Buxton last August I spent a good deal of my time in watching and occasionally feeding the water-fowl in the ponds of the garden. On week-days the ducks received large contributions from the visitors, but on Sundays they apparently were on rather short commons, judging by their greater activity in searching for food, and constantly standing *on their heads* in the water so as to search the bottom for aquatic plants. Of course every scrap of plant to the depth of ten or fifteen inches (eighteen inches where the geese were) was cleared away.

I was surprised one Sunday to see a common domestic duck (female) diving in three or four feet of water, and searching along the bottom, as if she had been "to the manner born," for plants, which, when she found, were brought to the surface; some fifteen or twenty other ducks watched her proceedings with great interest, and made an immediate rush at her when she came up to share in the food, exactly as the widgeon pounce upon the canvas-back ducks at the mouth of the Delaware River and other favourite winter feeding-places of these delicious birds, which, notwithstanding their difficulties with their thievish tormentors, must manage to pick up a fairly good living, as when killed they are usually in fine condition.

I saw only one duck (a mallard) at Buxton make any attempt to imitate the clever diver, but his efforts were always ignominious failures. Had I been living in Buxton I should have endeavoured to get some eggs of this diving duck and had them hatched, with the object of finding out if the progeny inherited the peculiarity of the mother.

Circular Rainbow seen from a Hill-top

IN the evening of the first Sunday in last September, when, it will be remembered, there was a very severe storm, I was walking alone up the south side of the top of the Belchen, in the Black Forest; the sun was setting in the west over the Rhine, and for some time my shadow was thrown on the mist filling up the valley to the east of the Belchen, and around it was a most distinct rainbow, with all the usual colours. It was so striking that it at once suggested the halo one sees in religious pictures, except that it was round the whole figure, and not confined to the head. I thought this anecdote might interest those gentlemen who have already written to you about this beautiful phenomenon, and especially Mr. Maynard, who I see writes from the Black Forest.

W. HALE WHITE

4, St. Thomas's Street, S.E., March 1

Girton College

IN reference to a paragraph in NATURE (vol. xxix. p. 388) respecting the representation of the students of the College Hall of Residence, Byng Place, on their governing body, allow me to state that the students of Girton College have been represented on the College Committee for some seven years past. The representatives of the students are three in number, one retiring annually; they are elected by those students who hold the college certificate, and have been chosen, so far, from among themselves. As the certificated students keep up a more or less close connection with the College, and their representatives pay regular visits of inspection, the views of past and present students can be formally laid before the College Committee. This privilege is much appreciated by the students. If you have received no other letter to this effect, may I ask you to insert the above information?

ANTHROPOLOGICAL NOTES IN THE SOLOMON ISLANDS

IN my last paper on the physical characters of the natives of St. Christoval and the neighbouring islands (NATURE, vol. xxvii. p. 607) I drew attention to the variation which was presented towards the opposite extremity of the Solomon group by the Treasury Islanders, of whom I considered the natives of the large adjacent island of Bougainville would prove to be a more pronounced type. My observations during 1883, which were confined, however, to the islands of the Bougainville Straits, and did not extend to the large island of that name, have confirmed the existence of this variation in the type of the natives at the western end of the group.

Proceeding at once to the comparison of the inhabitants of these two regions, I find that the most important distinction lies in the form of the skull. The cephalic indices obtained from forty head-measurements amongst the men of the islands of Bougainville Straits (Treasury Island, Shortland Islands, Faro Island) ranged between 76 and 85; three-fourths were included between 79 and 83 (inclusive); and the mean was 80·6. Of the same number of measurements amongst the men of St. Christoval, half produced cephalic indices between 75 and 78 (inclusive); the range was 69 to 83; and the mean 76·7. In the first region therefore brachycephaly may be said to prevail; in the latter, mesocephaly. But in addition to being more brachycephalous, the men of Bougainville Straits belong to a noticeably taller and more robust race, their average height being 5 feet 4½ inches to 5 feet 5 inches, as contrasted with 5 feet 3 inches to 5 feet 4 inches in the case of the St. Christoval natives. I should also add that the hue of the skin is of a darker shade, corresponding to numbers 35 and 42 of the colour-types of M. Broca. The character of the hair resembles that of the natives of the eastern islands of the group in being frizzly and bushy; but there is introduced among the populations of these islands in the Bougainville Straits an almost straight-haired element, to which further reference will be made.

The inhabitants of the islands just alluded to are also distinguished from those of St. Christoval and the eastern islands of the group in many of their arts and usages, to some of which I can here only just refer. Cannibalism is rarely if ever practised among the natives of Bougainville Straits: it is, however, frequent amongst those of St. Christoval. Polygamy is more prevalent in the former region, where Gorai, the powerful chief of the Shortlands, possesses between eighty and one hundred wives, and Mulé, the chief of Treasury Island, owns between twenty-five and thirty. The patriarchal and despotic rule of these chiefs must be contrasted with the little authority which belongs to the majority of the chiefs in the eastern islands. The women of Bougainville Straits manufacture a kind of unglazed pottery, employing for this purpose a wooden trowel, a large smooth pebble 3 to 4 inches across, and a ring-cushion of palm leaf; a rudely-shaped saucer is first made from a lump of the clay; and upon this the vessel is built up, strip by strip. A large number of the houses in the principal villages of Faro—an island in the middle of the Straits—are built upon piles. I should here refer to the greater prevalence amongst the natives of the islands in Bougainville Straits of the cutaneous disease—an aggravated form of "body-ringworm"—to which I alluded in my description of the St. Christoval natives: four-fifths of the inhabitants of Treasury Island are thus affected; and half of the chief's wives are covered with this disease from head to foot.

From frequent observation of the different modes of wearing the hair which prevail among the Solomon Islanders, I am of the opinion that their variety is to be attributed more to individual fancy than to any difference in the character of the hair. According to his taste, a man may prefer to wear his hair close and uncombed, when the short matted curls with small spiral give a woolly appearance like that of the hair of the African negro Should he allow his hair to grow, making but little use of his comb, the hair will hang in ringlets 3 to 8 inches long—a mode more frequent amongst the natives of the eastern islands of the group, and best described as the "mop-headed" style. More often from a moderate amount of combing, the locks are loosely entangled and the hair-mass assumes a somewhat bushy appearance, the arrangement into locks being still discerned and the surface of the hair presenting a tufted aspect. The majority of natives, however, produce by constant combing a bushy periwig in which all the hairs are entangled independently into a loose frizzly mass, the separate locks being no longer discernible. These four styles of wearing the hair—the woolly, the mop-like, the partially bushy, the completely bushy—prevail with both sexes, the fashion varying in different islands of the group. I am inclined to view the mop-headed style as the natural mode of growth, it being the one which the hair would assume if allowed to grow uncombed and uncut. The Solomon Islander unfortunately makes such a constant use of the comb that one rarely sees his hair as nature intended it to grow. When, however, a man with bushy hair has been diving for some time, the hairs, disentangling themselves to a great extent, gather together into long narrow ringlets—nature's *coiffure* of the Solomon Island native.

Amongst the natives of Bougainville Straits the hair is coarser and of a darker hue, corresponding to numbers 34 and 49 of the colour-types of M. Broca; whilst the lighter hue of the hair of the St. Christoval natives more accords with numbers 35 and 42. The diameter of the spiral when measurable varied between 5 and 10 mms.—its usual range throughout the group; but on account of the practice of combing it was often difficult to measure it with any accuracy. Here I may allude to the almost straight-haired element which has been infused among the inhabitants of Bougainville Straits. The individuals thus characterised have very dark skins, which for want of comparison might be termed black; the hue, however, nearly agrees with colour-type 42 of M. Broca; the hair, which is even darker, corresponding with types 34 and 49, is almost straight, often erect, and giving the person a shock-headed appearance; whilst it may in some instances tend to gather into curls of a large spiral. I was unable to detect any constant change in physical characters accompanying this variety in the growth of hair. The general colour of the iris amongst the natives of Treasury Island may be described as a deep muddy-violet, approaching nearest to number 11 of the colour-types of M. Broca.

The relation between the lengths of the upper and lower limbs in over thirty individuals was fairly constant, the mean intermembral index being 68. A steady index, giving a mean of 33·4, indicated the proportion of the length of the upper limb to the height of the body; but the corresponding index which my measurements gave for the lower limb was somewhat variable, and the mean 49·2 is therefore not so reliable. H. B. GUPPY

H.M.S. *Lark*, Auckland, N.Z., January 2

ON THE CLASSIFICATION OF THE ASCIDIÆ COMPOSITÆ

COMPOUND ASCIDIANS should undoubtedly be studied in the fresh condition. This becomes evident to any one who, after having admired the graceful forms, gorgeous colouring and transparency of tissue exhibited by the living animals on our western and southern coasts, or in such a favoured spot as the Chausey Archipelago, seeks in vain for these or any other beauties in the leathery repulsive-looking masses usually exhibited in a collection of Tunicata.[1] And it becomes painfully impressed upon one when working through a large collection which has been in alcohol for about ten years. Laborious dissection and the preparation of large numbers of sections are necessary to reveal characteristics which may often be seen in the living specimen by observation merely. And, what is of more consequence, there is a risk of being led into errors and misinterpretations by the abnormal contraction and distortions caused by the alcohol.

---

[1] There are exceptions: some few species retain both form and colour airly well when preserved.

Such plates as those of Prof. Giard,[1] and of Dr. R. von Drasche's beautifully illustrated monograph on the Synascidiæ of the Bay of Rovigno,[2] which has just appeared, show how much can be made out from a natural representation of the living animal, and leave little or nothing to be desired so long as we must be content with some substitute for the actual specimen. In this important work von Drasche criticises Giard's classification of the Synascidiæ, and explains fully a scheme of his own which appeared in the *Zoologischer Anzeiger* for 1882. Many attempts have been made to classify naturally this difficult group, and this latest effort, although it has corrected some previous errors, appears still to be susceptible of improvement, especially as regards the interesting forms which occupy the borderland between simple and compound Ascidians. Some of these (the Clavelinidæ) are placed by Giard and von Drasche in the Synascidiæ, while in 1880 I tried to show that their proper position was amongst the Ascidiæ Simplices, and close to the genus *Ciona*. At the present moment I confess that I am unable to find a single satisfactory character by which to distinguish these two large groups, the simple and compound Ascidians.

Savigny, in 1815, in his "Observations sur les Alcyons gélatineux à six tentacles simples,"[3] first rescued the compound Ascidians from the Alcyonaria with which they had previously been associated, and demonstrated their affinity with the other Tunicata.[4] In the "Tableau Systématique" Savigny gives no formal statement of the characters distinguishing the two groups, but it is evident from some passages in his "3e Mémoire" that he relied chiefly, if not entirely, for their separation upon the arrangement of the Ascidiozooids of the compound forms around a central cloaca—a character which he declared was visible even in the young embryo. In this latter point he was mistaken, and it seems rather singular that he should have laid such stress upon the union of the atrial apertures when we find that he describes and figures their separate and independent existence in *Diazona* and *Distoma*, two of the genera of his "Téthyes Composées." *Clavelina* in his system is placed next to the "Phallusiæ Cionæ" (= the modern genus *Ciona*) in the Ascidiæ Simplices.

Savigny classified the nine genera which he recognised amongst compound Ascidians by means of characters taken from the branchial and atrial apertures. But although such characters are most useful and constant marks of affinity in the simple Ascidians, they fail signally as applied by Savigny to the compound forms, and result in the separation of his closely allied genera *Didemnum* and *Eucœlium*, while *Diazona*, *Distoma*, and *Sigillina* are thrown together in one group, and *Eucœlium* is placed with *Botryllus*, a genus with which it has certainly no close relationship.

Lamarck's arrangement of the Tunicata, published about the same time, showed no improvement upon that of Savigny.

In 1841 Milne-Edwards[5] established the group of "Ascidiæ Sociales" as occupying an independent position between the simple and compound forms. This group (in which he placed the genera *Perophora* and *Clavelina*) he defines as comprising Ascidians which reproduce by buds as well as by eggs, and which live united by common radiciform prolongations, but which otherwise are free of all adhesion to one another. He distinguished the simple Ascidians as forms which never reproduced by gemmation and were never found in groups united by a common tegumentary tissue; while he separated the compound from the social Ascidians on account of their possessing a test common to all the members of the colony. If we unite the simple and social Ascidians, which I have shown in the Report upon the *Challenger* Tunicata there is reason for doing, we shall have, according to Milne-Edwards, the simple and compound Ascidians distinguished merely by the members of the colony in the latter being united by a common test, while in the former each individual has its own distinct tunic. This character, although better than the one made use of by Savigny, is, as we shall see later on, by no means an infallible guide.

Milne-Edwards formed a classification of the genera of compound Ascidians into "Polycliniens," "Didemniens," and "Botrylliens," which, with our present knowledge of the group, still seems fairly natural. These three divisions are distinguished by such anatomical characters as the relations of the other viscera to the branchial sac. In the "Polycliniens" the body has three regions—the "thorax," containing the branchial sac; the "abdomen," formed by the stomach and the greater part of the intestine; and the "post-abdomen," having the reproductive organs and the heart. In the "Didemniens" there are only two regions—thorax and abdomen—the reproductive organs and heart being placed on the intestine. In the third group, the "Botrylliens," the viscera form a single mass, in which the alimentary canal lies alongside the branchial sac.

This arrangement of the Ascidiæ Compositæ was generally accepted until 1872, when Giard published[1] his important memoir, "Recherches sur les Ascidies Composées ou Synascidies," in which is given a classification based upon the method of gemmation. He distinguishes three points of origin for the buds—the pyloric region of the alimentary canal, the reproductive organs, and the posterior end of the body. The latter region is the place of gemmation in his "Catenatæ," a group which contains three families—the Clavelinidæ, the Perophoridæ, and the Botryllidæ. But he gives no sufficient reasons for placing the first two families in the compound Ascidians, and, as von Drasche has pointed out, the third one does not really exhibit the essential character of the Catenatæ.

Giard's second group, the "Glomeratæ," is characterised mainly by the formation of ovarian buds. It corresponds to Milne-Edwards' "Polycliniens," in addition to half of the "Didemniens." The remainder of the "Didemniens" correspond to Giard's third group, the "Reticulatæ," and are characterised by gemmation taking place from the pyloric region. This seems a natural and well-defined section, including two families, the Didemnidæ and the Diplosomidæ, but the "Glomeratæ" cannot stand without several changes which von Drasche suggests, and which really reduce it merely to Milne-Edwards' section "Polycliniens." Upon the whole, there can be little doubt that Milne-Edwards' classification is preferable to that proposed by Giard.

We come now to Dr. von Drasche, the latest authority, who, both in his preliminary note[2] and in the detailed memoir,[3] wisely abstains from any attempt to form main divisions, and merely groups the genera in a series of carefully chosen families. Of these the Botryllidæ corresponds to Milne-Edwards' section "Botrylliens," while the Didemnidæ and Diplosomidæ are identical with Giard's families bearing the same names. The Polyclinidæ and Distomidæ do not correspond exactly to any of Giard's families, but the former is Milne-Edwards' "Polycliniens" without change. A new family, the Chondrostachyidæ, has been formed for the reception of Macdonald's *Chondrostachys* and von Drasche's *Oxycorynia*, remarkable forms in which the Ascidiozooids are placed upon a common peduncle penetrated by large canals. I am inclined to admit the necessity for this new family, and several undescribed and interesting forms obtained during the *Challenger* Expedition will, I hope, take up a position within its bounds. The two remaining families of von Drasche's system, the Clavelinidæ and the Perophoridæ, I would still maintain are more closely allied to the simple than to the compound Ascidians. They correspond to Family IV. Clavelinidæ of my arrangement of the Ascidiæ Simplices.

[3] "Die Synascidien der Bucht von Rovigno" (Wien, 1883).

Dr. von Drasche does not define the Synascidiæ, and from one or two passages in his work it seems probable that he is in very much the position in which I now find myself, viz. unable to find any character or combination of characters which will serve to distinguish simple from compound Ascidians. Reproduction by gemmation and the formation of colonies in the latter group will not hold, since it is possible to pass from *Ciona*—a typical simple Ascidian—to *Distoma* and the very heart of the compound Ascidians through the following series of forms, which shows a perfect gradation of these characters :—*Ciona, Rhopalæa, Ecteinascidia, Clavelina, Diazona, Chondrostachys, Oxycorynia, Distoma*. The formation of common cloacal cavities, canals, and apertures cannot be considered as a diagnostic feature of the compound Ascidians. Although Giard has demonstrated their presence in some genera in which they were previously unknown, yet there are some forms considered by all authorities as Synascidiæ, such as *Chondrostachys*, *Diazona*, *Distoma*, and others, in which the atrial apertures of the Ascidiozooids open independently on the surface of the colony, and no common cloaca is formed.

Lastly, we come to characters taken from the condition of the test, but these break down like the others. In the first place, in passing along the series of forms mentioned above as connecting *Ciona* and *Distoma*, we encounter all stages between a distinct test or tunic for each individual and a common mass in which a number of Ascidiozooids are embedded. And, secondly, the remarkable group "Polystyelæ," briefly characterised by Giard in 1874. presents many of the characters of highly differentiated simple Ascidians (the Cynthiidæ), along with the supposed Synascidian feature of a colony composed of many Ascidiozooids completely buried in a common test.

In the *Challenger* collection there is an interesting series of Polystyelæ—all from southern seas—in which it is possible, I believe, to trace a passage from such aggregated Styelinæ as *Polycarpa* to the Botryllidæ. If this passage indicated genetic affinity between these two very distinct groups, which I greatly doubt, it would be impossible to escape from the conclusion that the Ascidiæ Simplices and the Ascidiæ Compositæ have *two* points of connection, almost at the extreme ends of the two series. I think I am justified in believing that probably both groups were derived from a form not unlike *Ecteinascidia* or *Clavelina*. From this common ancestor the simple Ascidians diverged through the Ascidiidæ to the Cynthiidæ (including *Polycarpa*) and the Molgulidæ, while the compound Ascidians diverged through *Diazona* and the Chondrostachyidæ to the Polyclinidæ, Didemnidæ, and Botryllidæ. Hence it seems much more probable that the Polystyelæ have acquired independently certain characters of *Polycarpa* or of *Botryllus* (I have not yet been able to determine to which of the two they are really most closely related) than that there is any direct affinity between such highly differentiated groups as the Cynthiidæ and the Botryllidæ. This, however, does not affect the practical difficulty that the Polystyelæ completely bridge across the gap between simple and compound Ascidians as distinguished by the nature of the test or tunic, and consequently it is extremely difficult to separate them from either of these two great series.

Thus all the diagnostic features usually employed fail utterly, and we find ourselves unable to discover a single character or combination of characters which will serve to distinguish the Ascidiæ Simplices from the Ascidiæ Compositæ.

W. A. HERDMAN

A METEOROLOGICAL LABORATORY

TO the last issue of *Science et Nature* M. L. Mangin contributes an interesting account of the chemical laboratory recently installed on the Pic du Midi, Pyrenees, at an altitude of nearly 9500 feet above the sea. As shown in our first illustration, the laboratory stands between the dwelling-house and the Observatory, of which it forms a dependency, under the direction of MM. Müntz and Aubin. In the second illustration a fuller view is given of the building, which faces southwards, and the slated roof of which is so constructed as to constitute a sort of pluviometer registering the annual rainfall, and retaining sufficient for chemical analysis. This unique establishment, which promises to render great services both to meteorology and to the economic industries, is at present chiefly occupied with the constituent elements of the terrestrial atmosphere, especially in connection with vegetable life. The student of chemistry need scarcely be reminded that, besides oxygen and nitrogen, the air contains in smaller proportions carbonic acid, ammonia, and certain nitric compounds playing an important part in the nutrition of plants, and supplying them with nearly all the nitrogen and carbon that enter into the composition of their tissues. During the summer months of the years 1881-82, MM. Müntz and Aubin were mainly engaged with the quantitative analysis of these substances, under conditions peculiarly favourable for the prosecution of such investigations. The results so far obtained may here be briefly resumed.

Carbonic Acid.—The proportion of this element found in the air at different altitudes is still a subject of discussion amongst analytical chemists. But de Saussure's average of from ·0004 to ·0006 has been shown to be considerably too high by various observations taken of late years at different stations on the globe. These observations are now fully confirmed by the researches on the Pic du Midi, which reduce the average to 2·86 ten-thousandths.

Another important conclusion is that the carbonic acid does not perceptibly vary with the altitude, as had hitherto been supposed. Thus the proportion is found to be much the same at Vincennes near Paris, Luz (740 m.), Pierrefitte (500 m.), and Pic du Midi (2900 m.). On the other hand, the quantity varies slightly in the same locality, being somewhat greater at night and in moist weather than during the day and in dry weather. The subjoined table shows the average quantity of carbonic acid present in the atmosphere during the day and at night at various meteorological stations in different parts of the world :—

	Night	Day
Vincennes	2·98 ...	2·84
Pic du Midi.. ...	2·90 ...	2·86
Hayti	2·92 ...	2·70
Florida	2·94 ...	2·89
Martinique	2·85 ...	2·73
Mexico...	2·86 ...	2·66
Patagonia	2·67 ...	2·66
Chili	2·82 ...	2·66

Ammonia.—Although the presence of ammonia in the air has long been known, Schlösing was the first to show that for this substance, as well as for carbonic acid, the sea is the great reservoir whence the atmosphere receives its supplies. But no light had hitherto been thrown upon

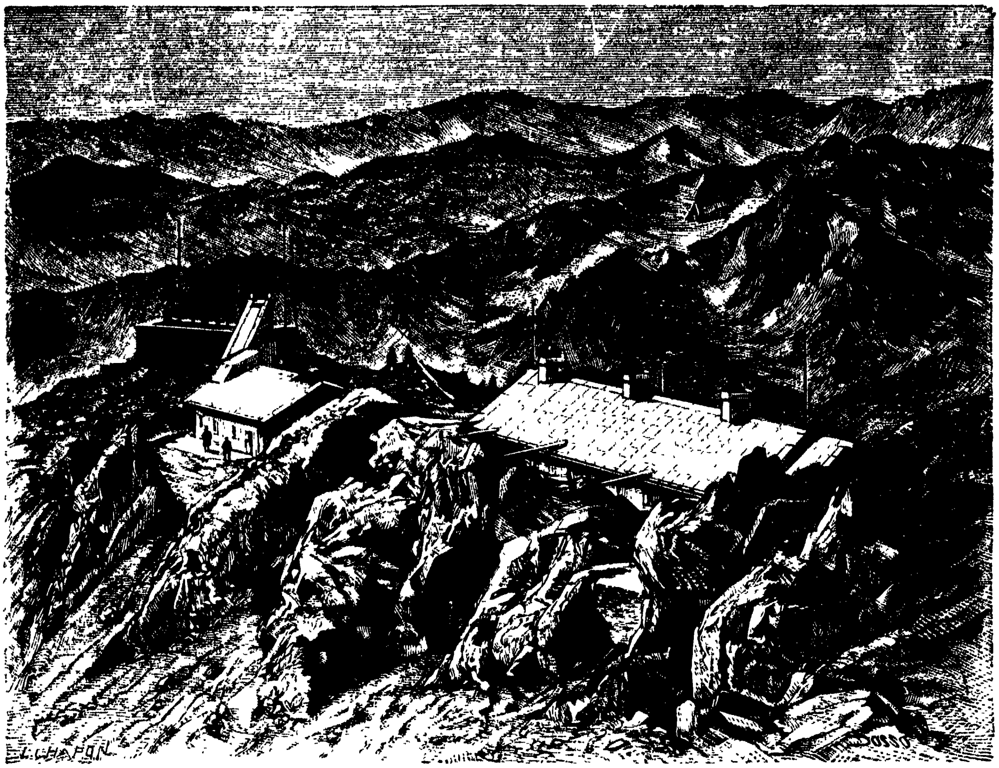

FIG. 1.—General View of the Pic du Midi Observatory.

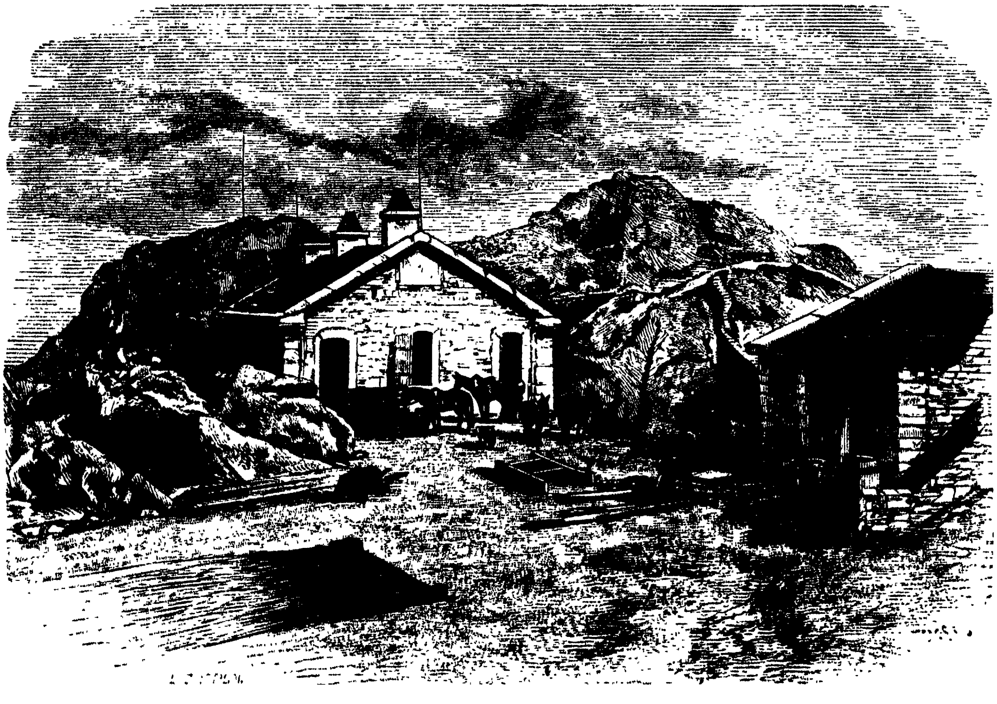

FIG. 2.—The Observatory and Laboratory.

the distribution of ammonia at different altitudes. Examining the atmosphere from this point of view, MM. Müntz and Aubin now find that at an elevation of nearly 3000 m. the quantity does not sensibly differ from that at extremely low levels, which is ascertained to be about 1·35 mgr. to 100 c.m. Hence the diffusion of ammonia in the air is as complete as that of carbonic acid. Consequently it is in the gaseous state that this substance is incessantly transmitted from the marine basins to the atmosphere. The rain and snow collected on the Pic du Midi also revealed the presence of ammonia in solution, as was to be expected.

Atmospheric Nitrification.—The analysis of rain falling during thunderstorms is known invariably to yield certain nitrous compounds in the form of sal ammoniac. From what is known regarding the affinities of nitrogen, it is argued that these compounds are developed under the influence of electric discharges. The nitrous compounds (nitric acid and sub-nitric acid) are converted, in the presence of water and of ammonia, into sal ammoniacs, which are precipitated by the rain. Hence electric disturbances in the air came to be regarded as the chief source of nitrous compounds.

MM. Müntz and Aubin have analysed by the most delicate processes the rain-water collected on the Pic du Midi, but never succeeded in detecting any nitrates in it, although they are always present in rain-water collected on the plains. Their absence corresponds with the absence of thunderstorms taking their rise above the Pic du Midi. Of 184 storms observed during a period of nearly nine years by M. de Nansouty, the director of the Observatory, not more than twenty-three originated at an altitude of over 2300 m.; but in no case were electric phenomena observed at an elevation higher than 3000 m. Hence the electric discharges, which give rise to the nitrates, are limited to the lower atmospheric regions between sea-level and 3000 m. above the sea.

To the general results here resumed MM. Müntz and Aubin have added some details concerning the formation of vegetable soil. They have distinctly determined the presence of nitric ferment in the ground on the highest summits. But owing to the low temperature prevailing at those altitudes, the activity of this ferment is extremely weak.

It may be observed in conclusion that the uniform proportion of carbonic acid and ammonia in the atmosphere, as determined by these remarkable researches, is a fresh confirmation of Schlösing's theory regarding the interchange of gases between the sea and the air. The marine basins are incessantly discharging or absorbing carbonic acid and ammonia in such a way as to maintain the constant proportion of these substances. They thus constitute a vast regulator, restoring to the atmosphere the nitrous or carbonic compounds of which it had been deprived by vegetation.

SCIENCE IN ROME

THE recent changes introduced into the constitution of the Accademia dei Lincei, followed by its removal to new and sumptuous quarters in Trastevere, seem to call for more than a passing notice. There are certainly many other famous societies scattered over the Peninsula, all the large towns of which have long possessed one or more scientific, literary, or artistic corporations. But, with perhaps the single exception of the Florentine Academy, none of them have been so intimately identified with the progress of the physical sciences since the "Renaissance" as this oldest of still existing learned institutions. Founded on August 17, 1603, by the young prince, Federigo Cesi, for the express purpose of cultivating "le scienze matematiche e filosofiche," it began its useful career forty years before the birth of Newton, and six before Galileo had rendered Jansen's telescope a suitable instrument for astronomic observation. The very name of the Lincei, or "Lynx-eyed,"[1] breathes the quaint spirit of the times, when every capital in Italy had its centres of intellectual movement, bearing such eccentric titles as the Accademia dei Sonnacchiosi ("The Drowsy"), dei Sitibondi ("The Thirsty"), dei Svegliati ("The Wide-Awake"), degli Ottusi ("The Dull"), degli Innomati ("The Nameless"), dei Storditi ("The Dazed"), dei Tenebrosi ("The Darklings"), and so forth. But while most of these ephemeral corporations have left little but their names behind them, the Lincei have gone on prospering and continually widening the field of their utility until the Academy now finds itself formally constituted the chief national exponent of the natural sciences in Italy, thus taking rank with the French Institute and the Royal Society of London.

Although such a proud position could scarcely have been anticipated by its founder, the Academy none the less possessed from the outset certain elements of stability, which under favourable circumstances could not fail to insure it a prolonged existence. Its generous patron not only provided it with a home in his ancestral palace, but also placed at its disposal a botanical garden, a rich museum and a choice library soon increased the valuable collection of Virginio Cesarini. Its three first members, the founder, Fabio Colonna, and Francesco Stellati, were all noted for their varied accomplishments, and Colonna especially, at once a mathematician, philosopher, painter, musician, and *savant*, may be regarded as the greatest of botanists previous to Linné.[2]

During the seven first years after its foundation, Gaetano Marini tells us that the Academy "dared to stand up against the tyranny of the Peripatetics, and to introduce a new and more certain method of philosophy, bravely and religiously enduring a long and most unworthy persecution" (*Ist.* i. p. 493). The reference in the last clause, necessarily worded somewhat vaguely, is to the action taken by the Lincei in defence of Galileo, who had joined the Academy, and who had in 1615 received his first summons to Rome to recant his "errors." A feeble attempt seems to have been made to continue the struggle between light and darkness till 1632, when Galileo was finally "suppressed." The "Lynx-eyed" were now shrewd enough to perceive that they had fallen upon times when silence was "golden." Henceforth for many years their records are practically a blank, broken only in 1651 by the publication under their auspices of Francisco Hernandez's great work on the natural history of Mexico.

After the untimely death of Prince Cesi in 1630 the Academicians, now numbering thirty-two members and foreign associates, received a temporary shelter in the house of the Commendator Cassiano del Pozzo. Their first organic constitution had been issued in 1624, and since that period both residence and regulations have been subjected to many changes. After the political unification of Italy and the selection of Rome for its capital, fresh modifications became inevitable, and a new constitution was published in the year 1875. But so rapid has been the progress of the natural sciences, and so great the zeal displayed by the Lincei in the cause for which their predecessors endured "a long and most unworthy persecution," that further alterations in the sense of expansion were soon felt to be imperative. According to the reform introduced in July 1883, better provision is made for the cultivation of all branches of physics by the final and absolute exclusion of the arts and letters. The new conditions have of course necessitated this departure from the original scope of the Institute, which, as we are expressly told by Tiraboschi, did not exclude the "humanities."[1] The scheme of the natural sciences itself has also been entirely recast, with a corresponding increase and redistribution of members among the various sections. As regards foreign membership the Lincei take the lead in an important innovation, which will doubtless be adopted in due course by the great scientific institutes of other countries. In a truly "international" spirit, they henceforth practically abolish the distinction between *Associates* (Socî, or home members) and *Correspondents* (Corrispondenti, or foreign members). The clause bearing on this point in the President's Circular of June 26, 1883, deserves to be here quoted in full:—

---

[1] Tiraboschi tells us that this title was adopted "per chè gli accademici presero a lor simbolo un lince, a spiegar l'acutezza con cui si erano prefissi di osservare e di studiar la natura" (viii. p. 72).

[2] "Quicumque," says Boerhaave, "historiam antiquitatis plantarum scire vult, legat opera Fabii Columnæ, qui vix habet similem, sed quidem imitatores" ("Method. discend. Medic.," pars 4, § 8). Colonna, who was born in Naples in 1567, and died an octogenarian in 1647, was also the inventor of the musical instrument by him named the "sambuco linceo," in honour of the Academy.

"Per ciò che concerne gli stranieri fu unanime il pensiero di togliere la distinzione fra i Socî ed i Corrispondenti: distinzione la quale riferendosi a pochi personaggi eminenti nelle scienze a cui attendono e disseminati in tutto il mondo civile, riesce difficilissima e di utilità molto dubbia. Per le scienze fisiche, matematiche, e naturali parve necessario un aumento nel numero degli stranieri aggregabili all' Accademia, non solo per dare una dimostrazione d'onore a personaggi cosi benemeriti, ma anche per agevolare le relazioni scientifiche le quali si fanno ogni giorno più frequenti, più necessarie, e più intime fra i cultori delle stesse scienze ed i direttori di analoghi stabilimenti scientifici, independentemente dai confini politici che li separono."[2]

Amongst the foreign *savants* who thus receive full membership, occur the names of Airy, Adams, Lockyer, and Huggins in Astronomy, Ramsay in Geology, Hooker in Botany, Huxley in Zoology, Cayley and Roberts in Mathematics, Whitney in Philology, Freeman in History and Geography, Gladstone in Social Science.

As reorganised under the new constitution, the Academy consists henceforth of two classes: (1) Physical, Mathematical, and Natural Sciences; (2) Moral Sciences,—distributed into a number of Categories and Sections as under:—

CLASS I.

Categories	Sections	Members
1. ...	Mathematics	15
	Mechanics	11
	Astronomy...	11
	Geography (Physical)	4
2. ...	Physics	17
	Chemistry	8
	Crystallography and Mineralogy ...	9
3. ...	Geology and Palæontology ...	11
4. ...	Botany	9
	Zoology and Morphology... ...	8
5. ...	Agronomy	3
	Physiology...	6
	Pathology	3

CLASS II.

Categories	Members
1. Philology	17
2. Archæology	19
3. History and Historical Geography ...	16
4. Philosophy	15
5. Jurisprudence	10
6. Social Science	21

On May 14, 1881, an Act was passed granting a large sum for the purpose of erecting or purchasing a suitable edifice for the Lincei, henceforth officially recognised as the "Royal Academy of Sciences." After protracted negotiations, an arrangement was made with Prince Tommaso Corsini, in virtue of which for the sum of 95,400*l.* the Academy acquired the perpetual use of the magnificent Palazzo Corsini, situated in the Via della Longara, Trastevere. The purchase, which was effected in May 1883, included the furniture, fittings, gardens, and annexes, but not the Library and Pinakothek, which, being entailed, the prince had no power to alienate. To meet this difficulty a special Act was subsequently passed, which removed the entail, and enabled the prince to make a free gift of the Pinakothek to the nation, and of the Library to the Accademia dei Lincei. The Library, originally collected by Cardinal Neri Corsini, and bequeathed by him in 1774 to his nephew, Duca don Filippo Corsini, comprises the prints, drawings, books, and manuscripts occupying the nine rooms on the first floor of the north side of the building so well known to English visitors in Rome. It passes to the Lincei on the condition of being preserved by them for the public use under the name of the "Biblioteca Corsiniana." It is also to be kept for ever not only in Rome, but in Trastevere, as set forth in the disposition of its chief founder, Cardinal Neri Corsini. Some of our readers may possibly remember the two allegorical busts at the main entrance of the palace. These are now to be replaced by busts of the Cardinal and of Prince Tommaso Corsini, with inscriptions recording their services to the cause of the arts and sciences. The prince also receives from the Academy the gift of a complete copy of its *Atti* or *Proceedings*, of which there are three series: (1) under the Pontifical "dispensation," 23 vols.; (2) 1873-76, 8 vols.; (3) 1876-83, 7 vols. On the yellow wrapper of the present series the tiara gives place to the royal crown of Italy above the lynx, and the Lincei pass from the shadow of the now silent Sant' Uffizio to a right royal residence on the banks of yellow Tiber.

A. H. KEANE

---

[1] "E benchè il principal loro oggetto fosser le scienze matematiche e filosofiche, non trascuravono però l'amena litteratura e gli studi poetici" (viii. p. 73).

[2] As finally modified in the new articles, the clause affecting foreign members runs thus:—"I soci stranieri sono equiparati ai nazionali allorquando essi sono in Italia."

NIELS HENRIK CORDULUS HOFFMEYER

WE have already (p. 387) briefly referred to the death of Capt. Hoffmeyer; the importance of his work in meteorology deserves more detailed notice.

Capt. Hoffmeyer was born at Copenhagen, June 3, 1836. His father was Col. A. B. Hoffmeyer. He commenced his studies with a view to a professional career, but the idea was soon abandoned, and he was entered as a pupil in the military academy. At the age of eighteen he became an officer, and on completing his studies he received an appointment in the artillery service.

He was engaged in the Schleswig-Holstein war of 1864, but as early as February he was compelled by illness to retire from active service. In early youth he had suffered from rheumatic fever, and the exposure and fatigues of the winter campaign soon laid him prostrate with another severe attack of the same fever. On the reduction of the army at the close of that year, Capt. Hoffmeyer was placed on the retired list.

He spent the early part of the summer of 1865 recruiting his health at Sophienbad, a watering-place near Hamburg, and in August he proceeded to Paris, where and at Nantes he remained a year studying the works carried on at the iron foundries there. On his return to Denmark he took an active part in establishing a similar foundry at Christiansholm, but in 1867 he was appointed to a post in the War Department, and became at the same time a captain of the militia of Copenhagen.

It was while residing in France that Hoffmeyer's attention began to be directed to meteorology. At that time, fortunately, the principles which distinguish modern meteorology were being developed and prosecuted by the genius and energy of Leverrier, in the daily publication in the *Bulletin International* of a weather map for all Europe, which had been begun only two years before. After his appointment to the War Department, he devoted his energies with characteristic ardour to the study of meteorology, and when the Danish Government established the Meteorological Institute in 1872, Capt. Hoffmeyer was appointed director.

He continued to suffer from occasional attacks of rheumatic fever, and during the last year of his life was never quite well; but in spite of the great weakness under which he laboured, his overmastering passion for hard work would not be controlled. His health again gave way at the end of January, and he finally succumbed at one o'clock on the afternoon of February 16.

It was from a singularly clear and firm apprehension of the characteristic principles of modern meteorology, and an unflinching application of them to the facts of observation, that Capt. Hoffmeyer has left his mark on the science,—these principles being the relations of winds, temperature, and rainfall to the distribution of atmospheric pressure. In working out the weather problem of Europe, no country occupies a more splendid position for the observation of the required data than does Denmark with its dependencies of Farö, Iceland, and Greenland. Denmark was slow to occupy the field, nothing being done in this direction by the Danish Government prior to Hoffmeyer's appointment as Director of the Meteorological Institute. In a short time these important regions were represented by stations in Greenland, Iceland, and Farö. The meteorology of Denmark proper was pushed forward with great vigour. In truth, the monthly meteorological *Bulletin* of Denmark is in several respects among the best that reach us. The number for January, 1884, just received, presents the monthly results of pressure for 13 stations, temperature for 109 stations, and rainfall and other forms of precipitation for 159 stations. These results are graphically shown on four maps, accompanied with a full descriptive letter-press—one map giving the isobars for the month, another the isothermals, and on the same map the mean temperature at each of the 109 stations; a third map, the minimum temperature at each of the stations; while the fourth gives isohyetal lines showing the rainfall, and here again the amount at each of the 159 rain stations is entered in plain figures on the map. The educative effect of these instructive monthly sheets on a people whose industries are so largely pastoral and agricultural must be very great.

It was, however, to the department of meteorology which is concerned with the preparation and study of synoptic weather charts that Hoffmeyer chiefly directed his attention. The great services he rendered in this direction may be indicated by a reference to his atlas of daily weather maps of the Atlantic, embracing a period of fully three years, the expense of which was almost wholly borne by himself, and his annual reports giving tri-daily observations for the Denmark, Farö, Iceland, and Greenland stations—a work which no working meteorologist can afford to be without. It was arranged last summer to resume the publication of the synoptic charts in conjunction with Neumayer, and the work was so far advanced that the first sheets were printed off on February 17, the day after his death.

Of the positive additions Hoffmeyer made to science, the most noteworthy are his papers on the Greenland foehn (NATURE, vol. xvi. p. 294), and on the distribution of atmospheric pressure in winter over the North Atlantic, and its influence on the climate of Europe (NATURE, vol. xviii. p. 680). The latter is an original and highly important contribution to science, whether regard be had to the method of investigation or to the results. He showed that the character of the weather, as regards mildness or severity of the winter of the regions surrounding the North Atlantic, is really determined by the position of the region of minimum pressure, according as it is localised to the south-west of Ireland, in Davis Straits, or midway between Jan Mayen and the Lofoden Islands.

It was but fitting that he should have occupied the honourable position of Secretary to the International Polar Commission, one of the principal objects of which was to collect materials for a satisfactory discussion of the different questions raised by the weather maps of the northern hemisphere. For this office the sincerity of his convictions, his honesty of purpose, and his business habits, eminently fitted him. To all who knew him, the memory of his eager readiness to assist fellow-workers, the urbanity of his manner, his joyous nature, and the unusual warmth of his friendship, cannot but awaken the keenest feelings of regret for his early death.

NOTES

As the British Association meets this year—its fifty-fourth—on August 27, in Montreal, preparations for the meeting have had to be made unusually early. Already everything is ready, and we are able to announce the lists of officials. President: the Right Hon. Lord Rayleigh, D.C.L., F.R.S., Professor of Experimental Physics in the University of Cambridge. Vice-Presidents: His Excellency the Governor-General of Canada; the Right Hon. Sir John Alexander Macdonald, K.C.B., D.C.L.; the Right Hon. Sir Lyon Playfair, K.C.B., M.P., F.R.S; the Hon. Sir Alexander Tilloch Galt, G.C.M.G.; the Hon. Sir Charles Tupper, K.C.M.G.; Sir Narcisse Dorion, C.M.G.; the Hon. Dr. Chauveau; Principal J. W. Dawson, C.M.G., F.R.S.; Prof. Edward Frankland, M.D., D.C.L., F.R.S.; W. H. Hingston, M.D.; Thomas Sterry Hunt, LL.D., F.R.S. General Treasurer: Prof. A. W. Williamson, LL.D., F.R.S. General Secretaries: Capt. Douglas Galton, C.B., D.C.L., F.R.S.; A. G. Vernon Harcourt, F.R.S. Secretary: Prof. T. G. Bonney, D.Sc., F.R.S., P.G.S. Local Secretaries for the meeting at Montreal: L. E. Dawson, R. A. Ramsay, S. Rivard, S. C. Stevenson, Thomas White, M.P. Local Treasurer for the meeting at Montreal, F. Wolferstan Thomas. The Sections are the following:—**A.**—Mathematical and Physical Science.—President: Prof. Sir William Thomson, M.A., LL.D., D.C.L., F.R.SS.L. and E., F.R.A.S. Vice-Presidents: Prof. J. B. Cherriman, M.A.; J. W. L. Glaisher, M.A., F.R.S., F.R.A.S. Secretaries: Charles H. Carpmael, M.A.; Prof. A. Johnson, M.A., LL.D.; Prof. O. J. Lodge, D.Sc.; D. MacAlister, M.A., M.B., B.Sc. (Recorder). B.—Chemical Science.—President: Prof. H. E. Roscoe, Ph.D., LL.D., F.R.S., F.C.S. Vice-Presidents: Prof. Dewar, M.A., F.R.S., F.C.S.; Prof. B. J. Harrington, B.A., Ph.D. Secretaries: Prof. P. Phillips Bedson, D.Sc., F.C.S. (Recorder); H. B. Dixon, M.A., F.C.S.; T. McFarlane, Prof. W. W. Pike. C.—Geology.—President: W. T. Blanford, F.R.S., F.G.S., F.R.G.S. Vice-Presidents: Prof. Rupert Jones, F.R.S., F.G S.; A. R. C. Selwyn, LL.D., F.R.S., F.G.S. Secretaries: F. Adams, B.Ap.Sc.; G. M. Dawson, D.Sc., F.G.S.; W. Topley, F.G.S. (Recorder); W. Whitaker, B.A., F.G.S. D.—Biology.—President: Prof. H. N. Moseley, M.A., F.R.S., F.L.S., F.R G.S., F.Z.S. Vice-Presidents: W. B. Carpenter, C.B., M.D., LL.D., F.R.S., F.L.S., F.G.S.; Prof. R. G. Lawson, Ph.D., LL.D. Secretaries: Prof. W. Osler, M.D.; Howard Saunders, F.L.S., F.Z.S. (Recorder); A. Sedgwick, B.A.; Prof. R. Ramsay Wright, M.A., B.Sc. E.—Geography.—Vice-Presidents: Col. Rhodes; P. L. Sclater, M.A., Ph.D., F.R.S., F.L.S., F.G.S., F.R.G.S. Secretaries: R. Bell, M.D., LL.D., F.G.S.; Rev. Abbé Laflamme; E. G. Ravenstein, F.R.G.S.; E. C. Rye, F.Z.S. (Recorder). F.—Economic Science and Statistics.—President: Sir R. Temple, G.C.S.I., C.I.E., D.C.L., F.R.G.S. Vice-Presidents, J. B. Martin, F.S.S.; Prof. J. Clark Murray, LL.D. Secretaries: Prof. H. S. Foxwell, M.A., F.S.S.; J. S. McLennan, B.A.; Constantine Molloy (Recorder); Prof. J. Watson, M.A., LL.D. G.—Mechanical Science.—President: Sir F. J. Bramwell, F.R.S., M.Inst.C.E. Vice-Presidents: Prof. H. T. Bovey, M.A.; P.G. B. Westmacott, M.Inst.C.E. Secretaries: A. T. Atchison, M.A., C.E.; J. Kennedy, C.E.; L. Lesage, C.E.; H. T. Wood, B.A. (Recorder). H.—Anthropology.—President: E. B. Tylor, D.C.L., LL.D., F.R.S. Vice-Presidents: Prof. W. Boyd Dawkins, M.A., F.R.S., F.S.A., F.G.S.; Prof. Daniel Wilson, LL.D., F.R.S.E. Secretaries: G. W. Bloxam, M.A., F.L.S. (Recorder); Rev. J. Campbell, M.A.; Walter Hurst, B.Sc.; J. M. P. Lemoine. It is expected that the public lectures will be by Mr. Crookes, Dr. Dallinger, and Prof. Ball. Liberal reductions of fares will be made by the steamship companies and the American railways; the Canadian Pacific Railway, indeed, gives free travelling to all members from August 1 to the time for the excursion to the Rocky Mountains, which it offers free to 150 members. Many other excursions have been arranged for, and the American Association invites the members to join its meetings and excursions at Philadelphia on September 3. We are glad to see that Section A is following the good example set by Prof. Lankester in Biology last year. A circular signed by Sir William Thomson has been issued by the Committee of Section A, inviting the co-operation of mathematicians and physicists, and requesting those willing to read papers and take part in the discussions to send their names to the Secretaries of Section A, British Association, Albemarle Street. The following subjects have been selected for special discussion by the Committee:—On Friday, August 29, The Seat of the Electromotive Forces in the Voltaic Cell. On Monday, September 1, The Connection of Sunspots with Terrestrial Phenomena.

THE death is announced on March 1 of Dr Isaac Todhunter, F.R.S., the well-known mathematician, at his residence, Brookside, Cambridge. Dr. Todhunter was born in 1820, and having passed some years of his life as usher in a school, proceeded to University College, London, and when twenty-four years of age, entered as an undergratuate of St. John's. He graduated in the Mathematical Tripos of 1848, obtaining the distinction of Senior Wrangler and first Smith's Prizeman in a year which produced some remarkably able men. Dr. Todhunter was in due course elected to a Fellowship at St. John's, and subsequently filled the offices of assistant tutor and principal lecturer in mathematics. Dr. Todhunter is well known as the author of numerous mathematical treatises, which have obtained a wide circulation, and are recognised as standard works of education in the universities and public schools. His treatises on the "Differential Calculus," "Analytical Statics," "Plane Coordinate Geometry," "Plane Trigonometry," and "Spherical Trigonometry," greatly enhanced his reputation. He also published various elementary works, all of which enjoyed a large circulation. In 1871 he obtained the Adams Prize for an essay, "Researches on the Calculus of Variations." He published, in 1873, "A History of the Mathematical Theories of Attraction and the Figure of the Earth from the time of Newton to that of Laplace." In 1876 there also appeared from his pen, "An Account of the Writings of William Whewell, D.D., Master of Trinity College, with selections from his literary and scientific correspondence." By the new University statutes the University was authorised to confer the degrees of Doctor in Science and Doctor in Letters. Dr. Todhunter was among the first upon whom the distinction of Doctor in Science was conferred, and last year proceeded to that degree. A few years previously he had been elected an honorary Fellow of his College as a mark of recognition of his great mathematical attainments. It may be mentioned that Dr. Todhunter took an active part in University affairs, was a member of several Syndicates and Boards of Studies, and an elector to the Plumian Professorship of Astronomy. He had been in failing health for some time, and a few weeks ago was attacked with paralysis, which precluded all hope of recovery.

NATURAL HISTORY, and especially Palæontology, in Sicily, have sustained a great loss in the decease of the septuagenarian Abbé Brugnone, who died at Palermo on the 3rd of last month. He published several excellent papers on the recent and Pliocene shells of his native island, which were illustrated by his own pencil. His real name appears from the obituary card to have been Rugnone. We understand that his valuable collections are for sale.

M. FAYE read at the last meeting of the Academy of Sciences the draft of a resolution which will be presented by the Special Commission appointed to report on the removal of the Observatory, and which will be discussed by the Academy at one of its next private sittings. It approves the removal of the Observatory to a site in close proximity to Paris, and the sale of the grounds, on condition that the existing building will remain intact, and so much land as is necessary for executing astronomical observations in the establishment.

THE Academy of Sciences has nominated M. Darboux a member in the Section of Geometry. Mr. Darboux is the editor of a mathematical paper published in Paris, and the author of numerous memoirs on analysis and geometry printed in the *Transactions* of the Academy.

M. BERTRAND has issued the first number of a monthly astronomical journal published by the Observatory of Paris under the title of the *Bulletin*. It is edited by M. Tisserand, with the co-operation of a number of astronomers of the Paris Observatory.

UNDER the auspices of the Paris Geographical Society a course of lectures is being delivered by some of the most eminent French men of science. These lectures, eight in number, are held every Monday, at 8.30 p.m.; they began on February 11, and end on March 31, in the Hall of the Geographical Society. The following are the subjects of these lectures:—M. Faye, of the Institute, the connection of astronomy and geography in the principal periods of history; M. de Lapparent, M.E., reliefs of the globe; M. E. Fuchs, M.E., distribution of minerals; M. Mascart, director of the Meteorological Bureau, climate; M. Vélain, lecturer at the Sorbonne, glaciers and their action on the reliefs of the globe; M. Bureau, professor at the Museum of Natural History, geographical distribution of plants; M. Ed. Perrier, professor at the Museum of Natural History, the depths of the sea and their inhabitants; M. Alphonse Milne-Edwards, of the Institute, geographical distribution of animals. The course will be continued next year. Information respecting the above lectures, to which the public is admitted, may be had at the rooms of the Geographical Society, 184, Boulevard St. Germain.

THE Rev. Marc Dechevrens, S.J., of Zi-ka-wei Observatory, writes to us under date January 22, that the sky there continues to exhibit remarkable colours; during this winter the zodiacal light appeared to M. Dechevrens to be more feeble than in preceding years. He incloses a letter from Dr. D. J. Macgowan of Hankow to the *North China Daily News*:—"A phenomenon similar to the 'green sun in India' (observed at Ceylon from September 9 to 11 inclusive; from various portions of the Indian Ocean on the 10th and 13th; and at Trichinopoly, for some three weeks preceding October 2) has been witnessed several times at Hankow; on November 17 by the Rev. A. W. Nightingale, and on another occasion about the same time (date unrecorded), and again so recently as December 29 by the Rev. G. John and Rev. A. Foster. On these occasions the sun shortly before setting was of a pale green tint, the colour deepening as the orb declined; then followed an exhibition of the glowing redness of the western and southern horizon, which since the early part of December last has been observed from the sea-board far into the interior. Information from other parts of China respecting the 'green sun' is a desideratum."

The latest official report on the condition of the districts overwhelmed by the Krakatoa eruption states that the surviving inhabitants of the various villages have reassembled under their headmen, and are erecting their huts. The volcanic ashes did little harm to the soil, the growing crops all presenting a luxuriant appearance. The trees, however, have suffered greatly, as had some of the coffee plantations. Two bays, Lampong and Semengka, which were blocked up by the fields of pumice, were free by the middle of December.

On a summer night of 1882 a woman in Högsby parish, in Sweden, saw a shining object fall from the sky, disappearing behind a stable. Search was made for the meteorite, according to the statements of the woman, but without success. Last autumn it was, however, accidentally discovered near the spot indicated, and has now been forwarded to proper quarters in the town of Oskarshamn. The surface of the meteorite appears as if it had been welded from various substances; it is about the size of a billycock hat, very thick, and weighs a little over 14 lbs.

M. W. de Fonvielle writes:—"I took the liberty of suggesting in one of the last issues of the *Ville de Paris* a scheme for discovering clock-work in parcels deposited in luggage-rooms. All the luggage should be laid flat on wooden tables supported by iron feet, and not nailed to them; the least noise within the parcels would be made audible if a microphone of proper construction were placed on each table. The charge for keeping should be made heavier to diminish the number of parcels, and the right of opening optional with the railway companies."

The Commission for Montsouris Observatory held its annual sitting at the end of February. It was resolved to ask from the Municipal Council an increase of the annual allocation, which is somewhat less than 1200*l.*, exclusive of some extra charges. But it is not supposed the request will be granted, and a diminution is rather expected. It must be remembered that meteorological observations are now conducted at Montsouris, at Parc Saint Maur, and at the Paris Observatory, almost on the same principles and with analogous instruments. It is curious to see this triple working by almost independent administrations.

The long isolated kingdom of Corea having now been definitely opened by treaties to European trade and residence, we may soon expect English scholars to take their part in exploring its language, literature, and history. For the benefit of those about to study in the new field, it may be well to recall the fact that, so far, we are entirely dependent on French priests for the meagre knowledge we possess of the country. There is a paper in the *Transactions of the Royal Asiatic Society*, by Mr. Aston of Japan, on the Corean language, but the two works to which for some years to come European students must first resort are the Grammar and Dictionary edited by Msgr. Ridel, and published by Lévy of Yokohama. The latter appeared in 1879, and is a large volume of some 700 pages, containing about 30,000 words. The native words are accompanied not only by a French transliteration, but also by the Chinese characters representing them, so that the work can be used by a Chinese as well as a European, and, to those who already know Chinese or Japanese, an additional explanation is thus supplied. All that is known respecting the country to the priests—its fauna, flora, arts, manners, and customs—finds a place in the volume. An appendix gives a brief sketch of the grammar, while another contains the geography, the names, and position of the provinces, mountains, rivers, and chief towns. The Grammar was published last year, and contains an introduction on the character of the Corean language, and a comparison of it with Chinese, as well as appendices on the divisions of time, weights, measures, the mariner's compass, &c. Throughout the East the Catholic missionaries have been the advanced guard of European science and methods of study. The volumes which they produced nearly a hundred years ago on China are still as necessary to thorough study of that country as they were then. The student who cannot refer to the original authorities, as, for instance, Chinese history, had, until the recent publication of Mr. Boulger's work, to go to the long series of volumes published towards the close of the last century by the Société des Missions Étrangères under the editorship of de Mailla, Amyot, and other missionaries.

We learn from *Science* that at 7.24 p.m. on January 25 earthquake waves were indicated by the delicate levels of the astronomical instruments of the San Francisco Observatory. The amplitude of each vibration was three seconds of arc in three seconds of time, and they continued for twenty minutes.

At the last meeting of the Sociological (Spencerian) Section of the Birmingham Natural History Society it was decided to commence making an index to the study of Sociology. Letters were read from Mr. Spencer approving of the system about to be adopted, and stating that time and health had alone prevented him commencing such an undertaking previously.

The Westphalian Provinzial Verein for Science and Art is about to publish a large work entitled "Westphalen's Thierleben in Wort und Bild." The Society also intends establishing a Provinzial Museum.

At Berlin a branch of the German Meteorological Society was founded on January 29 last.

We are pleased to learn that a complete catalogue of the Reference Department of the Nottingham Free Library is in course of preparation, but as that will be the work of some time, class lists have been issued for public use in the meantime. The publication noticed in these columns on January 31 was one of these, already supplemented considerably.

At the suggestion of the Austrian Crown Prince, a work on the ethnography of the Empire is about to be written. Maurus Jokaj, the well-known Hungarian, has been intrusted with the task of editing it.

A severe shock of earthquake, lasting two seconds, was felt at 4 a.m. on February 25 at Chios, Tchesme, and Vourla. So far as is known at present no damage has been done. An earthquake-wave, lasting about fifteen minutes, and inundating part of the town, was noticed at Montevideo on January 14, at 7.30 a.m. The weather was fine; the direction of the wave was from the Patagonian coast. Several people were drowned on the south side of the town.

The death is announced of Prof. Heinrich Karl Berghaus, the well-known geographer and historian. Born at Kleve on May 3, 1797, he died at Stettin on February 17 last.

An Engineering Exhibition will be held at Breslau from June 9 to 11 next.

The additions to the Zoological Society's Gardens during the past week include a Grey Ichneumon (*Herpestes griseus*) from India, presented by Mr. J. B. Drew; an Arabian Gazelle (*Gazella arabica* ♀) from Arabia, presented by Lieut. Brown, R.N.; two Herring Gulls (*Larus argentatus*), European, presented by Mr. G. D. Macgregor; a Ring-necked Parrakeet (*Palæornis torquatus*) from India, presented by Mr. J. Biehl; a Black-headed Gull (*Larus ridibundus*), European, presented by Miss Elise Cooper; eight Hoary Snakes (*Coronella cana*) from South Africa, presented by Mr. C. B. Pillans; a Robben Island Snake (*Coronella phocarum*) from South Africa, presented by Mr. R. A. Robertson; a Common Heron (*Ardea cinerea*), a Cirl Bunting (*Emberiza cirlus*), British, a Banded Parrakeet (*Palæornis fasciatus*) from India, purchased; three Mute Swans (*Cygnus olor*), European, received in exchange; eight Brown-tailed Gerbilles (*Gerbillus erythyrurus*), born in the Gardens.

THE SIX GATEWAYS OF KNOWLEDGE[1]

I THANK you most warmly for the honour you have done me in electing me to be your president. I value the honour very highly; but when I look at the list of distinguished men who have preceded me in the office, I feel alarmed at the responsibility I have undertaken. A very pleasing duty, however, has been already performed in the interesting and not onerous function we have now gone through. I would gladly speak on the several subjects, for merit in the study of which these prizes have been awarded; but I am afraid that if I were to do so, it would be more for my own gratification than for your pleasure and profit, and I feel that I shall best consult your wishes in passing on at once to the subject of the address which it becomes my duty to give.

The title of the subject upon which I am going to speak this evening might be—if I were asked to give it a title—"The Six Gateways of Knowledge." I feel that the subject I am about to bring before you is closely connected with the studies for which the several prizes have been given. The question I am going to ask you to think of is: What are the means by which the human mind acquires knowledge of external matter?

John Bunyan likens the human soul to a citadel on a hill, self-contained, having no means of communication with the outer world, except by five gates—Eye Gate, Ear Gate, Mouth Gate, Nose Gate, and Feel Gate. Bunyan clearly was in want of a word here. He uses "feel" in the sense of "touch," a designation which to this day is so commonly used that I can scarcely accuse it of being incorrect. At the same time, the more correct and distinct designation undoubtedly is, the sense of touch. The late Dr. George Wilson, first Professor of Technology in the University of Edinburgh, gave, some time before his death, a beautiful little book under the title of "The Five Gateways of Knowledge," in which he quotes John Bunyan in the manner I have indicated to you. But I have said *six* gateways of knowledge, and I must endeavour to justify this saying. I am going to try to prove to you that we have six senses—that if we are to number the senses at all we must make them six.

The only census of the senses, so far as I am aware, that ever made them more than five before was the Irishman's reckoning of seven senses. I presume the Irishman's seventh sense was common sense; and I believe that the large possession of that virtue by my countrymen—I speak as an Irishman—I say the large possession of the seventh sense, which I believe Irishmen have, and the exercise of it, will do more to alleviate the woes of Ireland than even the removal of the melancholy ocean which surrounds its shores. Still I cannot scientifically see how we can make more than six senses. I shall, however, should time permit, return to this question of a seventh sense, and I shall endeavour to throw out suggestions towards answering the question—Is there, or is there not, a magnetic sense? It is possible that there is, but facts and observations so far give us no evidence that there is a magnetic sense.

The six senses that I intend to explain, so far as I can, this evening, are according to the ordinary enumeration, the sense of sight, the sense of hearing, the sense of smell, the sense of taste, and the sense of touch, divided into two departments. A hundred years ago Dr. Thomas Reid, Professor of Moral Philosophy in the University of Glasgow, pointed out that there was a broad distinction between the sense of roughness or of resistance, which was possessed by the hand, and the sense of heat. Reid's idea has not I think been carried out so much as it deserves. We do not, I believe, find in any of the elementary treatises on natural philosophy, or in the physiologists' writings upon the senses, a distinct reckoning of six senses. We have a great deal of explanation about the muscular sense, and the tactile sense; but we have not a clear and broad distinction of the sense of touch into two departments, which seems to me to follow from Dr. Thomas Reid's way of explaining the sense of touch, although he does not himself distinctly formulate the distinction I am now going to explain.

The sense of touch, of which the organ commonly considered is the hand, but which is possessed by the whole sensitive surface of the body, is very distinctly a double quality. If I touch any object, I perceive a complication of sensations. I perceive a certain sense of roughness, but I also perceive a very distinct sensation, which is not of roughness, or of smoothness. There are two sensations here, let us try to analyse them. Let me dip my hand into this bowl of hot water. The moment I touch the water, I perceive a very distinct sensation, a sensation of heat. Is that a sensation of roughness, or of smoothness? No. Again, I dip my hand into this basin of iced water. I perceive a very distinct sensation. Is this a sensation of roughness, or of smoothness? No. Is this comparable with that former sensation of heat? I say yes. Although it is opposite, it is comparable with the sensation of heat. I am not going to say that we have two sensations in this department—a sensation of heat, and a sensation of cold. I shall endeavour to explain that the perceptions of heat and of cold are perceptions of different degrees of one and the same quality, but that that quality is markedly different from the sense of roughness. Well now, what is this sense of roughness? It will take me some time to explain it fully. I shall therefore say in advance that it is a sense of force; and I shall tell you in advance, before I justify completely what I have to say, that the six senses, regarding which I wish to give some explanation, are: the sense of sight, the sense of hearing, the sense of taste, the sense of smell, the sense of heat, and the sense of force. The sense of force is the sixth sense; or the senses of heat and of force are the sense of touch divided into two, to complete the census of six that I am endeavouring to demonstrate.

Now I have hinted at a possible seventh sense—a magnetic sense—and though out of the line I propose to follow, and although time is precious, and does not permit much of digression, I wish just to remove the idea that I am in any way suggesting anything towards that wretched superstition of animal magnetism, and table-turning, and spiritualism, and mesmerism, and clairvoyance, and spirit-wrapping, of which we have heard so much. There is no seventh sense of the mystic kind. Clairvoyance, and the like, are the result of bad observation chiefly, somewhat mixed up, however, with the effects of wilful imposture, acting on an innocent, trusting mind. But if there is not a distinct magnetic sense, I say it is a very great wonder that there is not.

Many present know all about magnetism. A very large number of pupils have gained an immense amount of valuable knowledge in various subjects, from the classes carried on nightly within the walls of the Birmingham and Midland Institute; and I can see from the prizes that have been awarded, and that I have just now had the pleasure of distributing for excellence and proficiency in this department, that many have learned of magnetism. I had the pleasure of seeing the class-rooms this morning, and I wished I could be in them in the evening to see the studies as carried on in them every evening. Well now, the study of magnetism is the study of a very recondite subject. We all know a little about the mariner's compass, the needle pointing to the north, and so on; but not many of us have gone far into the subject, and not many of us understand all the recent discoveries in electromagnetism. I could wish, had I the apparatus here, and if you would allow me, to show you an experiment in magnetism. If we had before us a powerful magnet, or say the machine that is giving us this beautiful electric light by which the hall is illuminated, it, serving to excite an electromagnet, would be one part of our apparatus; the other part would be a piece of copper. Suppose then we had this apparatus, I would show you a very wonderful discovery made by Faraday and worked out admirably by Foucault, an excellent French experimenter. I have said that one part of this apparatus would be a piece of copper, but silver would answer as well. Probably no other metal than copper or silver—certainly no other one, of all the metals that are well known, and obtainable for ordinary experiments—possesses, and no other metal or substance, whether metallic or not, is known to possess, in anything like the same degree as copper and silver, the quality I am now going to call attention to.

The quality I refer to is "electric conductivity," and the result of that quality in the experiment I am now going to describe is, that a piece of copper or a piece of silver, let fall between the poles of a magnet, will fall down slowly as if it were falling through mud. I take this body and let it fall. Many of you here will be able to calculate what fraction of a second it takes to fall one foot. If I took this piece of copper, placed it just above the space between the poles of a powerful electromagnet and let it go, you would see it fall slowly down before you; it would perhaps take a quarter of a minute to fall a few inches.

This experiment was carried out in a most powerful manner by Lord Lindsay (now Lord Crawford), assisted by Mr. Cromwell F. Varley. Both of those eminent men desired to investigate the phenomena of mesmerism, which had been called animal magnetism; and they very earnestly set to work to make a real physical experiment. They asked themselves, Is it conceivable that, if a piece of copper can scarcely move through the air between the poles of an electromagnet, a human being or other living creature placed there would experience no effect? Lord Lindsay got an enormous electromagnet made, so large that the head of any person wishing to try the experiment could get well between the poles, in a region of excessively powerful magnetic force. What was the result of the experiment? If I were to say *nothing!* I should do it scant justice. The result was marvellous, and the marvel is that nothing was perceived. Your head, in a space through which a piece of copper falls as if through mud, perceives nothing. I say this is a very great wonder; but I do not admit, I do not feel, that the investigation of the subject is completed. I cannot think that the quality of matter in space which produces such a prodigious effect upon a piece of metal can be absolutely without any—it is certainly not without any—effect whatever on the matter of a living body; and that it can be absolutely without any *perceptible* effect whatever on the matter of a living body placed there seems to me not proved even yet, although nothing has been found. It is so marvellous that there should be no effect at all, that I do believe and feel that the experiment is worth repeating; and that it is worth examining, whether or not an exceedingly powerful magnetic force has any perceptible effect upon a living vegetable or animal body. I spoke then of a seventh sense. I think it just possible that there may be a magnetic sense. I think it possible that an exceeding powerful magnetic effect may produce a sensation that we cannot compare with heat or force or any other sensation.

---

[1] An Address at the Midland Institute, Birmingham, October 3, 1883, by Prof. Sir William Thomson, LL.D., F.R.S., president.

Another question that often occurs is, "Is there an electric sense?" Has any human being a perception of electricity in the air? Well, somewhat similar proposals for experiment might, perhaps, be made with reference to electricity; but there are certain reasons, that would take too long for me to explain, that prevent me from placing the electric force at all in the same category with magnetic force. There would be a surface action that would annul practically the force in the interior, there would be a definite sensation which we could distinctly trace to the sense of touch. Any one putting his hand, or his face, or his hair, in the neighbourhood of an electric machine perceives a sensation, and on examining it he finds that there is a current of air blowing, and his hair is attracted; and if he puts his hand too near he finds that there are sparks passing between his hand or face and the machine; so that, before we come to any subtle question of a possible sense of electric force, we have distinct mechanical agencies which give rise to senses of temperature and force; but that this mysterious, wonderful, magnetic force, due, as we know, to rotations of the molecules, could be absolutely without effect—without perceptible effect—on animal economy, seems a very wonderful result, and at all events it is a subject deserving careful investigation. I hope no one will think I am favouring the superstition of mesmerism in what I have said.

I intend to explain a little more fully our perceptions in connection with the double sense of touch—the sense of temperature and the sense of force—should time permit before I conclude. But I must first say something of the other senses, because if I speak too much about the senses of force and heat no time will be left for any of the others. Well, now, let us think what it is we perceive in the sense of hearing. Acoustics is one of the studies of the Birmingham and Midland Institute, of which we have heard many times this evening. Acoustics is the science of hearing. And what is hearing? Hearing is perceiving something with the ear. What is it we perceive with the ear? It is something we can also perceive without the ear; something that the greatest master of sound, in the poetic and artistic sense of the word at all events, that ever lived—Beethoven—for a great part of his life could not perceive with his ear at all. He was deaf for a great part of his life, and during that period were composed some of his grandest musical compositions, and without the possibility of his ever hearing them by ear himself; for his hearing by ear was gone from him for ever. But he used to stand with a stick pressed against the piano and touching his teeth, and thus he could hear the sounds that he called forth from the instrument. Hence, besides the Ear Gate of John Bunyan, there is another gate or access for the sense of hearing.

What is it that you perceive ordinarily by the ear—that a healthy person, without the loss of any of his natural organs of sense, perceives with his ear, but which can otherwise be perceived, although not so satisfactorily or completely? It is distinctly a sense of varying pressure. When the barometer rises, the pressure on the ear increases; when the barometer falls, that is an indication that the pressure on the ear is diminishing. Well, if the pressure of air were suddenly to increase and diminish, say in the course of a quarter of a minute—suppose in a quarter of a minute the barometer rose one-tenth of an inch and fell again, would you perceive anything? I doubt it; I do not think you would. If the barometer were to rise two inches, or three inches, or four inches, in the course of half a minute, most people would perceive it. I say this as a result of observation, because people going down in a diving bell have exactly the same sensation as they would experience if from some unknown cause the barometer quickly, in the course of half a minute, were to rise five or six inches—far above the greatest height it ever stands at in the open air. Well, now, we have a sense of barometric pressure, but we have not a continued indication that allows us to perceive the difference between the high and low barometer. People living at great altitudes—up several thousand feet above the level of the sea, where the barometer stands several inches lower than at sea-level—feel very much as they would do at the surface of the sea, so far as any sensation of pressure is concerned. Keen mountain air feels different from air in lower places, partly because it is colder and drier, but also because it is less dense, and you must breathe more of it to get the same quantity of oxygen into your lungs to perform those functions, which the students of the Institute who study animal physiology—and I understand there are a large number—will perfectly understand. The effect of the air in the lungs—the function it performs—depends chiefly on the oxygen taken in. If the air has only three quarters of the density it has in our ordinary atmosphere here, then one and one-third times as much must be inhaled, to produce the same oxidising effect on the blood, and the same general effect in the animal economy; and in that way undoubtedly mountain air has a very different effect on living creatures from the air of the plains. This effect is distinctly perceptible in its relation to health.

But I am wandering from my subject, which is the consideration of the changes of pressure comparable with those that produce sound. A diving bell allows us to perceive a sudden increase of pressure, but not by the ordinary sense of touch. The hand does not perceive the difference between 15 lbs. per square inch pressing it all around, and 17 lbs., or 18 lbs., or 20 lbs., or even 30 lbs. per square inch, as is experienced when you go down in a diving bell. If you go down five and a half fathoms in a diving bell, your hand is pressed all round with a force of 30 lbs. to the square inch; but yet you do not perceive any difference in the sense of force, any perception of pressure. What you do perceive is this: behind the tympanum, is a certain cavity filled with air, and a greater pressure on one side of the tympanum than on the other gives rise to a painful sensation, and sometimes produces rupture of it in a person going down in a diving bell suddenly. The remedy for the painful sensation thus experienced, or rather I should say its prevention, is to keep chewing a piece of hard biscuit, or making believe to do so. If you are chewing a hard biscuit, the operation keeps open a certain passage, by which the air pressure gets access to the inside of the tympanum, and balances the outside pressure and thus prevents the painful effect. This painful effect on the ear experienced by going down in a diving bell is simply because a certain piece of tissue is being pressed more on one side than on the other; and when we get such a tremendous force on a delicate thing like the tympanum, we may experience a great deal of pain, and it may be dangerous; indeed it is dangerous, and produces rupture or damage to the tympanum unless means be adopted for obviating the difference in the pressures; but the simple means I have indicated are, I believe, with all ordinary healthy persons, perfectly successful.

I am afraid we are no nearer, however, to understanding what it is we perceive when we hear. To be short it is simply this: it is exceedingly sudden changes of pressure acting on the tympanum of the ear, through such a short time and with such moderate force as not to hurt it; but to give rise to a very distinct sensation, which is communicated through a train of bones to the auditory nerve. I must merely pass over this; the details are full of interest, but they would occupy us far more than an hour if I entered upon them at all. As soon as we get to the nerves and the bones, we have gone beyond the subject I proposed to speak upon. My subject belongs to physical science;—what is called in Scotland, Natural Philosophy. Physical science refers to dead matter, and I have gone beyond the range whenever I speak of a living body; but we must speak of a living body in dealing with the senses as the means of perceiving—as the means by which, in John Bunyan's language, the soul in its citadel acquires a knowledge of external matter. The physicist has to think of the organs of sense, merely as he thinks of the microscope; he has nothing to do with physiology. He has a great deal to do with his own eyes and hands, however, and must think of them, if he would understand what he is doing, and wishes to get a reasonable view of the subject, whatever it may be, which is before him in his own department.

Now what is the external object of this internal action of hearing and perceiving sound? The external object is a change of pressure of air. Well, how are we to define a sound simply? It looks a little like a vicious circle, but indeed it is not so, to say it is sound if we call it a sound—if we perceive it as sound, it *is* sound. Any change of pressure, which is so sudden as to let us perceive it as sound is a sound. There [giving a sudden clap of the hands]—that is a sound. There is no question about it—nobody will ever ask, Is it a sound or not? It is sound if you hear it. If you do not hear it, it is not to you a sound. That is all I can say to define sound. To explain what it is, I can say, it is change of pressure, and it differs from a gradual change of pressure as seen on the barometer only in being more rapid, so rapid that we perceive it as a sound. If you could perceive by the ear, that the barometer has fallen two-tenths of an inch to day, that would be sound. But nobody hears by his ear that the barometer has fallen, and so he does not perceive the fall as a sound. But the same difference of pressure coming on us suddenly—a fall of the barometer, if by any means it could happen, amounting to a tenth of an inch, and taking place in a thousandth of a second,—would affect us quite like sound. A sudden rise of the barometer would produce a sound analogous to what happened when I clapped my hands. What is the difference between a noise and a musical sound? Musical sound is a regular and periodic change of pressure. It is an alternate augmentation and diminution of air pressure, occurring rapidly enough to be perceived as a sound, and taking place with perfect regularity, period after period. Noises and musical sounds merge into one another. Musical sounds have a possibility at least of sometimes ending in a noise, or tending too much to a noise, to altogether please a fastidious musical ear. All roughness, irregularity, want of regular, smooth periodicity, has the effect of playing out of tune, or of music that is so complicated that it is impossible to say whether it is in tune or not.

But now, with reference to this sense of sound, there is something I should like to say as to the practical lesson to be drawn from the great mathematical treatises which were placed before the British Association, in the addresses of its president, Prof. Cayley, and of the president of the mathematical and physical section, Prof. Henrici. Both of these professors dwelt on the importance of graphical illustration, and one graphical illustration of Prof. Cayley's address may be adduced in respect of this very quality of sound. In the language of mathematics we have just "one independent variable" to deal with in sound, and that is air pressure. We have not a complication of motions in various directions. We have not the complication that we shall have to think of presently, in connection with the sense of force; complication as to the place of application, and the direction, of the force. We have not the infinite complications we have in some of the other senses, notably smell and taste. We have distinctly only one thing to consider, and that is air pressure or the variation of air pressure. Now when we have one thing that varies, that, in the language of mathematics, is "one independent variable." Do not imagine that mathematics is harsh, and crabbed, and repulsive to common sense. It is merely the etherealisation of common sense. The function of one independent variable that you have here to deal with is the pressure of air on the tympanum. Well now in a thousand counting houses and business offices in Birmingham and London, and Glasgow, and Manchester, a curve, as Prof. Cayley pointed out, is regularly used to show to the eye a function of one independent variable. The function of one independent variable most important in Liverpool perhaps may be the price of cotton. A curve showing the price of cotton, rising when the price of cotton is high, and sinking when the price of cotton is low, shows all the complicated changes of that independent variable to the eye. And so in the Registrar-General's tables of mortality, we have curves showing the number of deaths from day to day—the painful history of an epidemic, shown in a rising branch, and the long gradual talus in a falling branch of the curve, when the epidemic is overcome, and the normal state of health is again approached. All that is shown to the eye; and one of the most beautiful results of mathematics is the means of showing to the eye the law of variation, however complicated, of one independendent variable. But now for what really to me seems a marvel of marvels: think what a complicated thing is the result of an orchestra playing—a hundred instruments and two hundred voices singing in chorus accompanied by the orchestra. Think of the condition of the air, how it is lacerated sometimes in a complicated effect. Think of the smooth gradual increase and diminution of pressure—smooth and gradual, though taking place several hundred times in a second—when a piece of beautiful harmony is heard! Whether, however, it be the single note of the most delicate sound of a flute, or the purest piece of harmony of two voices singing perfectly in tune; or whether it be the crash of an orchestra, and the high notes, sometimes even screechings and tearings of the air, which you may hear fluttering above the sound of the chorus—think of all that, and yet that is not too complicated to be represented by Prof. Cayley, with a piece of chalk in his hand, drawing on the blackboard a single line. A single curve, drawn in the manner of the curve of prices of cotton, describes all that the ear can possibly hear, as the result of the most complicated musical performance. How is one sound more complicated than another? It is simply that in the complicated sound the variations of our one independent variable, pressure of air, are more abrupt, more sudden, less smooth, and less distinctly periodic, than they are in the softer, and purer, and simpler sound. But the superposition of the different effects is really a marvel of marvels; and to think that all the different effects of all the different instruments can be so represented! Think of it in this way. I suppose everybody present knows what a musical score is—you know, at all events, what the notes of a hymn tune look like, and can understand the like for a chorus of voices, and accompanying orchestra—a "score" of a whole page with a line for each instrument, and with perhaps four different lines for four voice parts. Think of how much you have to put down on a page of manuscript or print, to show what the different performers are to do. Think, too, how much more there is to be done than anything the composer can put on the page. Think of the expression which each player is able to give, and of the difference between a great player on the violin and a person who simply grinds successfully through his part; think, too, of the difference in singing, and of all the expression put into a note or a sequence of notes in singing that cannot be written down. There is, on the written or printed page, a little wedge showing a diminuendo, and a wedge turned the other way showing a crescendo, and that is all that the musician can put on paper to mark the difference of expression which is to be given. Well now, all that can be represented by a whole page or two pages of orchestral score, as the specification of the sound to be produced in say ten seconds of time, is shown to the eye with perfect clearness by a single curve on a riband of paper a hundred inches long. That to my mind is a wonderful proof of the potency of mathematics. Do not let any student in this Institute be deterred for a moment from the pursuit of mathematical studies by thinking that the great mathematicians get into the realm of four dimensions, where you cannot follow them. Take what Prof. Cayley himself, in his admirable address, which I have already referred to, told us of the beautiful and splendid power of mathematics for etherealising and illustrating common sense, and you need not be disheartened in your study of mathematics, but may rather be reinvigorated when you think of the power which mathematicians, devoting their whole lives to the study of mathematics, have succeeded in giving to that marvellous science.

(*To be continued.*)

THE GEOLOGICAL POSITION OF THE HUMAN SKELETON FOUND AT TILBURY

IN a paper on this subject read by Mr. T. V. Holmes, F.G.S., at the meeting of the Essex Field Club on Saturday, February 23, at Buckhurst Hill, the author pointed out that the Tilbury skeleton was found in recent alluvium. The section at

Tilbury, consisting of blue clay with peaty bands, above sand and gravel, strongly resembles those given by Prof. Sollas of the alluvial deposits of the estuary of the Severn; the amount of subsidence, as shown by the present position of the lower peaty band, being also nearly the same. Mr. Holmes considered the notions promulgated in the brief newspaper reports regarding the antiquity of the remains to be entirely misleading. If any strata were entitled to be styled "recent," those at Tilbury must be so; for their deposition would now be going on but for the embankment of the Thames during the Roman occupation of Britain. Yet the newspaper reports described these beds by the extremely vague term "Pleistocene," while the skeleton was styled "Palæolithic." The remains of man, however, have been found in alluvial deposits fifty feet above the present level of the Thames, and remains found in such beds must be immensely more ancient than any discovered in recent alluvium. Geological position furnishes the only absolute test of relative age. The test of association with extinct mammalia is largely dependent on negative evidence. A hint on this point was given by the results of the drainage of Haarlem Lake thirty years ago. Excellent sections were made in all directions across its bed, and carefully examined by skilled geologists. Hundreds of men were known to have perished in its waters three centuries before, and it had always been the centre of a considerable population. Yet no human bones were found, though works of art were. Thus hundreds or even thousands of mammalia, incapable of producing works of art, might be interred in particular strata, and yet leave no signs whatever of their former existence two or three centuries afterwards. And, on the other hand, were extinct mammalia present in the Tilbury Dock beds no additional antiquity would thereby be conferred on the beds themselves, but the period at which the animals became extinct would be shown to be later than had been supposed. Similarly as regards the rude implements known as Palæolithic; their presence could confer no antiquity on recent beds. Still, as the skeleton was found thirty-two feet below the surface, in alluvium that has received no additions since Roman times, it is unquestionably prehistoric. And the extreme rarity of prehistoric human skeletons gives to this discovery an interest greater than could have been claimed for that of a bushel of flint implements. The age of the Tilbury skeleton may possibly be not far removed from that of the Neanderthal man, to which it is said to have a strong resemblance: a resemblance which, if as great as it is stated to be, goes far to show that we have in each a normal type of prehistoric man.

At the same meeting a communication from Mr. Worthington G. Smith was read. Mr. Smith stated that he had seen the skeleton, and specimens of the sand in which it was found. Palæolithic sands with fossil bones and stone implements occur about a mile to the north of Tilbury, and with these Mr. Smith was well acquainted. The Palæolithic sand is quite different in colour from the Tilbury sand, and the former swarms with fossil shells of land and freshwater mollusks. As far as could be seen no such shells were present in the Tilbury sand sent to the British Museum. Mr. Smith's specimens of fossil bones from the Palæolithic sand were in an entirely different mineral condition from the bones of the Tilbury skeleton, and he could trace no resemblance whatever either in sand or bones. Mr. Smith made this statement with great deference to the opinion of Sir Richard Owen, and confessed that a Palæolithic skeleton might have been washed from the high ground to the low, and got into the mineral state of the Tilbury skeleton, although at present there was no evidence of anything of the sort having taken place. His opinion was that there was no proof of the Palæolithic age of the Tilbury relic.

NOTES ON THE VOLCANIC ERUPTION OF MOUNT ST. AUGUSTIN, ALASKA, OCTOBER 6, 1883[1]

On the western side of the entrance to Cook's Inlet (forty-five miles wide) lies Cape Douglas; and to the northward of the cape the shore recedes over twenty miles, forming the Bay of Kamishak. In the northern part of this bay lies the Island of Chernaboura ("black-brown"), otherwise called Augustin Island. It is eight or nine miles in diameter, and near its north-eastern part rises to a peak, called by Cook Mount St. Augustin. As laid down by Tebenkoff, the island is nearly round. The northern shores are high, rocky, and forbidding, and are bordered by vast numbers of rocks and hidden dangers. The southern shore is comparatively low.

Mount St. Augustin was discovered and named by Capt. Cook, May 26, 1778; and he describes it as having "a conical figure, and of very considerable height." In 1794 Puget describes it as—

"A very remarkable mountain, rising with a uniform ascent from the shores to its lofty summit, which is nearly perpendicular to the centre of the island, inclining somewhat to its eastern side. . . . Towards the seaside it is very low, from whence it rises, though regular, with a rather steep ascent, and forms a lofty, uniform, and conical mountain, presenting nearly the same appearance from every point of view, and clothed with snow and ice, through which neither tree nor shrub were seen to protrude; so that, if it did produce any, they must either have been very small, or the snow must have been sufficiently deep to have concealed them."

At that time there were native hunters, under the direction of two Russians, hunting or living in the vicinity of the north-eastern point of the island.

Vancouver placed the peak of this mountain in latitude 59° 22′; Tebenkoff places it in latitude 59° 24′.

The peak of St. Augustin is distant forty-nine miles nearly due west (true) from the settlement on the southern point of Port Graham, or, as it is sometimes called, English Harbour. This harbour is situated on the eastern side of Cook's Inlet, near Cape Elizabeth.

In connection with the fall of pumice-dust at Iliuliuk on October 16, 1883, it may be of interest to observe that the peak of Augustin is over 700 miles to the north-eastward of Bogosloff Island off Unalashka.

About eight o'clock on the morning of October 6, 1883, the weather being beautifully clear, the wind light from the south-westward (compass), and the tide at dead low water, the settlers and fishing parties at English Harbour heard a heavy report to windward (Augustin bearing south-west by west three-fourths west by compass). So clear was the atmosphere that the opposite or north-western coast of the inlet was in clear view at a distance of more than sixty miles.

When the heavy explosion was heard, vast and dense volumes of smoke were seen rolling out of the summit of St. Augustin, and moving to the north-eastward (or up the inlet) under the influence of the lower stratum of wind; and, at the same time (according to the statements of a hunting-party of natives in Kamishak Bay), a column of white vapour arose from the sea near the island, slowly ascending, and gradually blending with the clouds. The sea was also greatly agitated and boiling, making it impossible for boats to land upon or to leave the island.

From English Harbour (Port Graham) it was noticed that the columns of smoke, as they gradually rose, spread over the visible heavens, and obscured the sky, doubtless under the influence of a higher current (probably north or north-east). Fine pumice-dust soon began to fall, but gently, some of it being very fine, and some very soft, without grit.

At about 8.25 a.m., or twenty-five minutes after the great eruption, a great "earthquake-wave," estimated as from twenty-five to thirty feet high, came upon Port Graham like a wall of water. It carried off all the fishing-boats from the point, and deluged the houses. This was followed at intervals of about five minutes, by two other large waves, estimated at eighteen and fifteen feet; and during the day several large and irregular waves came into the harbour. The first wave took all the boats into the harbour, the receding wave swept them back again to the inlet, and they were finally stranded. Fortunately it was low water, or all of the people at the settlement must inevitably have been lost. The tides rise and fall about fourteen feet.

These earthquake-waves were felt at Kadiak, and are doubtless recorded on the register of the Coast Survey tide-gauge at that place. Also the pumice-ashes fell to the depth of four or five inches, and a specimen of the deposit was given to the tidal observer at St. Paul. It will be interesting to compare these ashes with those collected at Iliuliuk on October 16, and which, from a confusion of dates, were supposed to have come from the new Bogosloff volcanic island. I am of the opinion that they came from St. Augustin.

The condition of the Island of Augustin or Chernaboura, according to the latest accounts, is this:—

At night, from a distance of fifty or sixty miles, flames can be seen issuing from the summit of the volcano; and in the daytime vast volumes of smoke roll from it. Upon nearer approach from English Harbour it was found that the mountain had been split in two from peak to base by a great rupture extending across it from east to west, and that the northern slope of the mountain had sunk away to the level of the northern cliff.[1] This is corroborated by the statement of the hunting-party in Kamishak Bay. Smoke issued from the peak at a very short distance to the southward of the rupture.

---

[1] From *Science*.

The party of natives on Kamishak did not approach the islet, though they gave clear and distinct accounts of its eruption and subsequent appearance; but Capt. C. T. Sands, who was at English Harbour, gave the Alaska Company a full description; and Capt Cullie, of the *Kodiak*, states that, if there were plenty of water in the line of rupture, it would be possible for a vessel to sail through. At the time of Capt. Sands' observations the low ground of the island was visible, and seemed to be a vast crater, from which smoke and flames were issuing.

But beyond all these phenomena, apart from the volcanic eruption and the rupture of the island, we have the report of Capt. Cullie, of the schooner *Kodiak* (from whom we also obtain a statement in regard to the rupture), who approached the island from English Harbour on November 10, and found that a new island about a mile and a half long and seventy-five feet high, had been upheaved in the ten-fathom passage between Augustin and the mainland to the westward. This passage is from six to eight miles wide, and was sailed through by Puget in Vancouver's voyages of discovery.

This new island (also reported by the hunting-party in Kamishak) would appear to have arisen during the late volcanic activity. It lies to the north-westward of Chernaboura Island (Augustin), and was distinctly seen from the *Kodiak*, as that vessel lay ten miles to the north-eastward, and had clear weather.

To show the violence of the volcanic convulsions at this time, two extinct volcanoes on the Alaska peninsula, which are reported to be about west (true) from the active volcano Ilianna (twelve thousand feet high), had burst into activity; and during the day volumes of smoke were distinctly seen, and columns of flame at night. Usually, at that season, Augustin and the peak are covered with deep snow. On November 10, however, when Capt. Cullie approached the island, while there was a depth of four feet of snow at Port Graham (English Harbour), Mount St. Augustin was bare and black.

GEORGE DAVIDSON,
Assistant U.S. Coast and Geodetic Survey

THE ORIGIN OF THE SCENERY OF THE BRITISH ISLANDS[2]

THE Plains of Britain, like those elsewhere, must be regarded as local base-levels of denudation, that is, areas where, on the whole, denudation has ceased, or at least has become much less than deposit. Probably in all cases the areas they occupy have been levelled by denudation. Usually a greater or less depth of detrital material has been spread over them, and it is the level surface of these superficial accumulations that forms the plain. But in some instances, such as the flats of the Weald Clay and the Chalk of Salisbury Plain, there is hardly any such cover of detritus, the denuded surface of underlying rock forming the actual surface of the plain. Our plains, if classed according to the circumstances of their origin, may be conveniently regarded as (1) river plains—strips of meadow-land bordering the streams, and not infrequently rising in a succession of terraces to a considerable height above the present level of the water; (2) lake plains—tracts of arable ground occupying the sites of former lakes, and of which the number is ever on the increase; (3) marine plains—mostly flat selvages of alluvial ground, formed of materials originally laid down as a littoral marine deposit when the land lay below its present level: in the northern estuaries these up-raised sea-beds spread out as broad carse-lands, such as those of the Tay, Forth, and Clyde; (4) glacial drift plains—tracts over which the clays, sands, and gravels of the Ice Age form the existing surface; (5) submarine plains—the present floor of the North Sea and of the Irish Sea, which must be regarded as essentially part of the terrestrial area of Europe.

When plains remain stationary in level, they may continue for an indefinite period with no material change of surface. But, should they be upraised, the elevation, by increasing the slope of the streams, augments their erosive power, and enables them once more to deepen their channels. Hence, plains like that of the New Forest, which have been deeply trenched by the water-courses that traverse them, may with probability be assigned to a time when the land stood at a lower level than it occupies at present. In this connection the successive river-terraces of the country deserve attention. They may be due not to the mere unaided work of the rivers, but to the cooperation of successive uplifts. It would be an interesting inquiry to correlate the various river-terraces throughout the country, for the purpose of discovering whether they throw any light on the conditions under which the most recent uprise of the country took place. That the elevation proceeded intermittently, with long pauses between the movements, is shown by the succession of raised beaches. It may be possible to establish a somewhat similar proof among our river-terraces.

The submarine plains are by far the most extensive within the British area. In the case of the North Sea the tendency of tidal scour and deposit must modify the form of the bottom. This great basin of water is obviously being slowly filled up by the deposit of sediment over its floor. A vast amount of mud and silt is borne into it by the rivers of Western Europe, as well as by those that drain the eastern and larger part of Britain, and the sea itself is cutting away the land on both sides and swallowing up the waste. We have only to contrast the colour of the Atlantic on the west of Ireland or Scotland with that of the North Sea to be assured of the wide diffusion of fine mud in the water of the latter. There is practically no outlet for the detritus that is thus poured into the basin of the North Sea. From the north a vast body of tidal water enters between Scotland and Norway, and travelling southward, aided by the strong northerly winds, sweeps the detritus in the same direction. On the other hand, another narrower and shallower tidal stream enters from the Strait of Dover, and, aided by the south-west winds, drives the sediment northward. Yet, making every allowance for the banks and shoals which this accumulating deposit has already formed, we can still, without much difficulty, recognise the broader features of the old land-surface that now lies submerged beneath the North Sea. It presents two plains, of which the southern has an average level of perhaps a little more than 100 feet below the surface of the water. This upper plain ends northward in a shelving bank, probably the prolongation of the Jurassic escarpment of Yorkshire, and is succeeded by the far wider northern plain, which lies from 100 to 150 feet lower, and gradually slopes northward. As mentioned in a previous lecture, the drainage-lines of the united Rhine, Thames, &c, on the one side, and the Elbe, Weser, &c., on the other, can still be partially traced on the sea-floor. The Irish Sea was probably, in its later history, a plain dotted with lakes. It appears to have been submerged before the whole of the present fauna and flora had reached Ireland.

Some of the most characteristic and charming scenery of the British Islands is to be found along their varied sea-board. Coast-scenery appears to depend for its distinctive features upon (1) the form of the ground at the time when by emergence or submergence the present level was established; (2) the composition and structure of the shore-rocks; (3) the direction of the prevalent winds, and the relative potency of subaërial and marine denudation. The British coast-line presents three distinct phases: in many places it is retreating; in others it is advancing; while in a few it may be regarded as practically stationary. As examples of retreat, the shores of a large part of the east of England may be cited. In Holderness, for instance, a strip of land more than a mile broad has been carried away during the last eight centuries. Even since the Ordnance Survey maps were published, thirty-three years ago, somewhere about 500 feet have in some places been removed, the rate of demolition being here and there as much as five yards in a year. The advance of the coast takes place chiefly in sheltered bays, or behind or in front of projecting headlands and piers, and is due in large measure to the deposit of material which has been removed by the sea from adjoining shores. The amount of land thus added does not compensate for the quantity carried away, so that the total result is a perceptible annual loss. The best examples of a stationary coast-line where there is no appreciable erosion by the waves and no visible accumulation of detritus, are to be found among the land-locked fjords or inlets of the west coast of Scotland. In these sheltered recesses the smoothed striated rocks of the Ice Age slip under the sea, with their characteristic glaciated surfaces still so fresh that it is hard to believe that a long lapse of ages has passed away since the glaciers left them.

---

[1] Capt. Cullie's account.

[2] Abstract of fifth and concluding lecture by Archibald Geikie, F.R.S., Director-General of the Geological Survey, given at the Royal Institution, March 3. Continued from p. 420.

The remarkable contrast between the scenery of the eastern and western coast-line of the British Islands arises partly from the preponderance of harder rocks on the west than on the east side, but probably in large measure upon the greater extent of the submergence of the western sea-board, whereby the sea has been allowed to penetrate far inland by fjords which were formerly glens and open valleys. The details of coast-scenery vary with the rock in which they are developed. Nowhere can the effects of each leading type of rock upon landscape be more instructively studied than along the sea-margin. As distinct types of coast-scenery, reference may be made to sea-cliffs and rocky shores of granite, gneiss, basalt, massive sandstone and flagstone, limestone, alternations of sandstone shale or other strata, and boulder-clay, and to the forms assumed by detrital accumulations such as sand-dunes, shingle-banks, and flats of sand or mud.

The concluding portion of the lecture was devoted to an indication of the connection between the scenery of a country and the history and temperament of the people. This subject was considered from four points of view, the influence of landscape and geological structure being traced in the distribution of races, in national history, in industrial and commercial progress, and in national temperament and literature.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The proposal to allow women to enter for the same honour examinations as men met with less opposition in Congregation than was generally anticipated. By 100 votes to 46 the statute was passed by Congregation permitting women to enter for both Classical and Mathematical Moderations, and for the final Schools of History, Mathematics, and Natural Science. On March 11 the statute will come before Convocation, and will in all probability be passed.

In a Convocation held on March 4 a decree was passed authorising the Professors of Anatomy and Physiology to engage a table for the use of students of the University at the Zoological Station at Villefranche. The anti-vivisectionists were demonstrative, but did not divide the House.

The Professor of Medicine gives notice that the Testamurs for Chemistry and Physics in the Preliminary Honour Examination excuse candidates from the Chemistry and Physics Examination in the First M.B., but that the Testamurs for Chemistry and Physics in the Pass School are not recognised. Candidates may take up Chemistry and Physics separately from Anatomy and Physiology.

An examination will be held at Keble College on March 18 to elect a Scholar in Natural Science. Candidates may offer Chemistry and Biology.

CAMBRIDGE.—Plans have been obtained for the building of a new foundry and a temporary lecture-room and museum for the Department of Mechanism, suitable eventually for additional workshops. The cost is to be 450*l*. The number of pupils in this department has now increased to fifty-seven.

Plans have also been prepared for the new botanical class-rooms for microscopic work, the estimated cost being 1065*l*.

Messrs. E. C. Ames, B.A., B. H. Bent, and J. H Nicholl, B.A., have been appointed Demonstrators of Mechanism and Applied Mechanics.

The following Colleges hold Examinations for Open Scholarships in Natural Sciences on the respective dates mentioned:—Clare, March 18; Jesus, March 13; Downing, June 10; Cavendish, August 6. For particulars, application should be made to the tutors of the Colleges. A Clothworkers' Exhibition in Physical Science, tenable either at Oxford or at Cambridge, will be awarded in July. Information may be obtained from the Censor of Non-Collegiate Students, Cambridge.

SCIENTIFIC SERIALS

Journal of Botany.—The number for February commences with the first part of an important paper by Mr. Thomas Hick on protoplasmic continuity in the Florideæ. The connection of protoplasm from cell to cell has now been established in a number of instances in the vegetable kingdom. It may be seen with very great ease, as described and drawn by Mr. Hick, in the frond of some of the red seaweeds, as *Polysiphonia* and *Callithamnion*, without any chemical reagent, except one that causes a slight contraction.—Mr. Carruthers contributes a useful paper on the mode of distinguishing the seed of the sweet vernal grass, *Anthoxanthum odoratum*, from that of *A. Puelii*, an annual species with which it is often adulterated by seed-growers.

THE last part (vol. iii. heft 3) of Cohn's *Beiträge zur Biologie der Pflanzen* contains two important cryptogamic papers: one by E. Eidam, on the development of the Ascomycetes, in which two new forms are described; the other, by M. Franke, describing an interesting new genus of parasitic algæ, *Endoclonium*, dimorphic, and growing on decaying fronds of *Lemna gibba*.

Journal of the Russian Chemical and Physical Society, vol. xv. fasc. 9.—On the action of the hydrocarbons of the acetylene series upon oxide of mercury and its salts, by M. Kutscheroff. —Thermic data of pyrosulphuryl, by D. Konovaloff. The heat of formation of a molecule of $S_2O_5Cl_2$ from its elements in a gaseous state is equal to 180·6 calories.—On a hydrate of silicium obtained from cast iron, by G. Zabudsky.—On the characters of the infra-molecular force, by M. Bardsky (second article).—On electrolytic light, by N. Sloughinoff, being an experimental and mathematical inquiry into the light disengaged during the electrolysis of liquids at one of the electrodes: historical sketch of the subject; instruments employed; the laws of the extra-currents of Edlund; light disengaged in a water solution of sulphuric acid, and dependence of it upon the number of elements in the battery; oscillations of the force of the current; experiments with a rotating glass; wearing of the electrodes; spectrum; light in the acid solutions of salts; on the resistance, the electro-spheroidal state, and the heat disengaged; the oscillating currents.—On the theory of the curved nets, by A. Sokoloff.

Atti della R. Accademia dei Lincei, Rome, October 18 and 19, 1883.—On the alterations undergone by the red globules of the blood in malarious infections, by Prof. Ettore Marchiafava. —Meteorological observations made at the Royal Observatory of the Campidoglio during the months of August, September, and October, 1883.

December 2.—Remarks on Dr. F. Mercanti's memoir on the cilian muscle in reptiles, by Signor Moriggia.—On the alterations in the red globules of the blood in malarious infections, by S. Todaro.—Report on Prof. E. Millosevich's memoir on the diameter of Uranus, by S. Respighi.—On the molecular velocities of gaseous bodies, by A. Violi.—Note on fluorbenzine and fluorotoluine, by P. Emmuele and O. Vincenzo.—A new series of compounds of titanium, by A. Piccini.—On the transformation of the fluorbenzoic acids in the animal organism, by F. Coppola.—A study of the resins of *Thapsia garganica*, by Fr. Canzoneri.—On a new species of Salpa (*S. dolicosoma*), by Fr. Todaro).—Observations on the Pons-Brooks comet, by Pietro Tacchini.—On the unipolar induced electric current and nervous excitement, by G. Magini.—Archæological discoveries at Angera, Peschiera, Viterbo, Rome, Sulmona, and in other parts of Italy, from June to October, 1883.—S. Sella and S. Mamiani were elected president and vice-president for the ensuing four years, 1884-7.

Rivista Scientifico-Industriale, Florence, November 15-30, 1883.—Further applications of the nephoscope invented by Filippo Cecchi (four illustrations).—Description of a new electro-magnet recently exhibited before the Society of Natural and Economical Sciences at Palermo, by Prof. A. Riccò.—An account of some of the important results already obtained in the Acclimatisation Garden established ten years ago by General Vincenzo Ricasoli at Portercole, by G. Arcangeli. Amongst the exotics here successfully reared are *Cocos flexuosa*, *Calorica borbonica*, *Phœnix reclinata*, *Boldea fragrans*, *Citharexylon reticulatum*, *Casuarina quadrivalvis*, *Edwardsia grandiflora*, *Eugenia australis*, *Ficus elastica*, *Picconia fragrans*, besides numerous species of *Bignonia*, *Agave*, *Acacia*, and *Eucalyptus*, and other Australian plants.

Rendiconti del R. Istituto Lombardo, Milan, December 13, 1883.—On the distinctions observed in criminal law between the authors and accomplices in a felony, by Prof. A. Buccellati.—Inquiry into the nature of the underground disturbances that occurred at Ischia on July 28, 1883, by Prof. A. Serpieri.—On numbers irreducible by complex numbers, by Prof. C. Formenti. —On some forms of right lines produced by two reciprocal stars, by Prof. F. Aschieri.—Meteorological observations made at the Brera Observatory, Milan, during the months of October and November, 1883.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, February 14.—"On a New Reflecting Galvanometer of Great Sensibility, and on New Forms of Astatic Galvanometers." By Thomas Gray, B.Sc., F.R.S.E., and Andrew Gray, M.A., F.R.S.E. Communicated by Sir William Thomson, F.R.S.

The paper describes first a very sensitive galvanometer, of novel construction, which the authors have had made, with aid from the Government Research Fund, for their experiments on the electric resistance of glass and allied substances. It consists of two pairs of coils with hollow cores, arranged so that the axes of each pair are parallel and in a vertical plane, which act on a needle-system, consisting of two horse-shoe magnets of thin steel wire connected by a very light frame of aluminium, and hung with their planes vertical, so that a horse-shoe corresponds to each pair of coils and has its poles within the hollow cores. In the instrument constructed each pair of coils is carried by a vertical brass plate, and these two plates are set so as to make an angle with one another of about 106°. A line drawn from the suspension thread (a single fibre of silk) to a point near a pole of either of the needles, when the needles are at the same distance within both pairs of coils, is nearly at right angles to the axis of the coil, and the motion of the needle for small deflections is nearly along the axis. The needles enter the coils from the same side, and the current is usually sent through the coils, so that one pair cause their horse-shoe to move outwards and the other pair their horse-shoe to move inwards, thus turning the needle-system round the suspension fibre. A mirror fixed to the aluminium connecting-bar gives a measure of the deflection in the ordinary manner. This system of needles, when rightly adjusted, is practically astatic in a magnetic field of uniform intensity.

A magnet (or system of magnets) is generally arranged to give a differential field at the upper and lower ends of the needles, which are usually placed with unlike poles turned in similar directions; but any magnetic system may be employed to give directive force in the proper manner and degree for a particular purpose or arrangement.

Another form of the instrument is described in which the coils are all in one plane, and the connecting aluminium bar carrying the horse-shoe needles passes through the plate in which the coils are set from one side to the other, so that one horse-shoe enters its pair of coils from one side, and the other horse-shoe from the other side. When the needle-system is deflected thus, both needles are pushed out of the coils or both pulled in.

By the method of arranging the needles and coils adopted in these instruments the current is made, when the hollow cores are made small, to act very advantageously on the needles, and hence in great measure their high sensibility. By attaching to the suspended system a small needle to give directive force in a uniform field, the great magnetic moment and leverage of the horse-shoes may be taken advantage of.

The paper then describes a new and very compact form of distributing plate, by means of which a multiple coil galvanometer, or one in which the coil is wound in sections, may be connected in any desired manner to vary its resistance or its sensibility.

Finally, two forms of instrument are described, in which two perfectly vertical and straight needles connected together rigidly by bars of aluminium are used to give a perfectly astatic system, not disturbed by the magnetising or demagnetising action of neighbouring magnets, a result the authors think practically unattainable in any arrangement of horizontal needles. Two vertical needles, with their upper ends in the position occupied by the upper needle of a so-called astatic galvanometer, and their lower ends in the position of the lower needle, experience, if their like poles are turned in dissimilar directions, a similar electromagnetic action to that in the horizontal needles; and the authors propose when convenient to use such an arrangement instead of the ordinary needle system.

Also a pair of vertical needles may be used instead of the horse-shoe needles described above, the coils being so placed as to act advantageously, and give a convenient arrangement of the parts of the instrument.

Geological Society, February 15.—Annual General Meeting.—J. W. Hulke, F.R.S., president, in the chair.—The Secretaries read the Reports of the Council and of the Library and Museum Committee for the year 1883. In the former the Council congratulated the Fellows upon an improvement in the state of the Society's affairs since the date of their last Report, the income of the Society having been greater, and its expenditure less, in 1883 than in 1882, while, although the removal from the list of the names of twelve Fellows whose addresses were unknown, and whose election dated back before the incorporation of the Society in 1826, had produced an apparent loss of three Fellows during the year, the Society might really be regarded as having received an increase of nine Fellows. The increase in the number of contributing Fellows was twenty-two. The Council's Report further announced the awards of the various Medals and of the proceeds of the Donation Funds in the gift of the Society.

In presenting the Wollaston Gold Medal to Prof. A. Gaudry, F.M.G.S., the President addressed him as follows:—"Prof. A. Gaudry,—The Council of the Geological Society has awarded you the Wollaston Medal in recognition of the value of your palæontological researches and the important scientific generalisations you have deduced from long and laborious observations. The numerous papers on topographical geology and on palæontology you have contributed during the past thirty years, your important 'Recherches Scientifiques en Orient entreprises par les ordres du Gouvernement pendant les années 1853–1854,' your 'Animaux fossiles et géologie de l'Attique,' and, lastly, your work 'Les Enchaînements du monde animal dans les temps géologiques,' have made your name so familiar, wherever our branch of natural science is cultivated, that in receiving you we feel we are not receiving a stranger, but a scientific brother, and one who, by his labours and singleness of aim, has achieved a position as a palæontologist such as few can hope to attain. Personally it affords me great and sincere pleasure that it has fallen to my lot to hand you this medal, which, by the consent of all, has never been more worthily bestowed."

The President then presented the balance of the proceeds of the Wollaston Donation Fund to Mr. E. Tulley Newton, F.G.S., and addressed him as follows:—"Mr. Newton,—The Council has voted you the balance of the proceeds of the Wollaston Donation Fund, in recognition of the value of your researches amongst the Pleistocene Mammalia of Great Britain, and to assist you in the prosecution of further investigations. Your memoirs published by the Geological Survey of England and Wales, 'On the Vertebrata of the Forest-bed Series of Norfolk and Suffolk,' and on 'The Chimæroid Fishes of the Cretaceous Rocks,' and your papers published in our *Journal* are considered by the Council to evince great merit; they regard them as a bright earnest of future work which they hope may be promoted by this award."

In presenting the Murchison Medal to Dr. Henry Woodward, F.R.S., the President said: "Dr. Henry Woodward,—The Council has awarded you the Murchison Medal and a grant of ten guineas in recognition of your valuable researches into the structure and classification of the fossil Crustacea, especially of the Merostomata and Trilobita, and your services to the progress of geology in Great Britain by your conduct of the *Geological Magazine* for nearly twenty years. Your monograph on the 'Merostomata,' published by the Palæontographical Society, and your 'Catalogue of British Fossil Crustacea, with their synonyms and the range in time of each genus and order,' will long continue to be works of reference indispensable to every student of these interesting life-forms. But valuable as are these written records, they discover but a small part of the services you have rendered in the advancement of our science. How much more you have done by the assistance you have so freely given to all who have sought your help at the Museum in deciphering some difficult matters in palæontology will never be fully known."

The President then handed the balance of the proceeds of the Murchison Geological Fund to Mr. R. Etheridge, F.R.S., for transmission to Mr. Martin Simpson, of Whitby, and addressed him as follows: "Mr. Etheridge,—The balance of the proceeds of the Murchison Donation Fund has been awarded by the Council to Mr. M. Simpson, Curator of the Whitby Museum. 'He has devoted much attention to the fossils of that district, and he is the author of two books descriptive of them. The Council hopes that this cheque may be of assistance to him in continuing the useful extra-official work he has long been carrying on in that locality."

The President next handed the Lyell Medal to Prof. W. H. Flower, F.R.S., for transmission to Dr. Joseph Leidy, F.M.G.S., and addressed him as follows:—"Prof. Flower,—The Council has bestowed on Dr. J. Leidy the Lyell Medal, with a sum of 25*l.*, in recognition of his valuable contributions to palæontology, especially as regards his investigations on the Fossil Mammalia of Nebraska and the Sauria of the United States of America. These vast and, in comparison with our own country, but little explored territories have for some years past yielded a harvest of fossil vertebrate remains of exceeding richness, of which we have no example here. How well this harvest is being garnered by our Transatlantic *confrères* the flood of memoirs published by them during the last quarter of a century bears witness. Amongst these scientific labourers in the palæontological harvest-field, Dr. J. Leidy has held a foremost place. Careful in observing, accurate in recording, cautious in inferring, his work has the high merit which trustworthiness always imparts. The well-nigh astounding number of papers written by him between 1845 and 1873, amounting to 187, his Reports on the 'Extinct Vertebrate Fauna of the Western Territories,' his 'Synopsis of the Extinct Mammalia of North America,' and his 'Cretaceous Reptiles of the United States,' testify to the fertility of his pen."

In presenting to Prof. C. Lapworth, F.G.S., the balance of the Lyell Geological Fund, the President said: "Prof. Lapworth,—The Council has awarded to you the balance of the proceeds of the Lyell Donation Fund in recognition of the value of your researches into the palæontology and physical structure of the older rocks of Great Britain, carried on frequently under unfavourable circumstances and to the injury of your health, and to aid you in similar investigations. Your papers on 'The Girvan Succession,' 'The Moffat Series,' published in our *Journal*, and 'The Graptolites,' and 'The Secret of the Highlands,' contributed to the *Geological Magazine*, were the outcome of an extremely laborious and detailed exploration of the districts to which they refer—an exploration in conducting which you spared no pains and shrank from no hardships. No one who desires to know the structure of these districts can safely omit a careful study of these very instructive papers."

The President then handed to Prof. Bonney, F.R.S., for transmission to Dr. J. Croll, a portion of the proceeds of the Barlow-Jameson Fund, and said: "Prof. Bonney,—The Council, in recognition of the value of Dr. James Croll's researches into the 'Later Physical History of the Earth,' and to aid him in further researches of a like kind, has awarded to him the sum of 20*l.* from the proceeds of the Barlow-Jameson Fund. Mr. Croll's work on 'Climate and Time in their Geological Relations,' and his numerous separate papers on various cognate subjects, including the 'Eccentricity of the Earth's Orbit,' 'Date of the Glacial Period,' the 'Influence of the Gulf Stream,' the 'Motion of Glaciers,' 'Ocean Currents,' and the 'Transport of Boulders,' by their suggestiveness have deservedly attracted much attention. In forwarding to Dr. Croll this award, the Council desires you to express the hope that it may assist him in continuing these lines of research."

In handing to Prof. Seeley, F.R.S., a second portion of the proceeds of the Barlow-Jameson Fund for transmission to Prof. Leo Lesquereux, F.C.G.S., the President spoke as follows: "Prof. Seeley,—The Council has awarded to Prof. Leo Lesquereux the sum of 20*l.* from the proceeds of the Barlow-Jameson Fund, in recognition of the value of his researches into the palæobotany of North America, and to aid him in further investigations of a similar kind. Prof. Lesquereux's 'Contributions to the Fossil Cretaceous and Tertiary Flora of the Western Territories,' published in the 'Reports of the United States Geological Survey,' are works which, for their matter, typography, and illustrations, leave nothing to desire. In transmitting this award to Prof. Lesquereux, you will convey to him the hopes of the Council that it may assist him in prosecuting further investigations in the difficult branch of research in which he has already accomplished so much."

The President then read his Anniversary Address, in which, after giving obituary notices of some of the Members lost by the Society in 1883, he passed in review the principal work done by the Society since the last Anniversary Meeting, and finally referred more in detail to some important results obtained elsewhere in connection with the comparative osteology of the Vertebrata, dwelling particularly upon the question of the existence in the lower jaw of an unpaired bone occupying, or anterior to, the symphysis—the "os présymphysien" of M. Dollo, the "mento-Meckelian" of Cope, the "inferior intermaxillary element" of W. K. Parker,—and upon certain cranial and pelvic characters of the Dinosauria.

The ballot for the Council and Officers was taken, and the following were duly elected for the ensuing year:—President: Prof. T. G. Bonney, F.R.S. Vice-Presidents: W. Carruthers, F.R.S., John Evans, F.R.S., J. A. Phillips, F.R.S., Prof. J. Prestwich, F.R.S. Secretaries: W. T. Blanford, F.R.S., Prof. J. W. Judd, F.R.S. Foreign Secretary: Warington W. Smyth, F.R.S. Treasurer: Prof. T. Wiltshire, F.L.S. Council: H. Bauerman, W. T. Blanford, F.R.S., Prof. T. G. Bonney, F.R.S., W. Carruthers, F.R.S., John Evans, F.R.S., Col. H. H. Godwin-Austen, F.R.S., Henry Hicks, Rev. Edwin Hill, M.A., G. J. Hinde, Ph.D., J. Hopkinson, Prof. T. M'Kenny Hughes, M.A., J. W. Hulke, F.R.S., J. Gwyn Jeffreys, F.R.S., Prof. T. Rupert Jones, F.R.S., Prof. J. W. Judd, F.R.S., J. A. Phillips, F.R.S., Prof. J. Prestwich, F.R.S., F. W. Rudler, Warington W. Smyth, F.R.S., J. J. H. Teall, M.A., W. Topley, Prof. T. Wiltshire, F.L.S., Henry Woodward, F.R.S.

Chemical Society, February 21.—Dr. W. H. Perkin, president, in the chair.—The following gentlemen were elected Fellows of the Society:—L. Archbutt, J. H. Burland, D. Bain, W. H. Barr, R. A. Bush, P. S. Chantrell, A. F. Damon, H. C. Draper, T. R. Duggan, V. Edwards, W. T. H. Elsley, G. W. Gibson, F. W. Harris, T. Hilditch, R. E. Moyle, P. Morton, W. J. Orsman, F. R. Power, A. E. Simpson, C. W. Sutton, H. G. Shaw, E. F. Smith, F. W. Tompson, A. Tarn, and E. W. Voelcker.—The following papers were read:—On the composition of the ash of wheat grain and straw grown at Rothamsted in different seasons and by different manures, by Sir J. B. Lawes and Dr. J. H. Gilbert. This is an extremely lengthy paper giving the details of 253 analyses of ashes from produce whose history as to growth, soil, season, and manuring is known. The experiments are given in three series. The first gives the results obtained during sixteen consecutive seasons under three characteristically different conditions as to manuring, and thus illustrates the influence of the fluctuation of season from year to year. The second represents nine different conditions as to manuring obtained in four seasons—two favourable, two unfavourable—and so shows the influence of characteristic seasons under a great variety of manuring conditions. The third series represents the proportionally mixed produce for the ten years 1852–61, and again for the succeeding ten years, 1862–71, from ten differently manured plots, and thus brings out the influence of continuous exhaustion or supply of certain constituents. The general results are that the influence of the season on the composition of the ash is very much more marked than the influence of the manure, and that the composition of normally-ripened grain is very uniform and in fact only varies in any marked degree according to manure, when there is a very abnormal deficiency of one or more constituents; the amounts of mineral constituents in the straw have a very obvious connection with the supply or exhaustion of these constituents in the soil.—On the analysis of Shotley Bridge Spa water, by H. Peile. This is a chalybeate water containing 0·0155 grm. Fe_2O_3 per litre as ferrous bicarbonate, 1·73 grm. sodium chloride, calcium salts, some lithium chloride, magnesium bromide and iodide, &c.

Zoological Society, *February* 19.—Mr. Osbert Salvin, F.R.S., president, in the chair.—Mr. Sclater laid on the table and made some remarks on a copy of the lately issued "Guide to the Calcutta Zoological Gardens."—Mr. W. T. Blanford, F.R.S., made some observations on the collection of drawings of Himalayan birds lately presented to the Society's library by Brian H. Hodgson, F.Z.S.—Prof. F. Jeffrey Bell read the second part of his contribution to the systematic arrangement of the Asteroidea. In the present communication the author treated of the species of the genus *Oreaster*.—A communication was read from M. Fernand Lataste, C.M.Z.S., containing the description of a new species of Gerbille from Arabia. This new species was founded on specimens living in the Society's Gardens, which had been hitherto referred to *Gerbillus erythrurus*, Gray. M. Lataste considered the species to be undescribed, and proposed to call it *Meriones longifrons*.—A communication was read from Mr. J. Wood-Mason, F.Z.S., in which he gave a description of a new species of the Neuropterous genus *Corydalis*. The first example of this insect (a female) was captured by Lieut.-Col. H. H. Godwin-Austen, F.R.S., on the Naga Hills, north-east frontier of India; but male specimens had since been obtained. The author proposed to call this species *Corydalis asiatica*.—A communication was read from Dr. J. Gwyn Jeffreys, F.R.S., on the Mollusca procured during the *Lightning* and *Porcupine* Expeditions 1868-70, forming the seventh part of his series of papers on this subject. The present part comprised the genera from *Rissoa* to *Acirsa*, with seventy-four sp cies, of which fourteen were new to science, as was also one new genus.

Physical Society, February 23.—Prof. F. Guthrie, president, in the chair.—New Members:—Mr. E. F. J. Love, Mr. James Grundy, Rev. F. J. Smith, Mr. F. R. Bawley.—Prof. Silvanus P. Thompson read a paper on a new method of making resistance coils. This consisted in cutting off a piece of the wire of which the coil is to be made, long enough to give a resistance some 2 per cent. higher. From the formula—

$$\text{Shunt} = \frac{R\,r}{R - r}$$

(where R is the rough resistance, and r the final resistance), the value of a wire wherewith to shunt the first piece in order to give the resistance required is found. A length of wire giving this resistance (or, rather, about 2 per cent. more) is then cut off and soldered as a shunt to the first piece. Practice shows that this method is very quick and accurate. It is useful for shunts under 10 ohms. Prof. Thompson also described a new form of "meter bridge" devised by him. The wire is 2 m. long, and there are two wires, one of a resistance about ¼ ohm., the other 8·21 ohms. Contact is made by one or other by a sliding contact with vernier attached. This arrangement is more convenient than the single wire meter bridge, and allows of higher resistances being measured. A special switch board with an arrangement of mercury cups avoids the necessity of transposing the coils in Foster's method, this being effected by shifting the contact links in the mercury cups.—Mr. R. T. Glazebrook, F.R.S., explained a cam or axle key devised by Mr. Shaw to effect the contacts necessary to transpose the coils by a single movement. He pointed out that a certain pressure was necessary to make good contact with mercury. The ordinary way of making coils was to double the wire, cut the bight, bare the ends there, and solder a piece of copper across them, which could be shifted until the resistance was got. Prof. G. C. Foster said that the copper links in mercury cups should rest on the copper.—Prof. Foster read a paper by himself and Mr. Pryson on the difference of potential required to give sparks in air. Let $V =$ this difference of potential, $l =$ length of spark in centimetres, their experiments gave (approximately) $V = 102\,l + 7{\cdot}07$. Tables and curves of the sparking distances, potentials, and electric forces in the experiments were given. The results were got with brass balls 1·35 centimetres in diameter, a frictional machine, and a Foster absolute electrometer. When $l = {\cdot}142$, the electric force giving a spark was 154·76; $l = {\cdot}284$, the electric force was 133·35, or less than at a shorter distance; $l =$ 497, the electric force was 131·66; $l = {\cdot}9$, the electric force was 138·57; that is, it began to rise again.—Prof. G. Forbes made a communication on a magnetised chronometer watch. The watch slowed several minutes a day. He found the rate to vary with the position of the watch with respect to the cardinal points and also in a vertical plane. The bar of the balance was magnetised and some screw nails. He traced the variation of rate to magnetisation of the spring, the bar, and screws. The fact that it varied with position suggested that a magnetised ship's chronometer might be made which would integrate the course and give a mean course. Messrs. E. Dent and Co. had fitted a gold spring and a platinum iridium balance to the chronometer, and rendered it non-magnetisable.

Royal Meteorological Society, February 20.—Mr. R. H. Scott, M.A., F.R.S., president, in the chair.—T. G. Benn, Capt. C. F. Cooke, Francis Galton, M.A., F.R.S., Prof. S. A. Hill, B.Sc., Capt. A. W. Jeffery, G. Paul, F.G.S., F.R.H.S., R. Veevers, H. T. Wakelam, and E. Wells were elected Fellows of the Society.—The following papers were read:—The great storm of January 26, 1884, by William Marriott, F.R.Met.Soc. This storm was remarkable for its violence and large area, as well as for the unprecedentedly low barometer reading at its centre. The author has prepared isobaric charts for each hour from noon on the 26th to 3 a.m. on the 27th, and by this means has tracked the storm across the British Isles. The centre of the depression appears to have first reached the north-west coast of Ireland at noon, and passed in a north-easterly direction over the north of Ireland and across the middle of Scotland, reaching Aberdeen about midnight. Its rate of progress was therefore about thirty miles an hour. A violent gale was experienced all over the British Isles, the greatest hourly velocity of the wind being 68 miles at Valencia at 11 a.m., 70 miles at Holyhead at 2 p.m., 63 miles at Falmouth at 3 p.m., 69 miles at Armagh and 59 miles at Aberdeen at 5 p.m., 58 miles at Greenwich from 5 to 7 p.m., and 76 miles at Alnwick at midnight. Thunderstorms occurred on the south-eastern side of the depression, and travelled across the south of Ireland and England at the rate of about thirty miles an hour. The lowest readings of the barometer (reduced to sea-level) yet reported were 27·32 inches at Kilcreggan at 8.30 p.m., and 27·332 inches at Ochtertyre, near Crieff, at 9.45 p.m. In the southern part of England, directly after the minimum had occurred, there was a very sudden rise in the reading of the barometer, in some cases amounting to ·08 inch in five minutes. From an examination of previous records, it appears that there has never before been so low a barometer reading as 27·32 inches, so that this storm may be considered as one of the most remarkable that has occurred in the British Islands.—The height of the neutral plane of pressure and depth of monsoon currents in India, by Prof. E. D. Archibald, M.A., F.R.Met.Soc.—The sunrises and sunsets of November and December, 1883, and January, 1884, by the Hon. F. A. Rollo Russell, M.A., F.R.Met.Soc. The author gives a very interesting account of all the special features of the remarkable sunrises and sunsets which have been observed from November 8 to February 2. The following are stated to be the marks distinguishing the peculiar sky-haze from cirrus:—1. It is commonly much more evenly spread over the sky than cirrus. 2. It is visible (except when very dense or in the neighbourhood of the sun) only about the time of sunrise and sunset. During the day not the faintest trace obscures the clear azure, whereas cirrus becomes more distinct with more daylight. 3. When actually glowing with bright colour, it loses its wavy appearance. 4. It has no perceptible motion, unless perhaps when watched through a long period. 5. It does not interfere with the clear definition of the moon or brilliancy of the stars. 6. It lies, almost without exception, in long streaks, stretching from between south-south-west and west-south-west to between north-north-east and east-north-east. 7. Its radiant point lies, not on the horizon, but far below it. 8. If both cirrus and sky-haze be present, the sky-haze begins to shine with a red light soon after the cirrus has ceased to glow above the western horizon. When cirrus is present, however, there is in general a reaction of effects. 9. The sky-haze is destitute of the fibrous twists and angular branches of cirrus, and, since the sunlight leaves it in regular progression, it must be stratified at the same uniform level. 10. It has always been visible on every clear day for more than two months, and has been quite independent of wind and weather.

Entomological Society, February 6.—Mr. J. W. Dunning, president, in the chair.—The President nominated Sir S. S. Saunders and Messrs. F. P. Pascoe and R. Meldola as vice-presidents for the ensuing year. Two new members were elected.—Mr. P. Crowley exhibited specimens of *Castnia eudesmia*, with eggs, larval galleries, and pupæ.—Mr. W. F. Kirby exhibited a coloured photograph of an abnormal specimen of the genus *Samia*, which had been bred by M. Alfred Wailly.—Mr. H. T. Stainton remarked on the food of the larva of *Aglossa pinguinalis*.—The Secretary exhibited photographs of the female of *Hypocephalus armatus*, and read some notes on the subject by Dr. Sharp.—Mr. F. P. Pascoe exhibited a collection of *Curculionidæ* from New Guinea.—The President made some remarks on the attempt to introduce humble-bees into New Zealand. He also called attention to the disappearance of many common butterflies and moths from the neighbourhood of Huddersfield, upon which a discussion ensued, the opinion of most of the speakers being that butterflies were rapidly becoming much scarcer in England than they used to be.—The Secretary read a report from the Committee appointed to inquire into the alleged occurrence of *Phylloxera* in Victoria, confirming its presence in that colony.—Mr. J. W. Douglas communicated a description of a new species of *Orthezia* from Monte Cristo.—Sir S. S. Saunders communicated further notes on the caprification of domestic figs.

Anthropological Institute, February 12.—Mr. John Evans, F.R.S., vice-president, in the chair.—The election of Mr. Joseph

Fothergill, F.R.G.S., was announced.—Mr. Park Harrison exhibited some remains found last year in Castlefield, Wheatley, by Mr. E. Gale, the occupier of the land. The skulls were of two types, and belonged to subjects who have been interred for the most part in a flexed or contracted position, but some at full length. The objects associated with the skulls were also diverse. Amongst those lent by Mr. Gale were an unusually long and narrow spear-head and the boss of a target with rivets ornamented with tinned studs, such as have been found elsewhere in Oxfordshire. Other objects excavated at the expense of the late eminent archæologist, Mr. J. H. Parker, and given by him to the Ashmolean Museum, which he had intended to send, were not exhibited, owing to his lamented death. Mr. Harrison thought the remains at Wheatley dated from the time of the extension of the kingdom of Mercia to the Thames. Dr. Garson is preparing a description of the cranial peculiarities of the skulls.—Mr. Worthington G. Smith exhibited two skulls of the Bronze Age from a tumulus at Whitby.—Mr. Henry Prigg exhibited two Palæolithic implements and a fragment of a human skull from Bury St. Edmund's.—Mr. R. Morton Middleton exhibited some human bones from Morton, near Stockton.—Mr. John T. Young read a paper on some Palæolithic fishing implements from the Stoke Newington and Clapton gravels. Mr. Young exhibited a large collection of flints of various sizes, which he considered had been manufactured for use as fish-hooks, gorges, and sinkers; some of them showed evident traces of human workmanship; and the paper gave rise to an animated discussion.—Miss A. W. Buckland read a paper on traces of commerce in prehistoric times, in which she urged that the similarity of three cups of gold discovered, one in Cornwall, another at Mycenæ, and the third in the Necropolis of old Tarquinii, might be taken as evidence of the existence of commercial relations between Etruria and Ancient Britain.—A paper was read on a human skull found near Southport, by Dr. G. B. Barron.

Institution of Civil Engineers, February 26.—Sir J. W. Bazalgette, C.B., president, in the chair.—The paper read was on hydraulic propulsion, by Mr. Sydney Walker Barnaby, Assoc.M.Inst.C.E.

EDINBURGH

Royal Physical Society, February 20.—Ramsay H. Traquair, M.D., F.R.S., president, in the chair.—The following communications were read:—On the geological structure and age of the Harz Mountains, by H. M. Cadell, B.Sc., of H.M. Geological Survey of Scotland, a continuation of his former paper. The rocks of the Palæozoic core of the region had been deposited in an area subject to occasional volcanic outbursts. There were many patches of diabase on the Lower Harz which were usually associated with rocks of Hercynian age, and were regarded by German geologists as portions of interbedded sheets. Mr. Cadell believed they were intrusive sheets and bosses of later date, and gave as his reasons that (1) the adjacent strata were metamorphosed by heat on all sides; (2) the diabase sometimes cut obliquely through the sedimentary strata; (3) there was no tuff associated with these diabases as there was with the true interbedded lavas of the Harz; (4) these diabases did not, like the contemporaneous volcanic rocks, occur as continuous sheets, but were found in isolated patches like the intrusive diabases of the Scottish Midlands. The Whintill of Northumberland was cited as an example of an intrusive sheet which, like some of those on the Harz, kept on nearly the same horizon for considerable distances, but was not on that account alone to be regarded as interbedded. The first great break in the deposition of the Harz rocks took place in the middle of the Carboniferous period at the time of the irruption of the Brocken granite. The metalliferous veins of Clausthal and St. Andreasberg were all in faults traversing the culm strata and the granite, but were truncated by the Zechstein, which rested unconformably on the flanks of the Harz, and were therefore of Permian age. The Harz was bare during the Coal-measure and Permian periods, as conglomerates of Harz fragments were found in these strata. During the Secondary period the whole region appeared to have remained submerged, but the huge fault which bounded the north side of the Harz and inverted the whole of the Secondary rocks showed that the final upheaval had begun at the close of the Cretaceous period.—Remarks on the genus *Megalichthys* (Ag.), with description of a new species, by R. H. Traquair, M.D., F.R.S. This specimen was found at Burdiehouse, and was believed to be a different species from the *Megalichthys* of the Coal-measures.—On the principles of classification, by Prof. J. Cossar Ewart, M.D.—On the occurrence of an adult specimen of Sabine's gull (*Larus sabinii*) in Scotland, with exhibition of specimen, by Mr. E. Bidwell. This was a male bird shot last autumn on a loch in Mull, and is said to be only the second specimen of the bird in a mature state known to have been found in Europe. Immature specimens of this rare bird have occasionally been met with on the west coast of Ireland, but its home is on the borders of the Arctic region. In connection with this, Mr. Harvie-Brown, F.Z.S., made some interesting remarks on the migration of birds.

PARIS

Academy of Sciences, February 25.—M. Rolland in the chair.—Notice of the scientific labours of the late M. Th. du Moncel, by M. Edm. Becquerel.—A second communication on hydrophobia, by MM. Pasteur, Chamberland, and Roux. The results are reported of further experiments on dogs, rabbits, poultry, sheep, monkeys, and other animals who were inoculated with the virus, chiefly by trepanning. The object of the operation was to ascertain how far immunity could thus be secured against rabies communicated by mad dogs. As many as twenty-three dogs have by the process been rendered absolutely safe from the effects of the virus in whatever way and in whatever quantity administered. To make the whole species in this way free from the disorder would afford a practical solution of the question in a prophylactic sense, for human beings are never affected by rabies except from virus proceeding directly or indirectly from dogs.—On the equilibriums established between chlorhydric and fluorhydric acids, by MM. Berthelot and Guntz.—General considerations on the distribution of plants in Tunis, and on their chief botanical affinities, by M. E. Cosson.—On the quantities forming a group of nonions analogous to the quaternions of Hamilton, by M. Sylvester.—Note on the chief inventions of the Genevese watchmaker, G. A. Leschot, who died on Feb. 4, by M. D. Colladon. Leschot was the first to suggest the use of carbonado (fragments of Brazilian black diamonds) for piercing rocks and tunnelling.—Memoir on atmospheric movements above barometric depressions and risings; schemas deduced from the results of the work of Hildebrand-Hildebrandsson, entitled "On the distribution of the meteorological elements about the barometric minima and maxima," by M. A. Poincaré.—*Résumé* of the observations made at Cape Horn on atmospheric electricity, by M. Lephay.—Determination of the proportion of carbonic acid present in the air effected by the mission to Cape Horn, by MM. A. Müntz and E. Aubin. From these observations it appears that the quantity of carbonic acid present in the atmosphere at Cape Horn is only about 2·56 in 10,000 volumes of air, as compared with 2·84, the average in Europe.—Observations of the Pons-Brooks comet made at the Observatory of Marseilles, by M. Borrelly.—On the appendices to the nucleus of the Pons-Brooks comet, by M. P. Lamey.—On the red glows observed at sunset and sunrise during the mild winter of 1876–77, by M. P. Lamey.—On the rosy, crepuscular after-glows recently observed at Buenos Ayres, by M. Beuf.—On a sudden earthquake-wave observed on January 14, at Montevideo, by M. Beuf. At 7.30 a.m. the water suddenly fell several feet, and then rose in two successive waves about 1·5 m. above the ordinary sea-level. The disturbance seems to have been quite local, and was not felt at Buenos Ayres on the opposite side of the estuary.—On the calculation of the diurnal rotation of the solar spots, by M. Pansiot.—On the hyperfuchsian groups (mathematical analysis), by M. H. Poincaré.—On the propagation of a uniform shock communicated to a gas inclosed in a cylindrical tube, by MM. Sebert and Hugoniot.—On the lowering of the freezing-point of solutions of alkaline salts, by M. F. Raoult.—Heat of formation of the chloride and oxychlorides of antimony, by M. Guntz.—On the heat of formation of the oxybromides of mercury, by M. G. André.—Synthesis of the pyridic and piperidic bases, by M. A. Ladenburg.—On the addition of the chloride of iodine ICl to monochloruretted ethylene, $CH_2 = CHCl$, by M. L. Henry.—New reduction of the carbamate of ethyl, by M. G. Arth.—On ethyl and the methylacetylcyanacetate of ethyl, by M. A. Held.—On the action of bromuretted ethylene on benzine in the presence of chlorine of aluminium, by MM. Hanriot and Guilbert.—On the action of rennet on milk, by M. E. Duclaux.—Researches on the fermentation of farmyard manure, by M. U. Gayon.—Experimental researches on rabies, showing (1) that birds are liable to be attacked; (2) that they recover spontaneously, by M. P. Gibier.—Note on the electric reaction of the sensory nerves of the skin in ataxic animals, by M. M. Mendelssohn.—On the treatment by electricity of the elephantiasis prevalent amongst the Arabs, by MM. Moncorvo and Silva Araujo.—On the poison of the toad and other batrachians, by M. G. Calmels.—On the sexual differences of the *Corbœus bifasciatus*, and on the pretended eggs of this coleopterous insect injurious to the evergreen oak, by M. A. Laboulbène.—On the coincidences observed between the solar phenomena witnessed in 1831 and 1883, by M. A. Witz.

BERLIN

Physiological Society, February 1.—Dr. W. Wolff had had occasion to make an intimate study of the electrical plates of the torpedo, in the course of which he came upon a series of facts which served to explain the still very diverse views of authors on the structure of the electrical organ, and so confirmed his conception of the subject. The electrical organ of the fish in question consists, as is well known, mostly of hexagonal columns extending from the dorsal usually to the ventral side, though occasionally not so far. They were embedded in sheaths of ligamentous texture, in which were found the nerves and vessels of the organ, and consisted of single plates of 0·012 millimetres thickness piled one above the other, without any intermediary substance; detached cells of connective tissue, each with two or three fine offshoots, were now and again found between the plates, which themselves, in the main consisting of elastic fibres, were easily capable of being coiled in at the edges. In the plates, between the fibres were found detached round granules of a diameter equal to the thickness of the plates. These granules were for the most part enveloped each in a transparent sheath. On the lower side of the plate were seen punctiform organs consisting of small, powerfully refracting granules of a semi-liquid gelatinous consistence. Hitherto they had been for the most part regarded as the terminal organs of the nerves, and in the descriptions given of them by different authors the most diverse structures were imputed to them. According to Dr. Wolff, however, these were all accidental productions. The granules had no relation whatever to the nerves, their only function being probably that of making the plates cohere. The nerves ran in the sheaths of connective tissue belonging to the columns, and there split up into bundles of primitive fibers bending each to a single plate, in order to spread out on its lower side, dividing, as they constantly did, in a dichotomous manner. Soon the medullary sheath terminated either at a dividing spot or in the course of a twig, and all that remained was but the axial cylinder with the Schwann sheath. The dichotomous partition having been pushed forward to the most delicate filaments capable of being recognised, the Schwann sheath passed over into the membrane of the plate, while the axial cylinder in all probability came suddenly to an end.—Prof. Kronecker handed in a treatise for the *Proceedings*, in which he rebutted as unjustifiable the claims of priority advanced by M. Arloing in Paris against Herren Kronecker and Meltzer in the matter of the stoppage of the movements of swallowing.—Dr. Mœli gave a report on changes occurring in the cortex of the cerebrum of guinea-pigs, which he had observed after cutting through the capsula interna of the thalamus. Conjectures he had made on the course of the fibres in the cerebrum led him to cut through the fibrous courses of the corona (*Stabkranz*) radiating from the thalamus and running to the cerebrum at a point as far as possible from the cerebral cortex, and after a considerable time to examine the changes that had been produced in the cortical tissue in consequence of this cutting. By this examination he found that a large part of the fine filaments of the cortical substance had degenerated and faded away. A part of the ganglia, on the other hand, had continued unchanged, while another part had been essentially altered. Altogether Dr. Mœli distinguished in the cortex four species of ganglia: (1) round, (2) fusiform, (3) pyramidal, and (4) small and round, with short appendages. The first two, slightly tinged with colouring matter, remained unchanged on the side operated on, and like those on the sound side. The pyramidal and caudated cells, on the other hand, which were strongly tinged with colouring matter, had shrunk on the side operated on, and were greatly altered from those on the sound side. From this Dr. Mœli concluded that there was a centripetal propagation of the degeneration from the cut fibres to their central ganglia.—Dr. J. Munk took a survey of the various views held on the resorption of fat, and called to mind that in former experiments he had demonstrated how sebacic acids might, in the process of nourishment, take the place of neutral fat, but that even in the chyle neutral fats were alone to be found. By many physiologists the absorption of neutral fats from the food was disputed, and it was sought to derive the whole deposition of fat from decomposed albumen. Dr. Munk considered the arguments adduced in support of this view as not pertinent, and had repeated the fundamental experiment, which consisted in the absorption of a heterogeneous, and therefore easily demonstrable, neutral fat. He gave a dog, which through a long course of starvation had lost almost all the fat of its body, a large quantity of rape seed, and only so much albumen as was just necessary for the preservation of its life. After having been kept on this artificial food for a length of time, the dog was killed, and the fat of the skin, together with that of the ventral cavity, was melted in one lot, and compared with the fat of a dog that had been normally fed. The very appearance of the two kinds of fat under the temperature of the sitting-room was greatly different. The fat of the dog fed on rape seed was clear and fluid, and had but a little sediment of a firmer fat, while the fat of the normally fed dog formed a soft opaque mass. Chemically analysed, the first yielded some 80 per cent. of sebacic acid, while the normal fat contained but 68 per cent. of sebacic acid. Finally, Dr. Munk was able to demonstrate the presence of erucic acid in the fat of the rape-seed fed dog, though in a somewhat impure state, a fact which conclusively proved the absorption of rape seed, and therefore of alimental fat. Dr. Munk stated that at the next meeting of the Society he would communicate further experiments regarding the formation and deposition of the fat in the animal body.—After their addresses Dr. Wolff and Dr. Mœli gave demonstrations in the demonstrating hall of the Physiological Institute.

THURSDAY, MARCH 13, 1884

POLISH BONE CAVES

The Bone Caves of Ojcow in Poland. By Prof. Dr. Ferd. Römer. Translated by John Edward Lee, F.G.S., F.S.A., Author of "Isca Silurum," &c., Translator of Keller's "Lake Dwellings," Merk's "Kesslerloch," &c. (London: Longmans, Green, and Co., 1884.)

A RANGE of Oolitic hills, extending, in a north-westerly direction, from Cracow in Galicia to Czenstochau in Russian Poland, a distance of about ifteen German miles, contains the caverns termed, as we earn from the title of the work placed at the head of this article, "The Bone Caves of Ojcow," from a town of that name within the Russian frontier, and about three German miles north of Cracow. These caverns first attracted scientific attention from the fact that their deposits, worked for manure, were found to be rich in bones. Prof. Römer visited them first in 1874, and, having obtained funds from the Royal Prussian Ministry of Instruction, and subsequently from the Royal Academy of Sciences at Berlin, the work of investigation was begun in 1878, and carried on, at intervals, to the summer of 1882.

The facts disclosed, with speculations respecting them, were embodied in a work apparently published early in 1883; and there can be no doubt that, by preparing and publishing the translation now before us, Mr. Lee has added to the obligation under which his previous labours, both as author and translator, have laid English readers. The volume is enriched with twelve admirable plates; a charming Woodburytype frontispiece, exhibiting a magnificent skull of *Ursus spelæus;* and a useful sketch-map of the situation of the bone caves.

The caverns investigated were nine in number; and it must be stated here that, from 1873 to 1879, Count ohann Zawisza of Warsaw had with great care carried n researches in two of them—the Lower and the Upper Caves of Wierszchow, to the former of which he gave the ame of *Mammoth Cave.*

The following brief statements respecting the caves hemselves must suffice:—

The Cave of Jerzmanowice, about 1 German mile west-south-west from Ojcow, and the largest of the series, s about 230 metres long, tortuous, made up of a series of mall grottoes connected by narrow passages, and famous s the richest of the caves in its palæontological and rchæological relics.

The Cave of Kozarnia, about ·6 of a German mile west-orth-west from Ojcow, measured about 59 metres long, ad a large entrance, and was rich in remains of mammals ad of human industry, of which the greater part had en found, and unfortunately dispersed beyond recovery, fore Prof. Römer's researches began.

Near Wierszchow, almost on the frontier of Russian land and Galicia, rather more than 1 German mile due uth from Ojcow, there are two caverns known as the "ower" and the "Upper," the former being Count wisza's *Mammoth Cave*, as already stated. The Lower Cave is about 19 metres long, 13 metres wide, has two arrow lateral ramifications, and is about 577 metres from e Upper Cave.

The Cave of Zbójecka, about ·2 of a German mile south-west from Ojcow, is very low at the entrance, but expands at once into a tolerably high arched space, whence two branches are sent off; that on the right being 129 metres long and 4 wide, while that on the left is but short.

The Cave of Czajowice, a short distance south of that just mentioned, is about 165 metres long. Its stalagmites are more considerable than those of any of the other caverns, attaining in some places a foot in thickness.

Sadlana Cave, about ·5 of a German mile north-north-west from Ojcow, and the most northerly of the series, has four entrances, and throws off two lateral branches, which, being blocked up with stones, have not been examined.

Bembel Cave, about 1 German mile south-west from Ojcow, is of but small extent.

Górenice Cave, about 3 German miles west-south-west from Ojcow, the most westerly of the series, and on the frontier of Russian Poland and Galicia, is so very low that a man can rarely stand erect in it, and has two entrances about 40 metres apart.

An oolitic floor appears to be very seldom reached in any of them. They generally contain a deposit of angular pieces of oolite, from an inch in diameter to the size of the fist, mixed with dark brown calcareous clay, and attaining in some cases a thickness of 6 or 8 feet. A few blocks of oolite, some of them containing several cubic feet, are occasionally met with in the deposit, and it is believed that the entire mass was derived from the walls and roof. In most of the caves there are horizontal layers of coarsely crystalline stalagmite, varying from a few inches to upwards of a foot in thickness.

All the caverns have yielded bones, occurring sometimes under the stalagmite and not unfrequently embedded within it, and most of them have entirely lost their gelatinous matter. An entire infra-human skeleton has never been found, nor does there appear to have been anything like even a distant approach to it; indeed, except in one solitary case, the two rami of every lower jaw were separated.

Few, probably none, of the caves have received an exhaustive scientific exploration, and it is stated of most of them that they have only been very partially examined. Unfortunately, as we learn from Prof. Römer, it cannot be always positively stated from which bed the specimens were taken; "but," he adds, "the case is the same with most of the caves which have been excavated in Germany." We agree with him that this could only have been avoided by carrying the work on quite slowly and with great precaution under the continued superintendence of a scientific manager, and we venture to add that such a price would have been well worth paying. It must be stated, however, that Count Zawisza, having mainly devoted himself to one of the caves, in which the daylight was available for the whole work, and on which he appears to have spent at least portions of seven years, was able to note the exact situation of each specimen.

The caverns yielded remains of fifty species of mammals, twelve of birds, and two of reptiles. All the birds belong to species still inhabiting the British Isles as well as continental Europe, with the possible exception of very scanty relics of the genera *Emberiza* and *Hirundo*, and may be dismissed with the remark that they are usually represented by a single specimen only. The reptile remains consist of one humerus of the common frog, and numerous bones of toads, the species being undetermined.

The mammalian remains include those of thirty-two species familiar to explorers of British caverns. The remainder belong to twelve species forming part of the existing British fauna, including the domestic cat; three recent European, but not British, species, and three undetermined species of the genera *Capra*, *Ovis*, and *Sus*. On the other hand, certain forms for which some British caves have become famous are totally unrepresented in the Ojcow list, such as *Ursus priscus*, *Gulo luscus*, *Machairodus latidens*, *Cervus megaceros*, *Ovibos moschatus*, *Bos longifrons*, *Hippopotamus major*, *Elephas antiquus*, *Lagomys spelœus*, and *Castor fiber*. Not a single species appears to be represented by remains found in all the caves, and only one—the cave bear—by those found in eight of them. Twenty-two of the species—nearly one-half of the entire number—are restricted to one, not the same, cave.

The remains of the cave bear were not only more widely distributed in the caves, but were far more numerous than those of any of the other mammals, especially in the lower levels of the deposit. The Cave of Jerzmanowice alone is believed to have yielded fully 4000 canine teeth of this species, representing, of course, 1000 individuals at least. The animals were of all ages, from the sucking cub to a patriarch whose skull measured about 19·5 inches long and 12 inches broad across the zygomatic arch. The brown bear appears to have been represented by remains of one individual only, found in the *Mammoth Cave*, which also yielded bones and teeth of the great pachyderm from which it was named. Relics of this species were disinterred in four other of the caves; and it was concluded from the occurrence of numerous ivory tools that mammoths must have existed in considerable numbers. The woolly rhinoceros was found only in two caverns, and its remains do not appear to have been abundant. The cave hyæna was apparently very little, if at all, more prevalent, as it was represented in no more than three of the caves. Next to the cave bear, no animal was more generally distributed than the reindeer, whose relics occurred in six of the caverns—a distinction also reached by the common fox. Count Zawisza's researches have led him to the conclusion that the distinction between an older mammoth period and a more recent reindeer period, as made out from the researches in France, will not apply to these Polish caves.

The traces of man were numerous and varied, consisting of parts of his skeleton, hearths, and implements of various kinds. His bones were found in seven of the caverns, and several skulls were met with in five of them; but, unfortunately, the remains of the animals lying with them were not in all cases accurately noted. Some of these relics were near the surface, others lay deeper, and some were covered with a thick bed of stalagmite. A "skeleton," pressed against the side of the Czajowice Cave, was more than a metre below the surface; and in the Górenice Cave several skulls were also found close to the sides. From a report by Prof. Virchow, to whom the skulls have been submitted, it appears that some of them are dolicocephalic, others mesocephalic; that there is some doubt whether they are of the same age as the deposit containing the implements of the most ancient inhabitants; and that there is no peculiarity indicating any very high antiquity, nor any essential difference in the forms of the skulls from those of the present inhabitants of Poland.

The hearths, which occurred in six of the caves, were in some instances one above another with a thick mass of deposit between them; and some of them contained bones of ox, reindeer, mammoth, boar, and cave bear mixed together, broken artificially, and blackened by fire.

Flint implements and "cores" appear to have been found in all the caves, and Count Zawisza, in his *Mammoth Cave* alone, disinterred about 2000. The raw material was no doubt obtained from the Upper Oolitic Limestone of the district, in which flint nodules abound. The author speaks of the tools as being "Palæolithic" in all cases, but this must probably be understood as a synonym for "unpolished," and not taken necessarily in a chronological sense in all cases. It must be stated, however, that one flint tool was found with a vertebra of the cave bear in the same bed of firm crystalline stalagmite.

Of other stone tools, two axes were met with, one in each of the Wierszchow Caves: one, made of serpentine, was perforated to receive a helve; the other was of diorite. They were the only polished stone tools the caverns yielded. Several roundish cuboidal stones, the size of a man's fist, and believed to be "corn-crushers," were found. One of these also was of diorite. There were also "polishing stones," or "rubbers," some of fine-grained sandstone and others of black clay slate, apparently used for finishing bone tools.

Two glass beads, with inlaid threads of clear-coloured glass, were found in the Kozarnia Cave; and from their great depth in the deposit a considerable antiquity is claimed for them. It is believed they must have been of foreign origin. The Zbójecka Cave yielded three amber beads, rather flat, not quite symmetrical, but smoothed.

Of articles made of bone, there were rods artificially sharpened at one end, and, in some cases, perforated at the other; a knife made of a lower tusk of boar; a canine tooth of bear artificially perforated at the lower end, a stout needle having a large eye; straight hollow bones of birds, cut transversely at one end and broken at the other: a straight rod of ivory sharpened at both ends, and as "round as if turned in a lathe"; perforated teeth, including one of boar (ground flat on one side), wolf, fox and elk; four imperfectly rounded and smoothed beads; and seven ivory rods, compressed and lancet-shaped, the largest a foot long and 1·5 inch in greatest breadth. These rods were all found in one and the same bed, which contained charcoal, rough flint tools, and bones of wolf, polar fox, and reindeer. Long bones, broken artificially lengthways, were found in great numbers, as well as pieces of antlers having cut surfaces.

One fragment of the shell of *Cypræa tigris*, an Indian Ocean species, presented itself. It is supposed to have been obtained by the Cave-men by barter.

Pottery occurred in nearly every cave and at all levels. The lowest, roughly hand-made, slightly burnt, and unglazed, included part of a pot-like vessel, so porous as to render it improbable that it could have been intended to contain any liquid. Among specimens of later date, and better, though still rough, workmanship, was a small pipkin-like vessel, with its handle perfect. Some of these pieces were roughly and simply ornamented. Specimens from the uppermost level were clearly more modern.

Three of the caves yielded dark gray or black spindle-whorls of burnt clay, of fairly good workmanship.

The metal objects included a bronze fibula and ring, a silver coin supposed to be about the year 140, and iron arrow- and lance-heads of mediæval form.

We are grateful for this contribution to the palæontology and anthropology of Europe, and are encouraged by it to entertain the hope that Prof. Römer may be enabled to make arrangements for the *complete and systematic* exploration of at least one of the Ojcow caves at present untouched; and that sufficient means may be at his disposal to place the work under continued scientific superintendence.

OUR BOOK SHELF

Poisons: their Effects and Detection. By Alex. Wynter Blyth, M.R.C.S. (London: Charles Griffin and Co., 1884.)

THIS elaborate volume forms a part of the second edition of the author's treatise on "Practical Chemistry," which has been wisely split up into two volumes, one on "Foods," the other on "Poisons." Mr. Blyth's experience as a health-officer and public analyst guarantees that his conclusions are largely based on actual practice as a toxicologist; and the book will be found to abound in records of his own experiences.

But Mr. Blyth is also an accomplished linguist, and his book bears ample evidence of extensive reading, and a wide acquaintance with the European literature of toxicology. Almost every page teems with references to original memoirs in the French, German, and Italian languages; and this circumstance alone would render it an indispensable work of reference to be placed in the library of every toxicologist. But "Poisons" has other and distinguishing merits.

The general reader will find the introductory chapter on the old poison-lore of great interest, and replete with many but little known facts and fables relative to the history of poisons and their secret administration. Following on this we find a succinct account of the growth and development of the modern methods of chemically detecting poisons, at the end of which nearly three pages are devoted to a bibliography of the chief works on toxicology of the present century, in which we miss any reference to one of the most complete treatises on poisons extant—that forming the bulk of the seventeenth volume of Ziemssen's "Cyclopædia of Medicine."

In giving a scientific definition of a poison, Mr. Blyth somewhat enigmatically remarks that "The definition of a poison, in a scientific sense, should be broad enough to comprehend not only the human race, but the dual world of life, both animal and vegetable." He finally defines a poison thus:—"A substance of definite chemical composition, whether mineral or organic, may be called a poison, if it is capable of being taken into any living organisms, and causes, by its own inherent chemical nature, impairment or destruction of function." He excludes the bacteroid bodies met with in certain diseases, but apparently ignores the views of those observers who are of opinion that these organisms form or excrete true poisons of definite chemical constitutions.

A novelty in the work is the devotion of a section to what are termed "life-tests," *i.e.* the identification of poisons by their effects on living animals. This, and the elaborate instructions given on the authority of various writers, as to the methods to be adopted for separating and identifying the various poisons, will be found invaluable to the analyst; and his only difficulty will be the choice of one out of the almost innumerable methods given for the separation of a single poison, say arsenic or opium.

THOMAS STEVENSON

Informe Official de la Comision cientifica agregada al estado mayor general de la Expedicion al Rio Negro (Patagonia) realizada en los meses de Abril, Mayo, y Junio de 1879, bajo las órdenes del General D. Julio A. Roca Entrega I. Zoologia (con 4 laminas). Part I. 4to, 168 pp. (Buenos Ayres, 1881.)

IN 1879 the Government of the Argentine Republic despatched an expedition to the southern confines of their territory for the suppression of the hordes of Indians that had for many years previously rendered the district of the Rio Negro unsafe to travellers and to settlers. Under the command of General Roca these marauding savages were successfully driven off to the south of the Rio Negro, and a new frontier, which they are not allowed to cross northwards, was established. General Roca (whose excellent example on this occasion it would be well if some of the Governments of Europe would follow) having invited a commission of scientific men to accompany his expedition, Dr. P. G. Lorentz and Mr. G. Niederlein were sent with him as botanical collectors, and Herr Schulz, Inspector of the Zoological Museum of Cordoba, as zoologist. The results of the last-mentioned naturalist's labours are contained in the volume now before us, which has been prepared by Dr. A. Doering, with the assistance of Dr. Berg, Dr. Holmberg, and D. Enrique Lynch Arribálzaga, and is highly creditable to the youthful Academy of Natural Sciences of Cordoba, to whom, it would appear, the task of working out the scientific collections was intrusted.

Dr. Doering commences his labours by a chapter of general observations upon the fauna of the newly occupied territory, which he divides into four "zoogeographic zones"—(1) the region of the Southern Pampas; (2) the river-region of Northern Patagonia; (3) the central mountain-region; and (4) the eastern slopes of the Cordillera. The two last regions being very little known and not having been traversed by the expedition, are not discussed in the present essay, but the two former are subdivided into minor districts, and the principal zoological characters of each of their subdivisions are pointed out. Lists are also given of the principal mammals, birds, amphibians, and land-mollusks that are chiefly peculiar to the different districts.

Dr. Doering's instructive "zoogeographical" essay is followed by the systematic portion of the volume, in which the vertebrates and land-shells are treated of by the same naturalist, while his colleagues, Dr. Berg and Dr. Lynch Arribálzaga, have worked out the insects, and Dr. Holmberg the arachnidans. We have thus before us an excellent basis for a fauna of this hitherto little-known portion of the great Neotropical Region, which does credit alike to the Government of the Republic which instituted the investigation, and to the Academy of Natural Sciences of Cordoba, under whose auspices the work has been elaborated.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Instinct

IN his letter under this heading in last week's NATURE (p. 428), Mr. Romanes says that I *now* admit that the actions of animals testify to some corresponding mental states. If he will kindly refer to my original paper he will find that my views have not undergone the change he implies, for I *then* wrote: "We have therefore grounds for believing that, running parallel to the neuroses of animals, there are certain psychoses"; and again: "Animal minds are also ejective; they are more or less distorted images of our own minds"; and, in my "Conclusion," "While fully admitting the great interest that attaches to the study of the inferred mental faculties of the higher brutes," &c.

Were I to take his concluding remark seriously, and say that, if I were the only individual to hold the view that the mental life of animals cannot be the subject-matter of a science, this would not prove my view untrue, Mr. Romanes would smile at my want of appreciation of his powers of sarcasm. I content myself with drawing Mr. Romanes' attention, and that of your readers, to the following quotations from Prof. Huxley's volume on the Crayfish:—"Under these circumstances it is really quite an open question whether a crayfish has a mind or not; moreover, the problem is *an absolutely insoluble one*, inasmuch as nothing short of being a crayfish would give us positive assurance that such an animal possesses consciousness. . . . So we may as well leave this question of the crayfish's mind on one side for the present, and turn to *a more profitable investigation*," &c. (p. 89). And again: "At the most, one may be justified in supposing the existence of something approaching dull feeling in ourselves, and so far as such obscure consciousness accompanies the molecular changes of its nervous substance, it will be right to speak of the mind of a crayfish" (p. 126).

The question now seems to turn on what we mean by a science. Animal minds, as ejects, are distorted images of our own minds. Can we frame a *science* which deals with these distorted ejects? Could we frame a *science* of astronomy if the only method of procedure were to observe the stars and planets in mirrors *of varying and unknown curvature?* If we can give an affirmative answer to the latter question, I am ready to admit that, in the same degree, we can give an affirmative answer to the former. C. LLOYD MORGAN

Circular Rainbow seen from a Hill-top

READING Mr. Fleming's letter in your issue of January 31 (p. 310), I am moved to put on record an observation of my own involving shadows and rainbows upon a cloud. On August 19, 1878, I was encamped upon a plateau known as Table Cliff, in the southern part of Utah Territory. The plateau has its longer dimension north and south, and ends southward in an acute promontory, precipitous toward the south, west, and east. The altitude is about 10,000 feet. On that day the air was moist, and scattering clouds were to be seen both in the valley beneath and in the sky above. A strong wind blew from the west. On that side of the promontory the air was clear; but at the crest a cloud was formed, so that the view eastward was completely cut off. This phenomenon is not unusual on mountain summits, and has been plausibly explained as due to the sudden rarefaction of the air on the lee-side of an obstacle. Standing on the verge of the cliff just before sunset, I saw my own shadow and that of the cliff distinctly outlined on the cloud. The figure appeared to be about fifty feet distant, and was not colossal. About the head was a bright halo with a diameter several times greater than the head. Its colours included only a portion of the rainbow series, but I neglected to record them, and do not venture to recite from memory. At the usual angle outside there appeared two rainbows of great brilliancy, likewise concentric with the head. They did not describe complete circles, but terminated at the left and beneath, where they met the shadow of the cliff. I estimated that 225° of arc were displayed. The phenomenon was continuous for some hours, the cloud-mass being persistent in position, notwithstanding the fact that its particles had a velocity of twenty-five or thirty miles an hour.

The observation has more than a scientific interest, because, in the popular imagination, the heads of scientific observers are not usually adorned with halos. G. K. GILBERT

Washington, U.S.A., February 25

Right-sidedness

IN all the letters thus far published in NATURE on the subject of the tendency to deflection in walking, I find two things confounded which are quite distinct. There are two distinct senses in which we may use the term *right-leggedness*: the one refers to *strength*, the other to *dexterity* or accurate co-ordination of muscular action. In the arm these two always go together; for dexterity gives greater use (dexterity, I believe, is largely inherited), and use gives greater strength. But in the leg these may be and often are dissociated. As Prof. Darwin truly says, the left leg is often the stronger, but I believe the right is nearly always the more dexterous. My own case is a typical one. I hop on my left leg, and rise from it in jumping. But I do so not only because the left is stronger, but also, and I think mainly, because I use the right more dexterously as a swinging weight. The dexterous management of the free leg is certainly no less important than the strength of the jumping leg. In kicking or performing any other movement requiring dexterity, I stand on the left leg and use the right.

In my own case the whole body is *right-sided*, as far as dexterity is concerned. Impressions on my left eye are as vivid, perhaps even more vivid, than on my right, yet I see more intelligently (as, for example, in using a microscope) with my right. In the case of double images of near objects when looking at a more distant one, it is the left-eye image (the right in position) which I neglect. In pointing with the finger, whether of the right or left hand, with both eyes open, it is the right-eye image of the finger (the left in position) that I range with the object. In the case of two or three left-handed persons on whom I have made observations, I have found, on the contrary, that it is the right-eye image that they neglect, and the left-eye image that they use in pointing. "Suicide" of Black Snakes

WHILE encamped near Mount Wynne, Kimberley district, for a few days from June 13, 1883, our survey party saw and killed several black snakes averaging about five feet in length. In three days I saw seven of these unpleasant visitors in our camp. As is well known, the black snake is one of the most venomous of the Australian serpents, and whenever met with is if possible destroyed. I have seen many killed, but usually they die hard; and even when the back is broken in several places will linger for more than an hour, still capable of revenging themselves on an incautious assailant.

On this occasion our men had disabled one, and as I was anxious to obtain the skin I induced them to let it alone (they usually cut off the head so as to insure death). While we were looking at it some large black ants attacked the wounded part—about three feet from its head—when it instantly turned short round and hit itself twice in the neck, with seeming determination. In less than one minute it was dead. There can be no doubt, therefore, that it was poisoned by its own venom.

I do not know if such a custom on the part of snakes has been recorded. However, my men assured me that they had often witnessed similar occurrences, especially in the case of the "death" or "deaf" adder, a very venomous Australian snake. One man informed me that he had often insured the death of this reptile by simply pinning him to the ground by means of a forked stick. In all cases the reptile would turn round, bite himself, and die instantly.

Sea Fish in Freshwater Rivers

DURING my journey up the Fitzroy River with the surveying party from King's Sound to the Leopold Ranges (between lat. 17° 4' and 18° 20' S.), I observed many specimens of sword- and saw-fish. They appeared at intervals the whole way up the river, but none observed were more than three feet or three feet six inches long. About 300 miles up on the Margaret River I procured the saw of a small one. It measures about nine inches long and two inches wide. A few days after this, a little higher up the river, some of our men found a shark five feet long, and recently killed, probably by natives. I could not visit the place, as we were then about to break up camp for our return, but the men showed us some of the teeth, which were unmistakably those of a shark. They were, besides, well acquainted with the appearance of that fish.

Some time after this, when returning down a branch of the Fitzroy, and camped in the sand of the river bed, I found the body of a small young shark. It was about eighteen inches long. I secured this as evidence. This locality is about 170 miles from the mouth of the river.

During the six months we were in the country, the bed of the river, which varies from 50 to 800 yards in width, was almost dry, with the exception of deep pools at intervals connected with each other by a narrow stream, often very shallow, running under the high banks. In the summer time the river is deeply flooded, the water rising ten to twenty feet (as shown by drift wood in trees) above the banks, in many places from forty to fifty feet high. The force of the flood might at its height prevent fish going up, but they could easily ascend in the intermediate season. In some cases the fish must have lived months in the upper waters, for portions of the Margaret, at least, are absolutely dry in the winter season, May to November usually.

I am not aware that such a circumstance has ever been noted before. If not, the fact is sufficiently interesting in itself. It is also important from a geological point of view, as showing that some caution must be observed in the classification of strata as freshwater or marine on the evidence of fish alone. No doubt many of these remains are embedded in the river detritus, and if discovered at some future time when the physical geology of the country has altered, might lead to the conclusion that these deposits were of marine origin.

The Zodiacal Light

ONE of the members of the staff of this establishment, Mr. E. G. Constable, observed a brilliant appearance of the zodiacal light at about 7 p.m. on the evening of Wednesday the 5th inst., the cone of light being exceedingly well defined. The phenomenon was not visible long, having completely disappeared by 7.20 p.m.

THE AXIOMS OF GEOMETRY

SINCE the time when Riemann and Helmholtz began their investigations on the axioms of geometry so much has been written on this subject in learned papers and in a more or less popular form that it might have appeared superfluous again to call the attention of writers on, and teachers of, elementary geometry to it, had it not been for the publication a year or two ago of a new edition of the first six books of Euclid's "Elements," with annotations and notes, by Prof. Casey. I hope the eminent author of this in many respects excellent book will excuse me for criticising some points in it, and making them the opportunity for again returning to the question about the axioms in geometry.

The points I object to besides his treatment of Book V., of which I may possibly say a few words on another occasion, is contained in Note B at the end of the book. Here Prof. Casey gives Legendre's and Hamilton's proofs of I. 32, that the sum of the interior angles of any triangle is equal to two right angles, implying, of course, that he considers these proofs valid, proofs which are independent of the theory of parallels. The theorem in question depends in Euclid upon Axiom XII., and all depends upon the question whether this axiom is necessary. For the two propositions in this axiom and in Theorem I. 32 stand in such a relation that either is a consequence of the other. Hence if I. 32 can be proved independently, the Axiom XII. changes into a theorem. But the investigations above referred to show that it is this axiom which tells us what kind of a surface the plane really is, and that until this axiom is introduced all propositions apply equally well to the spherical and to the plane surface.

I select for discussion the "quaternion proof" given by Sir William Hamilton, this being the easiest of the two. But that by Legendre can be treated in exactly the same way.

Hamilton's proof consists in the following:—

One side A B of the triangle A B C is turned about the point B till it lies in the continuation of B C; next, the line B C is made to slide along B C till B comes to C, and is then turned about C till it comes to lie in the continuation of A C. It is now again made to slide along C A till the point B comes to A, and is turned about A till it lies in the line A B. Hence it follows, *since rotation is independent of translation*, that the line has performed a whole revolution, that is, it has been turned through four right angles. But it has also described in succession the three exterior angles of the triangle, hence these are together equal to four right angles, and from this follows at once that the interior angles are equal to two right angles.

To show how erroneous this reasoning is—in spite of Sir William Hamilton and in spite of quaternions—I need only point out that it holds exactly in the same manner for a triangle on the surface of the sphere, from which it would follow that the sum of the angles in a spherical triangle equals two right angles, whilst this sum is known to be always greater than two right angles. The proof depends only on the fact, that any line can be made to coincide with any other line, that two lines do so coincide when they have two points in common, and further, that a line may be turned about any point in it without leaving the surface. But if instead of the plane we take a spherical surface, and instead of a line a great circle on the sphere, all these conditions are again satisfied.

The reasoning employed must therefore be fallacious, and the error lies in the words printed in italics; for these words contain an assumption which has not been proved. In fact they contain an axiom which completely replaces Euclid's Axiom XII., viz. it expresses that property of a plane which differentiates it from the sphere.

On the sphere it is, of course, not true that rotation is independent of translation, simply because every translation—sliding along a great circle—is a rotation about the poles of the great circle.

From this it might be said to follow that the calculus of quaternions must be wrong. But this again is not correct. The fact is that the celebrated author of this calculus had built it up with the full knowledge of the fundamental space properties in his mind, and making full use of them. Afterwards, on reasoning backwards, he got these space properties out of his formulæ, forgetting that they were exactly the facts with which he started. The process is, as far as logic is concerned, not very different from that practised by some alchemists, who pretended to make gold, and actually did produce gold out of their crucibles, but only as much as they had themselves put in.

The following considerations may help to clear up this point still further:—

Prof. Sylvester once conceived, in illustration of some points connected with our subject, an infinitely thin bookworm living in a surface, and consequently limited in its space conceptions to the geometry on such surface. In a similar manner we may imagine an intelligent being consisting merely of an eye occupying a fixed point in space, but capable of perceiving rays of light in every direction. For such a being space would have two dimensions only, but in this space it could conceive figures for which most of Euclid's definitions and all axioms with the exception of the twelfth, and therefore all propositions up to the twenty-sixth in the first book, would hold. Only the names *point*, *line*, *angle*, &c., would stand for objects different to those which they represent to our mind. Nothing can put the vagueness of Euclid's definitions and the real nature of his axioms, viz. that they contain the real logical definitions of the geometrical entities, in a clearer light than the fact that it is possible to use these so-called definitions for objects quite different from those to which Euclid applied them.

To return to our imaginary being: let us suppose it capable of studying Euclid. A ray of light, that is, a line, would appear to it as having no extension but only position, and would answer Euclid's definition of a point. Two such rays determine a plane, but to the eye this would have one dimension only, and it would *lie evenly between its boundaries*; calling the latter "points" it answers the description of lying evenly between its extreme points, and may be called a straight line, whilst the angle between the two rays would be the *distance* between the points. If two of these lines be drawn from the same point, we get as the inclination between them a *rectilineal angle*; this being to our mind the dihedral angle between two planes. If a line A B were made to revolve about its fixed end A, the other point B would describe a *circle*; in our space a cone of revolution.

The following is a list of those definitions and axioms from Euclid with which we have here to deal. It will be seen that they hold, every word of them, for the figures above described as conceived by our eye-being. Only it must be remembered that a point for the eye-being is to our mind a line through the eye, and so for the line, &c. The words in square brackets indicate what the figures are to our mind.

DEFINITIONS

I. A point [line through the eye] is that which has no parts or which has no magnitude.
II. A line [conical surface with vertex in the eye] is length without breadth.
IV. A straight line [plane through the eye] is that which lies evenly between its extreme points [lines through the eye].
IX. A rectilineal angle [dihedral angle] is the inclination of two straight lines [planes through the eye] to one another which meet together but are not in the same straight line [plane].
X. When a straight line [plane] standing on another straight line [plane] makes the adjacent angles equal to one another, each of the angles is called a right angle [right dihedral angle].
XV. A circle [cone of revolution with vertex at the eye] is a figure contained by one line [surface] which is called the circumference, and is such that all straight lines [angles] drawn from a certain point within the figure to the circumference are equal to one another.
XVI. And this point [line] is called the centre of the circle [axis of the cone].

AXIOMS CALLED POSTULATES IN EUCLID

I. Let it be granted that a straight line [plane through the eye] may be drawn from any one point [line through the eye] to any other point [plane determined by two lines through the eye].
II. That a terminated straight line may be produced to any length in a straight line [plane through intersecting lines may be produced beyond these lines].
III. And that a circle may be described from any centre at any distance from that centre [a cone about any axis with any angle at the vertex].

AXIOMS

X. Two straight lines cannot inclose a space [two planes through a point cannot inclose a space].
XI. All right [dihedral] angles are equal to one another.

Starting with the above definitions and axioms, the eye-being would have no difficulty in mastering the constructions and theorems contained in the first propositions of the "Elements." Only in Proposition IV. a difficulty might occur. For it may perhaps prove to be impossible to make the two triangles coincident. In Euclid's triangles, namely, it may be necessary to take of one of the triangles the side opposite to the one originally given by taking it out of the plane and turning it over before it can be made to coincide with the other triangle. So perhaps our being would find out, if the two triangles [trihedral angles] were right- and left-handed, that it has to take of one of the triangles the opposite side, viz. that on the other side of itself [formed by the continuations of the rays], which then will answer the purpose. After this every other proposition would follow without difficulties till parallel lines were introduced, which might sorely puzzle our eye-being, and finally be dismissed as downright nonsense, parallel lines being absolutely inconceivable. And if Sir William Hamilton's proof of the proposition that the sum of the angles in a triangle equalled two right angles were given to it, it would grant the construction and every step as possible and correct, but it would "shake its head" about the conclusion included in the words printed above in italics. It might even consider Euclid a fit subject for a "Budget of Paradoxes." For it is difficult to imagine that this being *without moving in space* should be able to generalise and invent a geometry in a space of zero curvature.

If in any one of the first twenty-six propositions of Euclid the changes above indicated are made from our conceptions to those of the eye-being, we get a series of well-known fundamental propositions in solid geometry which when obtained in this manner do not require any further proof. O. HENRICI

THE SCIENTIFIC WORK OF THE "VEGA" EXPEDITION[1]

THE second volume of this work is as rich an addition to our knowledge of the far north as the previous one. It contains also not only the bare results of the observations of the scientific staff of the *Vega*, but also a series of elaborate papers connected with the various topics which were within the circle of the researches of the expedition.

F. R. Kjellman contributes two more papers on the Arctic flora. In the first of these he deals with the phanerogamous flora of the island of St. Lawrence, situated under the 63rd parallel in the Behring Straits. This island has been represented in Middendorff's work as quite devoid of trees and shrubs, although Chamisso had seen on it large spaces covered with a *Salix*. M. Kjellman found, during his very short stay at the island, no less than 96 species of phanerogams, of which 53 are new for the island, the whole of the phanerogamous species known reaching thus 113 (22 Monocotyledons, and 91 Dicotyledons). They are chiefly Gramineæ (11 species), Compositæ, and Ranunculaceæ (9 species each), Saxifragaceæ, Cruciferæ, and Caryophyllaceæ (8 species each); the Scrophulariaceæ, Salicineæ, and Cyperaceæ are represented by 7 species each. The flora is purely Arctic; 105 species being East Siberian, 79 West Siberian, and 101 West American. The island proves to have thus taken in species indifferently from the eastern and from the western continent. Having, however, a few genera more in common with Siberia than with America, and these genera having also a wider extension in Siberia, it would seem that the island stands in a somewhat closer connection with Asia than with America. It is worthy of notice that M. Kjellman found no endemic species; only the variety *tomentosa* of the *Cineraria frigida*, and *Saxifraga neglecta*, var. *stolonifera*, which show such variations from the typical forms as might lead them to be considered perhaps as separate species. Both are figured on plates that accompany the paper, as well as *Saxifraga neglecta*, var. *congesta*, from the land of the Chukches.—Another paper, by the same author, deals with the phanerogams of the "Western Esquimaux Land," that is of the north-western extremity of North America, between Norton

Sound and Point Barrow. The *Vega* stopped at Port Clarence, and M. Kjellman added to the 242 formerly known species about 45 new ones for this locality, one of which—*Draba palanderiana*—is a new species.

M. Oscar Nordquist contributes, under the title of "Remarks and Studies on the Mammifers of the Coasts of the Siberian Polar Sea," an elaborate paper, the result of the observations made during the cruise, as well as of his studies at the museums of St. Petersburg, Stockholm, and Copenhagen. The North Siberian coast is very poor in mammals, only twenty-nine species altogether being known from the whole of the region; moreover, seven of them inhabit the sea, to which number six or seven species of whales ought to be added. Of the twenty species of mammals inhabiting the northern coast region, only seventeen or eighteen belong exclusively to the coast region, and do not penetrate into the forest region. No distinct zoological regions can be established on this wide space; it can only be said that the fauna of the Behring region has some marked differences (especially with regard to its birds) from that of the western parts of the littoral, and especially of the coasts of the Karian Sea. The most characteristic mammal from Behring Sound is *Phoca fasciata*, and *Odobænus rosmarus*, var. *obesus*, from the seas north of Behring Strait. The variety *largha* of *Phoca vitulina* does not penetrate north of the Strait. The Chukche peninsula has a few mammals and many birds characteristic of it, namely, *Spermophilus parryi*, *Lagomys hyperboræus*, *Lepus timidus*, var. *chukchorum*, and *Arvicola kamchatika*. The other parts of the littoral have no special characteristic mammals of their own, and *Phoca fœtida*, *Phoca barbata*, and the ice bear, extend from the Ugrian Strait to the utmost eastern extremity of Asia. The most common mammals throughout the Siberian sea coast are *Canis lagopus*, *C. vulpes*, and *C. lupus*, *Rangifer tarandus*, *Myodes obensis*, *Caniculus torquatus*, two species of Arvicola described by M. Polakoff under the names of *A. middendorffii* and *A. nordenskjöldii*, and the hare (probably its Kamchatka variety). The author mentions also the interesting periodical migrations, not only of the reindeer (well known from Wrangel's descriptions), but also of *Myodes obensis* and *Cuniculus torquatus*, and reproduces a little-known Russian paper, by M. Argentoff, dealing with the migrations of mammals in North-Eastern Siberia. This general sketch is followed by the descriptions of the North Siberian mammals, with plates figuring the skulls of *Lepus chukchorum*, *Odobænus obesus*, and *Phoca fasciata*.

The same volume contains a most valuable contribution to the fossil flora of Japan, by M. Nathorst, the well-known Swedish palæontologist, to whom we are already indebted for so many researches into the Quaternary flora of Europe. It is known from Nordenskjöld's general report that the *Vega* Expedition discovered—embedded in volcanic ashes at Mogi, close by Nagasaki—a very rich collection of plants belonging to the most recent Tertiary or to the earlier Quaternary period. This find was the more precious, as our knowledge of the fossil flora of Japan was exceedingly meagre. We knew from Japan only Jurassic plants, quite like those of Eastern Siberia, with but very few exceptions, like the *Podozamites reinii*. Besides, Reiss, to whom we were indebted for these plants, had brought also from "Nikawa, Niphon," one fossil Tertiary plant identified with the *Carpinus grandis* of Unger; and Mr. Godfrey has mentioned that the coal beds at Kiousiou contain fossil plants, probably belonging to the Chalk. If we add a collection of fossil leaves at the Berlin Museum—much like those of Mogi—and another collection brought in by Mr. Lyman, and determined by Prof. Lesquereux at Columbus, Ohio (the plants appear, according to his communication to the author, much like the Miocene flora of Sakhalin), we have enumerated all we formerly knew about the younger fossil flora of Japan. No wonder that with such scant material the climate of Japan during the Tertiary and Quaternary periods remained so little known, and that Engler in his "Entwickelungsgeschichte der Pflanzenwelt" arrived at the conclusion that "no such changes of climate as those undergone by Europe and Northern America have taken place in the Japanese region since the Tertiary period." This opinion of the great German botanist does not seem to be supported by the discoveries of the *Vega*. The fossil flora at Mogi shows that this southern island of Japan experienced about the end of the Tertiary epoch a colder climate than now; it was covered at the sea-level with a vegetation much like that of the forests which cover now only the mountains of Kiousiou; the description of these forests by Rein (at Fuji-no-yama) shows that they contain a great number of species identical with, or nearly akin to, those which are found as fossils at Mogi. These last originate from a forest which contained a great variety of trees and bushes; the most common of them was the beech, akin to an American species, but as nearly akin too to the present Fuji no-yama beech. There are, of course, at Mogi, a few plants that are not met with now in Japan, such as *Celtis nordenskjöldii*, *Rhus griffithsii*, *Liquidambar formosana*, and perhaps *Magnolia dicksoniana*; but they are few, and have but a secondary meaning; only the *Magnolia* and the beech are American, whilst the others have their nearest relations in the Caucasus and Afghanistan (as the *Celtis*), or on the Himalaya (as the *Rhus griffithsii*), where we find also several other Japanese species. Several species of the Mogi flora have disappeared since; however they have still near relations in the flora of the Japanese highlands. Such are the *Juglans kjellmani*, *Carpinus subcordata* and *stenophylla*, *Quercus stuxbergii*, *Aphananthe viburnifolia*, *Diospyros nordquisti*, *Clethra maximowiczi*, *Fripetaleja almquisti*, *Sorbus lesquereuxi*, *Rhus engleri*, *Acer nordenskjöldii*, and *Ilex heeri* (all new species of M. Nathorst), which have very closely allied representatives in the forest vegetation of the Japanese highlands and northern parts of the Japanese archipelago. At the same time the more southern forms which make a constituent part of the present flora of Japan are absolutely missing in the fossil flora of Mogi. M. Nathorst concludes, therefore, that this last shows undoubtedly a colder climate than that enjoyed now by Japan. As to its age it might be either younger Pliocene or Glacial, or post-Glacial; but its characters would exclude both the latter, and thus we must admit that it belongs to the younger Pliocene; but it would be impossible, until further researches are made, to determine its age with more precision.

M. Nathorst points out also that the Miocene flora of Sakhalin, situated 18° of latitude to the north of Mogi, testifies to a much warmer climate, whilst that of Alaska, of the same period, situated, however, 9° more to the north, scarcely corresponds to a colder climate. The Miocene flora of Japan ought to have been therefore still more different from that of Mogi, and M. Nathorst concludes that the fossil flora of Mogi is a sure testimony of the extension of a colder climate, before and during the Ice period, throughout the whole of the northern hemisphere, and that this colder climate could not depend on those local conditions which were resorted to for Europe and Northern America. We may add to this conclusion that a considerable lowering of temperature throughout Northern Asia is proved also by the unmistakable traces of glaciation found, not only in the deep valleys of the Olekma highlands, but also on the southern slope of the Sayan Mountains, close by Lake Kossogol. Though received at first with some distrust, the glaciation at least of the highlands of the Thian-Shan, the Sayan, and Stanovoy Mountains has since been confirmed by so many testimonies that there can be no more doubt about it. We can only mention here the very interesting sketch given by M. Nathorst of the relations of the Japanese flora to those of different parts of the Pacific basin; the paper ought to be translated in full in some language more familiar to the geologists of Western Europe. The memoir contains the description of seventy species of plants from Mogi, seven species from the coal-measures of Takasima, and seven species from the plants in the Berlin Museum. The descriptions are accompanied by sixteen plates.

Two other important papers, both in English, are contributed to the same volume by M. Otto Petterson. One of them embodies a general discussion, an account of which appeared in NATURE, vol. xxviii. p. 417, on the properties of water and ice between − 20° to + 15° Cels., on the ground of the author's own measurements. The second paper, "Contributions to the hydrography of the Siberian Sea," not only contains valuable information gathered from the very numerous measurements of depth, saltness, and temperature of water during Nordenskjöld's expeditions on the Kara Sea and along the Siberian coast, but also gives a most valuable sketch of the hydrography of the Kara Sea. It seemed that nothing new could be written on this northern Mediterranean Sea after the beautiful researches by Dr. Petermann based upon the recent researches of the Norwegian seal-hunters. Still Mr. Petterson introduces a new element into the discussion, namely, the influence of the warm water poured into its basin by the Siberian rivers. During the summer the Kara Sea north of the Obi and Yenisei is covered with a layer of almost fresh water which has a depth of nearly twenty metres in the south, and a temperature of 6° to 9° Celsius in the summer. This layer thins out and becomes cooler as it advances towards the north, but still it reaches the north-eastern extremity of Novaya Zemlya, where it meets with the salt oceanic current brought along the western coast of the island. On the other hand, the middle parts of the Kara Sea are invaded by the Arctic current bringing cold and much salter water from the north-east. It passes underneath the fresh-water current and reaches the surface about the middle of the Kara Sea, where a saltness of 3·03 has been observed. This cold current, which has in the deepest parts of the Kara Sea (100 to 222 metres) a temperature slightly oscillating between − 1°·4 to − 2°0, and a saltness of 3·19 to 3·49, is heated more or less on its surface, which reaches in the summer from 2° to 4° above zero in the south-western and north-eastern parts of the Kara Sea: whilst in the middle, even on the surface, the temperature is generally about zero, or even − 0°·8. This distribution of currents explains the very slow melting of ice in the middle parts of the Kara Sea, which Dr. Pettermann compared to an ice-shoal floating in the middle on the surface of our ponds after a free channel has been opened along its coasts. Two maps on a large scale, showing the distribution of temperature and saltness in the Siberian Sea from Novaya Zemlya to Behring Strait, and embodying the results of Nordenskjöld's determinations of latitudes and longitudes on the Siberian coast, accompany the papers of M. Petterson.

We find in the same volume an elaborate paper, by A. Wirén, on the Chætopods of the Siberian and Behring Seas. Six tables accompany this paper, which contains the description of seventy-three species of Chætopods. The chief features of this fauna already being known from Nordenskjöld's preliminary report, we only notice that the richest part of the Siberian Sea is the Kara Sea, where the *Vega* Expedition and those of 1875 and 1876 discovered no less than sixty-nine species, whilst in the remainder of the Siberian Sea only fifty-three species were found until now.

Finally, we notice in the same volume M. Aug. Wijkander's paper on the magnetic observations made during the expedition (in French), and an appendix to the paper on the geographical determinations, by A. Lindhagen. It appears from the former that the magnetic declination on the coast of North-Eastern Asia presents several anomalies. The position of the isodynams is quite different from those given on the map of the German Admiralty ("Isodynamen und Werthe des magnetischen Potentials für 1880"). As to the inclination, it is but slightly different from the values which would result from Sabine's work; but the declination differs notably from the values given on the maps both of the German and English Admiralties. For the Behring Strait region this last, however, is decidedly the best, the average corrections for the English map being − 2°·1, and − 3°·7 for the German Admiralty map. The errors result from the secular variation having been only calculated, and not yet measured directly.

The interest awakened by the expedition of the *Vega* towards the North Siberian Sea will be perpetuated by this work. The serious scientific spirit in which the different departments of natural history are dealt with in the records of the cruise of the *Vega* will contribute more towards the increase of our knowledge of the Arctic regions than many costlier expeditions.

The third volume, just published, is mostly occupied by F. Kjellmann's "Algæ of the Arctic Ocean" (430 pages, with 31 plates). This work—the result of the author's ten years' Arctic experience—not only contains a complete botanical description of all the Algæ of the Arctic Ocean which came under notice; the author gives also a general sketch of the Arctic marine flora, with its subregions; he discusses the causes which gave it its present character: structure of the coast-line, tides, characters of the bottom, temperature, and so on; and he endeavours to draw also the chief lines of its evolution, giving thus rich material for solid generalisations.

Mr. W. Leche contributes to the same volume a note on the forty-two species of Lamellibranchiata brought in by the *Vega*; Mr. P. T. Cleve describes (in English) the Diatoms collected in the Arctic Ocean and on the return journey of the expedition, his paper being illustrated by five plates, which figure eighty-four species, mostly new; and Prof. P. Kramer and Dr. C. J. Neuman describe (in German) thirteen new species of Acarids. P. K.

EARTH TREMORS

Of the various movements to which the crust of the earth is subject, the minute motions called earth tremors attract our attention by their universality. Between them and the other motions which affect the soil the difference is chiefly in degree.

Earthquakes are the sudden and violent movements of the ground. Earth pulsations, which may be observed as terminal phenomena of large earthquakes, are movements of considerable amplitude, but so slow in period that without the aid of instruments they may be passed by unnoticed. Earth oscillations are the secular movements of upheaval and depression evidenced to us by raised beaches, sunken forests, and other geological phenomena. Lastly, we have earth tremors, or movements quick in period, but which escape our attention on account of the smallness in their amplitude. As these latter are phenomena which are probably observable in all portions of the globe, and have as yet attracted but little attention, excepting perhaps where they have proved themselves troublesome intruders affecting astronomical and other observations of a delicate nature, I purpose giving an epitome of the more important results which their observation has yielded.

Earth tremors produced by artificial disturbances, such as the passing of carriages or trains, the movements of machinery or bodies of people, are at our disposal for daily observation. At Greenwich Observatory the tremulous motion in the soil, especially noticeable on bank holidays and at times when Greenwich Park was unusually crowded, resulted in the construction of an apparatus in which the dish of mercury used in the determination of the collimation error of the transit circle was suspended by flaccid springs. By means of this contrivance the tremulous motions of the ground were absorbed before they reached the mercury, and the difficulty of observation was overcome. French engineers, working with delicate surveying instruments in crowded cities, have similarly been compelled to suspend a portion of their apparatus, so that a steady image could be obtained. Prof. H. M. Paul, seeking for a site for the Naval Observatory at Washington, found that the image of a star reflected from a tray of mercury was disturbed by a train passing at the distance of a mile. Lieut.-Col. Palmer, when engaged in observing the transit of Venus in New Zealand, discovered that a ditch a few feet in depth was sufficient to intrench his instruments against the disturbance created by trains passing at a distance of 700 yards. Capt. Denman found the effect of a goods train to be transmitted 1100 feet over marshy ground, but vertically above the train, passing through a tunnel in sandstone, the disturbance extended only 100 feet. One result obtained from these and numerous other observations upon artificially produced tremors indicates that these disturbances are superficial, and although they may creep up the surface of a gently sloping hill, their spread is checked by a steep cutting.

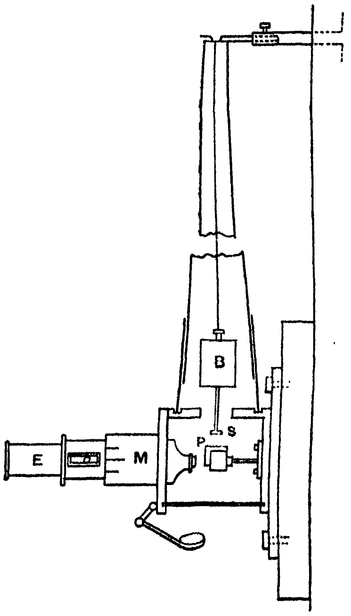
Naturally produced tremors differ from those just spoken of by the fact that their distribution is not so superficial, and not only are they to be observed in the most substantial structures which engineers can design, but they are to be equally well seen in cellars and in the walls of rocky caves. Some knowledge of the depth to which they extend might be obtained by a few microseismic observations in the deep mines of Lancashire and other parts of the United Kingdom. As the observations are so simple, and the instrument required so easily constructed—in fact, it may be home made—it is earnestly desired that some of our mine managers will spontaneously undertake this work.

I make this suggestion, not only on account of the scientific value of the work, but because there are reasons to believe that such observations may lead to results of a practical value by relations they may hold to the escape of gas, the circulation of subterranean waters, and other underground phenomena. The instrument I should recommend for this purpose is the tromometer of Bertelli and Rossi. This is shown in the accompanying figure. B is the bob of a pendulum about 100 grammes in weight, suspended by a very fine wire about 1½ metres in length. The whole is inclosed in a tube. The style S of this pendulum is seen reflected by the prism P by means of the microscope M. The eye-piece E of this microscope contains a micrometer scale, by which to measure the amplitude of the motion of the style.

The direction of motion may be obtained by turning the eye-piece until the scale is parallel with the direction of motion, and this direction then read off from the position of an index moving over compass divisions marked on the fixed tube of the microscope. To commence with, the style of a pendulum might be looked at directly with a microscope, or two microscopes placed at right angles, having magnifications of forty or fifty diameters; and if it was found that movements existed, the prism and micrometer scale might be added subsequently. The pendulums may be hung from spikes driven in the solid rock or from an iron stand.

The chief results which have been obtained with instruments of this type are those which have been arrived at in Italy. The father of the science of microseismology is Father Bertelli of Florence, who, since 1870, has made many thousands of observations under a variety of circumstances. Another ardent worker at this subject is Prof. M. S. de Rossi at Rome, by whose exertions numerous observatories have been established throughout the whole of Italy where these observations are systematically carried on. In making these observations every precaution appears to have been taken to avoid accidental disturbances, and the experiments have been repeated in a variety of forms. The results which from time to time have been announced are of the greatest interest to those who study the "physics of the earth's crust," and appear to be leading not only to the establishment of laws of scientific value, but also to the elucidation of phenomena which have an intimate connection with our every-day existence.

It would seem that the soil of Italy is in incessant movement, there being periods of excessive activity usually lasting about ten days. Such a period may be called a seismic storm. These storms are separated by periods of relative calms. The storms have their greater regularity in winter, and sharp maximums are to be observed in spring and autumn. In the midst of such a period, or at its end, there is usually an earthquake. Usually these storms are closely related to barometric depressions. To distinguish these movements from those which occur under high pressure, they are called *baro-seismic* movements, the latter being called *volcano-seismic* movements. The relation of these storms to barometric fluctuation has been observed to be very marked during the time of a volcanic eruption. At the commencement of a storm the motions are usually small, and one storm lasting two or three days may be joined to another storm. In such a case the action may be a local one. It has been observed that a barometrical depression tended to bring a storm to a maximum, whilst an increase of pressure would cause it to disappear. Sometimes these actions are purely local, but at other times they may affect a considerable tract of land.



If a number of pendulums of different lengths are observed at the same place, there is a general similarity in their movements, but it is also evident that the free period of the pendulum more or less disturbs the character of the record. The greatest amplitude of motion in a set of pendulums is not reached simultaneously by all the pendulums, and at every disturbance the movement of one will predominate. From this Rossi argues that the character of the microseismical motions is not constant.

Bertelli observed that the direction of oscillation of the pendulums is different at different places, but each place will have its particular direction dependent upon the direction of valleys and chains of mountains in the neighbourhood. Rossi shows that the directions of movement are perpendicular to the direction of lines of faults, the lips of these fractures rising and falling, and producing two sets of waves, one set parallel to the line of fracture and the other perpendicular to such a direction. These movements, according to Bertelli, have no connection with the wind, rain, change of temperature, and atmospheric electricity.

The disturbances, as recorded at different towns, are not always strictly synchronous, but succeed each other at short intervals. If, however, we take monthly curves of the disturbances as recorded at different towns in Italy, we see that these are similar in character. The maximum disturbances occur about the winter solstice and the minimum about the summer solstice, and in this respect they show a perfect accordance with the curves drawn by Mallet to show the periodicity of earthquakes.

At Florence before a period of earthquakes there is an increase in the amplitude and frequency of vertical movements. The vertical movements do not appear to come in with the horizontal barometrical disturbances, but they appear to be connected with the seismic disturbances. They are usually accompanied with noises in the telephone, but as the microphone is so constructed as to be more sensitive to vertical motion than to horizontal motion, this is to be expected. This vertical motion would appear to be a local action, inasmuch as the accompanying motions of an earthquake which originates at a distance are horizontal. Storms of microseismical motions appear to travel from point to point. Sometimes a local earthquake is not noticed on the tromometer, whilst one which occurs at a distance, although it may be small, is distinctly observed. To explain this, Bertelli suggests the existence of points of interference and the existence of nodes.

Similar results were arrived at by Rossi when experimenting at different points on the sides of Vesuvius. Galli noticed an augmentation in microseismic activity when the sun and moon are near the meridian. Grablovitz found from Bertelli's observations a maximum two or three days before the syzigies, and minimum three days after these periods. He also found that the principal large disturbances occurred in the middle of periods separating the quadrature from the syzigies, the apogee from perigee, and the solstice period from the nodes, whilst the smallest disturbances happened in the middle of periods opposed to these.

P. C. Melzi says that the curves of microseismical motions, earthquakes, lunar and solar motions, show a concordance with each other. With the microphone Rossi hears sounds which he describes as roarings, explosions, occurring isolated or in volleys, metallic and bell-like sounds, ticking, &c., which he says revealed natural telluric phenomena. These are sometimes intolerably loud. At Vesuvius the vertical shocks corresponded with a sound like volleys of musketry, whilst the undulating shocks gave the roaring. Some of these sounds could be imitated artificially by rubbing together the conducting-wires in the same manner in which the rocks must rub against each other at the time of an earthquake, or by placing the microphone on a vessel of boiling water, or by putting it on a marble slab and scratching and tapping the under side of it.

These then are some of the more important results which have been arrived at by the study of microseismic motions. One point which seems worthy of attention is that they appear to be more law-abiding than their violent relations, the earthquakes, and as phenomena in which natural laws are to be traced they are certainly deserving of our attention. As to whether they will ever become the means of forewarning us against earthquakes is yet problematical. Their systematic study, however, will enable us to trace the progress of a microseismic storm from point to point, and it is not impossible that we may yet be enabled to foretell where the storm may reach its climax as an earthquake. This, I believe, is a view held by Prof. de Rossi.

Before the earthquake of San Remo, on December 6, 1874, Rossi's tromometer was in a state of agitation, and similar disturbances were observed at Livorno, Florence, and Bologna. Since February, 1883, I have observed a tromometer in Japan, and such results as have been obtained accord with results obtained in Italy.

The increase in microseismical activity with a fall of the barometer is very marked. The style of the pendulum does not always oscillate about the same point—there is a deflection in the vertical. In Manila Father Faura also makes observations with a tromometer, which I am told gives him by movements very decided indications of approaching typhoons.

As to the cause of tromometric movements we have a field for speculation. Possibly they may be due to slight vibratory motions produced in the soil by the bending and crackling of rocks produced by their rise upon the relief of atmospheric pressure. If this were so, we should expect similar movements to be produced at the time of an increase of pressure.

Rossi suggests that they may be the result of an increased escape of vapour from molten materials beneath the crust of the earth consequent upon a relief of external pressure. The similarity of some of the sounds which are heard with the microphone to those produced by boiling water are suggestive of this, and Rossi quotes instances when underground noises like those which we should expect to hear from a boiling fluid have been heard before earthquakes without the aid of microphones. One instance was that of Viduare, a prisoner in Lima, who, two days before the shock, 1824, repeatedly predicted the same in consequence of the noises he heard.

A possible cause of disturbances of this order may be the sudden fluctuations in barometric pressure which are visible during a storm.

In addition to the observations which have been especially made for the purpose of recording earth tremors, there are numerous observations which have been made upon these disturbances when they have appeared as intruders in investigations on other subjects. Amongst these may be mentioned the endeavours to measure changes in the vertical, as for instance those which might be produced by the attractive influence of the moon.

Prof. Zöllner, who invented the horizontal pendulum, found that the readings of his instrument were always changing.

M. d'Abbadie, who for several years observed a reflected image in a pool of mercury contained in a basin of solid rock, found it a rare occurrence that the surface of the mercury was tranquil. Sometimes it appeared to be in violent motion.

George and Horace Darwin, in their experiments at Cambridge to determine the disturbing influence of gravity by lunar attraction, found that the irregular and persistent tremors in the ground, as indicated by the instruments, were sufficient to mask whatever effects may have been due to the influence of the moon.

A full account of these latter observations is to be found in Messrs. G. and H. Darwin's Report for 1882 to the British Association.

The general conclusion, then, is that from observations in England, France, Germany, Italy, the Philippines, Japan, and, I may add, the West Indies, it would appear that the crust of the globe is practically in a constant state of tremor. The variations in these movements are more law-abiding than the large earth movements, and they show a direct relationship to barometric fluctuation.

Their relationship to many other telluric and atmospheric phenomena, together with their cause, has yet to be discovered. As every one has the opportunity to observe these phenomena, they call for attention. Just as a turbulent sea outraces a coming typhoon and gives mariners warning of approaching danger, it is possible that these microscopic disturbances of the soil may hold connection with subsequent phenomena, and lead us by their study to the better understanding of the complexity of phenomena with which we are surrounded.

Tokio, Japan JOHN MILNE

THE MECHANICAL THEORY OF MAGNETISM

IF Prof. Hughes were as great a master of writing English as he is of experimenting, his views on magnetism would receive speedier acceptation, for they would then probably be understood without that close study which his involved sentences and heterogeneous paragraphs now demand. It is very remarkable that such an ardent worker, such a deep thinker, and such a clear and simple experimenter should have such difficulty in expounding his views on paper. His experimental demonstrations are always clear and convincing, his recent lecture at the Royal Institution appealed to every degree of intelligence present, but his papers at the Royal Society want some strong external directing influence to render their meaning evident.

What is magnetism, according to this expert philosopher? It is an inherent quality of the molecules of matter, as determined and constant as that of their gravity, affinity, or cohesion, and like these qualities it differs in degree with every kind of matter. He does not attempt at present to define it closer than this. We cannot tell what gravity is, neither need we say what magnetism is. All Prof. Hughes says is that every molecule in nature is a little magnet imbued with a certain polarity varying in degree but constant for each substance, in virtue of which it has a north and a south pole along the same axis, and that the only change that takes place is a change in the direction of this polar axis. When these molecules are symmetrically arranged by some external directing influence, so that all their poles lie in the same direction, we have *evident magnetism*. Iron becomes a magnet in virtue of the fact that its molecules are free to move under the influence of external magnetic action, while copper is not a magnet because its molecules are immovable and irresponsive to the same cause. Steel becomes permanently magnetised because its molecules are rigid, and retain the axial direction impressed upon them. Soft iron is readily demagnetised because its molecules have great freedom of motion. Coercive force is therefore simply absence of freedom of molecular motion—it is, indeed, molecular rigidity. The extent to which the axis of polarity can be deflected from its normal direction is its *point of saturation*.

Evident magnetism is the symmetrical arrangement of the polarised molecules along one line; *neutrality* is symmetrical arrangement of the same molecules in closed curves. In both cases the sum of the magnetic influence of all the molecules is the same; but in evident magnetism it is directed outwards, in neutrality it is directed inwards. Remaining magnetism is partial neutrality. The experimental way in which Prof. Hughes demonstrated these conclusions is the most beautiful investigation he has yet made. He proves the existence of the same polarity in the atmosphere and in the ether, and he attributes diamagnetic effects to the higher magnetic capacity of the ether than of the substances suspended in it. It is therefore a differential action. Molecules, moreover, have inertia—they resist being put in motion; and when in motion they resist stoppage—they possess momentum. The direction of the axis of polarity can be displaced by the physical forces, such as mechanical stress, heat, or electricity. He shows that mechanical motion, heat, and electricity are of similar kind—they are vibratory, or some mode of motion. Magnetism, however, he considers not to be a mode of motion, and therefore it is not a physical force. It is simply an arrangement of the molecules of matter in symmetry or dissymmetry under the influence of some physical force. He seems to imply, though he does not directly say so, that the influence of electric currents upon magnets is not due to any direct action between them, but to the fact that the currents have polarised the ether in which both are suspended.

His views are very broad and highly suggestive, but there are some points that are not clear and that demand further elucidation. Why, for instance, does mechanical elongation and contraction take place when bars of iron are magnetised and demagnetised? How can heat and strong sonorous vibrations be produced unless there be a considerable expenditure of energy? How does he account for the attractive and repulsive properties of magnets, and for magnetic induction? He has certainly wrested magnetism from the realms of hypothesis and brought it within the domain of theory. The days of Coulomb and Poisson's fluids and Ampère's elementary currents of electricity are over; the molecular character of magnetism is experimentally established; but what is a molecule, and how becomes it polarised unless it be in rotation? How does the external directing influence act? We are also inclined to ask, Has Prof. Hughes sufficiently grasped Ampère's theory? It was purely mathematical, based on the assumption of the circulation of currents around each molecule. He goes no further than Ampère did, for he has not answered the question, What is polarity? In fact his polarised molecules are all little magnets, and no theory of magnetism will be complete until it explains these little magnets. Thus the difference between Ampère and Hughes is the difference between a current and a magnet.

However, on the assumption that a molecule is a magnet, Prof. Hughes has built up a very complete theory, which he has demonstrated experimentally in a way that places him in the very front rank of experimental philosophers.

NOTES

THE number of candidates up this session for the Fellowship of the Royal Society is sixty-seven.

WE understand that Sir Joseph Hooker has been nominated one of the vice-presidents for the Montreal meeting of the British Association. Instead of Mr. Crookes, Prof. W. G. Adams will give one of the public lectures. For the reduction of the fares of members the sum of 14,000 dollars has been allotted, only those elected at or before the Southampton meeting being entitled to share in the subsidy. This is in addition to the liberal reductions that will be made by the steamship and railway companies. All the American railways will reduce their fares by one-half. The American Association, which meets at Philadelphia on September 3, has given a cordial invitation to the Montreal visitors to take part in its meetings and excursions. Those wishing to share in the subsidy of 14,000 dollars must apply before September 25. For the Aberdeen meeting in 1885, Sir Lyon Playfair will be proposed as president. A well-attended meeting of the Organising Committee of the Chemical Section has been held under the presidency of Prof. Roscoe. Promises of papers were received from several well-known chemists, and a small executive committee was formed to draw up a list of papers and to communicate with Canadian and American chemists. Section G has been particularly active. The Committee has prepared a list of subjects for papers which it is thought would be interesting to English visitors if treated by engineers and mechanicians in Canada; a good supply of papers is expected both from this country and America. We regret to learn that Prof. Williamson, the General Treasurer, will be unable to be present, and the Council have decided to engage the services, *pro hac vice*, of Mr. Hamy Brown, Assistant Secretary and Accountant of University College, as "Financial Officer," while Prof. Burdon Sanderson has virtually consented to act as deputy for the Treasurer at Montreal.

M. Caro, for the French Academy, and MM. Pasteur and d'Abbadie, for the Academy of Sciences, will attend as delegates the *fêtes* at Edinburgh in commemoration of the tercentenary of the foundation of the University of Edinburgh.

Dr. Koch and his colleagues of the German Cholera Commission will proceed shortly to Goalpara and Darjeeling to prosecute further inquiries. After passing a few days there, they will return to Germany, but they hope to be back in India next winter to carry on their very important and useful labours.

Dr. George Engelmann of St. Louis—the oldest United States botanist (excepting the venerable Lesquereux), as well as an eminent physician, for a time a fellow-student with Agassiz in Germany—died on February 11, at the age of seventy-five.

Commodore Samuel R. Franklin, U.S.N., has been detached from duty on the United States Naval Examining Board, and ordered as superintendent of the naval observatory, to succeed Rear-Admiral R. W. Shufeldt, who was placed upon the retired list on February 21.

At the sitting of the Academy of Sciences of March 10 M. Faye presented drawings which have been executed at Algiers by M. Trépied, Director of the Observatory, and which represent Pons' comet as seen on the very days on which have been noticed the changes that have excited such surprise amongst certain astronomers. M. Faye took advantage of this communication to give an explanation of these wonderful observations, which are more frequent than has been supposed in the history of astronomy. M. Faye does not suppose that they may be attributed to any collision with cosmical matter, but to a rapid change in the point of view of the comet itself, as observed from the earth. This theory will be illustrated by a woodcut published in the next number of the *Comptes Rendus*.

Considerable progress has now been made in the carrying out of the works connected with the marine station which some time ago the Scottish Meteorological Society resolved to establish at Granton; and it is anticipated that the operations of the station will be properly commenced towards the close of the present month. As the first instalment of the work to be done, it is hoped that a tolerably complete description of the Firth of Forth, in its biological, meteorological, physical, and chemical relations, may be prepared in the course of the next few years; and when this has been carried out, the result will have an exceptional, and indeed unique value, as a piece of work of the greatest scientific and national importance, produced by cooperation amongst scientific men. The Council of the Scottish Meteorological Society, it may be mentioned, recently asked Her Majesty's Government for a subscription of 1000*l.* for the purpose of building permanent laboratories in connection with the station—undertaking at the same time to raise an additional 1000*l.* by public subscription. The Government, however, have not seen their way to assist this school of research, notwithstanding that the grant was warmly recommended by Prof. Huxley, President of the Royal Society. The Council of the Meteorological Society have, however, every confidence that the scheme will be liberally supported by the general public.

Dr. Casey, F.R.S., has just written a new work on Analytic Geometry, which covers about two-thirds of the ground occupied by Salmon's Conics; in the author's opinion it will contain more new matter than any work on the subject since Salmon's book was written.

An interesting experiment is to be made by Dr. Zintgraff, who, in company with Dr. Chavanne, is about to visit the Congo and the interior of Africa. He takes with him a phonograph, wherewith to fix the speech and melodies of hitherto unknown tribes, which, thus received by the instrument, will be forwarded to scientific men in Germany. The apparatus (which will be used for such a purpose for the first time) has been made by Mr. Fuhrmann, of Berlin, and exactly corresponds with one he has in that city, so that the plates used in Africa can be sent to Berlin to be unrolled by that machine, and caused to re-emit the sounds received.

A remarkable occurrence is reported from Bona (Algeria). An isolated mountain, Jebel Naiba, 800 m. in height, is rapidly decreasing in altitude, and round its base a considerable cavity is being formed. The whole mass of the mountain is evidently sinking. The neighbourhood of Bona must, however, have already been the scene of a similar phenomenon. Lake Fezzara, which measures over 12,000 hectares in extent, did not exist during the time of the Romans. Its depth in the centre is only 2·60 m. Investigations which were made in 1870 showed that the remains of a Roman town now lie in the lake; this town has therefore probably sunk in the same manner as the mountain.

A prehistoric burial-ground has been discovered on the so-called Hasenburg, near Buhla (Kreis Nordhausen, Germany). Two complete human skeletons, numerous bronze rings, and several rings made of amber were found. The Hasenburg is an isolated rock on which stood formerly a castle of the Emperor Henry IV.; but the numerous prehistoric remains found in the neighbourhood point to its having been an ancient place of worship. The objects recently found have been deposited in the Museum of Nordhausen.

The appointment by the Swedish Government of an entomologist to assist farmers has been found of so much value that it has been decided to continue the same. Dr. A. Holmgren has been appointed agricultural entomologist for this year.

The city of Hamburg offers various prizes for the plans of a new Natural History Museum. The total cost of construction of the building must not exceed 45,000*l.* Five prizes of 50*l.* each will be awarded for the five best plans; further prizes of 200*l.* will be distributed amongst the victors for further work in connection with the scheme.

At a recent meeting of the Straits Branch of the Royal Asiatic Society at Singapore, it was decided to prepare and publish a school geography of the Malay peninsula and the adjoining regions, as well as a skeleton map of the peninsula, on a scale of a quarter of an inch to a mile, to be gradually filled in as may be determined by subsequent survey and research.

Dr. Benjamin Sharp has been appointed Professor of Lower Invertebrata by the Council of the Academy of Natural Sciences of Philadelphia. Dr. Sharp is a graduate of the University of Pennsylvania, from which he received the degrees of Doctor of Medicine and Doctor of Philosophy in 1881. He afterwards studied under Leuckart in Leipzig, and under Semper in the University of Wurzburg. Dr. Sharp was granted the privilege of studying at the Bavarian table in the Zoological Station at Naples, an honour rarely granted a foreigner. Dr. Sharp proposes delivering lectures, during the coming spring, on the lower forms of life.

Prof. Karpinsky points out, in the *Memoirs of the St. Petersburg Society of Naturalists* (vol. xiii.), the following interesting feature of the geological structure of Russia. The unmetamorphosed rocks in Russia appear mostly quite, or nearly quite, undisturbed and horizontal. There is, however, besides the Crimea, a region where some dislocation and disturbance of these deposits are apparent. This disturbed region runs from north-west to south-east, through the Sandomir ridge in Poland to Kaneff in Kiev, Isakchi in Poltava, the coal-basin of the Don, the Bogdo Mountains of the Astrakhan Steppe, and finally to the Kara-tan and Ak-tan Mountains to the east of the Caspian. Beyond this region even the older deposits (Silurian and Devonian) remain undisturbed, while within it the older gneisses and crystalline schists are disturbed, not only by the Silurian upheaval which has had a direction from north-east to south-west, but also by the more recent one just referred to, which has a direction perpendicular to it. It is worthy of notice that this line of upheaval would join that line of ridges which runs in Western Europe through the mountains of the Weser and the Teutoburger Wald, while in Asia it would join the Sheikh-jeli and Uiz-Dagh Mountains.

We notice in the same serial some very valuable observations of Prof. Beketoff about Dr. Sachs' theory as to the relations between the increase and segmentation of cells in the embryonal parts of plants. While he warns one against the application of geometrical theories to botany, he points out how some of the conclusions arrived at by Dr. Sachs could be more easily explained by the principles established by Wilhelm Hofmeister. Prof. Borodin's researches into the anatomy of the leaves of *Chrysosplenium* were made on very rich material collected by Prof. C. Maximowicz for his "Adumbratio Generis Chrysosplenii," and Prof. Borodin was enabled not only to thoroughly study the subject, but also to arrive at some most valuable conclusions as to the relations between the anatomical features of different species of this genus and the features on which the classification of these species has been made.

Traces of glaciation in Siberia, so boldly denied a few years ago, have been discovered in different parts of the country. While failing to detect them on the outer parts of the Altai Mountains, M. Sokoloff has found unmistakable traces of an incomparably wider extension of glaciers in the central parts of the ridge, and especially in the Katun Mountains. Numerous traces have also been found, pointing to a greater extension of lakes during the post-Glacial period, and to the gradual drying up of the existing ones.

In a paper recently published in the *Mémoires de l'Académie des Sciences de St. Pétersbourg* for 1883, Prof. Fr. Schmidt, while fully agreeing with the remarkable results of Mr. Walcott's researches as to the feet and respiratory organs of Trilobites (published in 1881 in the *Bulletin of the Harvard College Museum*), proposes to include in Mr. Walcott's second group of *Paleadæ* his own family of *Hemiaspidæ*. It consists of the genera *Hemiaspis*, Woodw., *Bunodes*, Eichw., and *Pseudoniscus*, Nieszk., which are much like Trilobites, but differ from them in the separate and freely-moving posterior parts of the body; formerly it was included in the group of Eurypterides.

Prof. Tarkhanoff contributes to the last volume of the *Memoirs* (*Trudy*) *of the Society of Naturalists of St. Petersburg* a very interesting inquiry into the structure of the eggs of birds. He has discovered that the albumen of the eggs of the *Insessores* (ousel, canary, pigeon, &c.) notably differs from that of the Autophagous birds (hens, ducks, geese, turkeys). When boiled it remains translucid; it is fluorescent; its rotation-power of the plane of polarisation is feebler; when diluted with much water it does not give a white deposit, but only gives a feeble opalescent coloration to the water; finally, it has a stronger basic reaction than the white of the eggs of the hen. It may, however, be transformed so as to become like it by various means, namely: the addition of neutral salts, or of bases, or of concentrated acetic and lactic acids, or even of carbonic acid. The most remarkable fact however is that the same result is also arrived at by incubation, and Prof. Tarkhanoff considers that the modifying agency in this case is the yolk; when moderately heated with yolk in closed vessels, during twenty-four hours or more, it is transformed into albumen like that of a hen's egg. As to the manner in which the yolk acts on it, it still remains unsettled; the supposition that the diffusion of salts is the cause of the change proved not to be true; and the cause must be searched for perhaps in the diffusion of gases. The interesting question, as to the albumen of hen's eggs not also undergoing the same stages of development within the ovarium, cannot yet be solved satisfactorily; but during his experiences M. Tarkhanoff observed once the most interesting fact that a small ball of amber introduced into the upper part of the ovarium occasioned the deposition around the ball of albumen and the formation of a shell, that is, the formation of a quite normal egg with its *chalazæ*, and other particularities of structure; this observation would thus strongly support the mechanical theory of the formation of the parts of an egg around its yolk.

Dr. King, retired Professor of Mineralogy, Geology, and Natural History in Queen's College, Galway, has lately been elected a Corresponding Member of the New York Academy of Sciences.

Mr. E. L. Layard writes to us from Noumea, New Caledonia, under date Jan. 6, that the sunsets there have been quite as extraordinary as elsewhere. "As soon," he says, "as the sun's disk has disappeared, a glow comes up from the west like that of white-hot steel, reddening somewhat as it mounts to the zenith, but changing the while to blue. From the zenith it passes into the most exquisite green, deepening as it loses itself in the east. As the sun sinks lower and lower, the red tints overpower the white-hot steel tints, and the blue of the zenith those of the green. At 7 p.m., or a little after, nearly the entire western half of the horizon has changed to a fiery crimson; as time goes on, the northern and southern areas lose their glory, and the grays of night contract, from the northern end first, most rapidly; the east is of the normal gray. The south now closes in, and presently, about 8 p.m., there is only a glare in the sky, just over the sun's path as of a distant conflagration, 'till the fire in the west fades out.' I have been attempting to describe one of our cloudless evenings, of which we have had only too many, having just come through a fearful drought that has lasted all this while; but who shall paint the glory of the heavens when flecked with clouds! Burnished gold, copper, brass, silver—such as Turner in his wildest dreams never saw! and of such fantastic forms! The wonderful light from above was reflected on every tree and flower; our scarlet and crimson geraniums, fuchsias, &c., blazed in the light as I never saw them before, and the general effect was most extraordinary."

The Cremation Society of Berlin now numbers 365 members, no less than 146 having joined the Society during 1883. The cremation movement is also progressing favourably at Hamburg, Königsberg, Dresden, Breslau, and Wiesbaden. At Gotha forty-six bodies were cremated during 1883, which is about double the number of those burnt in any of the four preceding years.

The additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♀) from India, a Pig-tailed Monkey (*Macacus nemestrinus* ♀) from Java, presented by Mr. G. H. Lee; two Herring Gulls (*Larus argentatus*), European, presented by Madam Fridalch; a Kagu (*Rhino-*

chetus jubatus) from New Caledonia, presented by Mons. J. M. Cornely, C.M.Z.S.; four Blue Titmice (*Parus cæruleus*), British, presented by Mr. Hanaeur; a Barn Owl (*Strix flammea*), British, presented by Mrs. W. Gittens; a Rhesus Monkey (*Macacus rhesus* ♂) from India, deposited; a Bosman's Potto (*Perodicticus potto*) from West Africa, purchased; a Yellow-billed Duck (*Anas xanthorhyncha*) from South Africa, received in exchange; a Bengalese Cat (*Felis bengalensis*) from India, received on approval; a Zebu (*Bos indicus* ♂), a Collared Fruit Bat (*Cynonycteris collaris*), an Emu (*Dromæus novæ-hollandiæ*), bred in the Gardens.

GEOGRAPHICAL NOTES

ALTHOUGH the Chefoo Convention made with China in 1876 has never been ratified, we are now reaping various advantages from its provisions. With the object of exploring South-Western China, and of watching the possibilities of the development of trade in these regions, it was arranged that an English Consular Agent was to reside at Chung-King in Sze-chuan on the upper waters of the Yang-tse. The officers who have held this post for the past six years have travelled widely through Yunnan, Sze-chuan, Kweichow, and other provinces, and have made most valuable contributions to the geography of China by the reports which have been published by them. Thus we have Mr. Colborne Baber's explorations in South-Western China published by the Royal Geographical Society, Mr. Parker's papers in the *China Review*, which we have already noticed, and now Mr. Hosie has made two reports, which have recently been published as Parliamentary Papers. The last of these deals with a journey of nearly 2000 miles from Chung-King to Chêng-tu, the provincial capital of Sze-chuan, thence by Tali in Yunnan to Yunnan-Fu, the capital of this province, returning to Chung-King by another route. The traveller does not think much of the European maps of these districts, for on p. 58 we find him complaining that "the number of mistakes in these maps, whether as regards boundary lines, names of places, &c., not to mention omissions, is truly alarming. As fairly accurate native maps are procurable, the occurrence of such mistakes as the above is astonishing." Mr. Hosie also gives some account of the aboriginal tribes, who usually avoid the frequented routes, as as they are afraid of being taken by the Chinese. He saw several Lolos, and a Si-fan or "tame wild man," as he is called by a kind of Hibernicism, as well as representatives of several other frontier tribes. There can be little doubt that in a short time, with these able and energetic English officers travelling far and wide from Chung-King as a centre, the geography of the south-western corner of China will be as well known to us as that of the districts adjoining the coast.

AT the opposite corner of the China Seas, another English officer, Consul-General Leys of Borneo, is endeavouring to promote the commercial development of little-visited districts in that wonderful island. He has recently visited the tracts watered by three considerable rivers flowing into Brunei Bay near Labuan, and hopes to get the Chinese merchants of the latter colony, as well as of Singapore, to send trading parties up these rivers. He further suggests the appointment of consular agents in the interior of the dominions of the Sultan of Brunei: a step which cannot fail largely to increase our knowledge of the geography and resources of Borneo.

THE December number of Guido Cora's *Cosmos*, which completes the first series (1873-1883) of that useful publication, contains the first part of Capt. C. F. Crema's journey to Morocco in connection with the Italian Mission under Commander Scovasso in 1882. The text, which gives us a graphic account of the progress of the mission from Tangiers through the maritime provinces southwards to the mouth of the Sebu in the Atlantic Ocean, is richly illustrated with numerous woodcuts from photographs and sketches taken by Crema himself. Some of the heads in these illustrations, such as those of Scovasso, the Kaid Raka, and the Arab Surgeon of Caria-ben-Auda, are capital studies of character and ethnical types. Others vividly reflect the salient aspects of the land, the architecture, and industries of its inhabitants. Conspicuous amongst these is the fine north-west gate of Shella near Rabat, which, with its two hexagonal towers, is the grandest monument of Moorish architecture still surviving in Morocco. The paper is also accompanied with a map to the scale of 1 : 750,000, which, being based on an accurate survey of the route, forms a valuable contribution to geographical exploration. It fills up many blank spaces, and gives numerous rectifications of existing maps, even in districts that have already been frequently visited by European travellers. In the same issue Gustavo Bianchi gives an account of his recent explorations in the Gurageh territory during the spring of the year 1880, accompanied by a useful map of the Galla country to the south and east of Shoa, which, with the exception of Cecchi and Chiarini's expedition in 1878, had been visited by no traveller since the time of Major Harris and d'Abbadie (1843-46).

THE *Boletin de la Sociedad Geografica di Madrid* for December 1883 has a paper by D. José Gomez San Juan, on the Spanish possessions in the Gulf of Guinea. The object of the writer is to establish the exclusive right of Spain to the islands of Annobon, Corisco, and the two Elobeis, as well as to the portion of the opposite mainland stretching from Punta del Campo to Punta Santa Clara on the right bank of the Gaboon. The paper is ably written, and contains much interesting historical and geographical information on the whole of the west coast of Africa from Sierra Leone to the equator.

THE German and Austrian Alpine Club now consists of no less than 100 sections. The last two sections formed were those at Bonn, on the Rhine, and at Schladming Radstadt in the Upper Enns Valley.

THE Stuttgart branch of the Berlin Centralverein für Handelsgeographie contemplates the establishment of a Museum for commercial geography at Stuttgart.

THERE will be several special exhibitions at Munich on the occasion of the fourth German Geographentag. The following are planned: (1) new maps and books; (2) curiosities of cartography and geographical literature; (3) Bavarian maps; (4) maps, reliefs, and books relating to the Alps; (5) maps, reliefs, atlases, and other objects suitable for instruction in geography; (6) work done by pupils in geography, to illustrate the methods of teaching.

LETTERS have been received from Herr Junker and from the Khartoum Consul, Herr Hansal, which, however, do not give satisfactory details about the traveller's doings during the last two years, nor about his present position. They are principally short notes dating from December 1882, August and October 1883, in which he refers to longer letters and reports, which have, however, not yet come to hand. Nevertheless, these notes prove that Junker was in good spirits and health in the Sennis Country at the beginning of October last, and far from being disheartened or disturbed by events in the Soudan, of which he knew, was fully occupied with his travels and the drawing of his maps.

DR. FINSCH of Bremen has now published the "Anthropological Results" of his journey to the Pacific, and they form a valuable addition to anthropological literature. The traveller does not solely rely upon his own researches and observations, but also upon his (according to Virchow) unexampled collection of plaster casts from the faces of living men and women, natives of the islands he visited. This collection consists of no less than 164 casts, and represents natives of sixty-one different islands; besides Polynesians, Micronesians, and Melanesians, it also contains Malays of the Indian Archipelago, for the sake of comparison. Copies of the casts will be a welcome means of instruction in anthropology, and can be obtained through Herr Louis Castan at Berlin (Panopticum).

AN expedition to the North Pole is being prepared by Capt. Fondacaro of the Italian navy. It is several centuries since an expedition to the North Pole was despatched from Italy.

THE SIX GATEWAYS OF KNOWLEDGE[1]

II.

THE sense of sight may be compared to the sense of sound in this respect. I spoke of the sense of sound being caused by rapid variations of pressure. I had better particularise and say how rapid must be the alternations from greatest pressure to least, and back to greatest, and how frequently must that period occur, to give us the sound of a musical note. If the barometer varies once a minute you would not perceive that as a musical note. But suppose by any mechanical action in the air, you could cause the barometric pressure—the air pressure—to vary much more rapidly. That change of pressure which the barometer is not quick enough to show to the eye, the ear hears as a musical sound if the period recurs twenty times per second. If it recurs twenty, thirty, forty, or fifty times per second, you hear a low note. If the period is gradually accelerated, you hear the low note gradually rising, becoming higher and higher, more and more acute, and if it gets up to 256 periods per second, we have a certain note called C in the ordinary musical notation. I believe I describe it correctly as the low note C, of the tenor voice—the gravest C that can be made by a flute. The note of a two-foot organ pipe open at both ends has 256 periods per second. Go on higher and higher to 512 periods per second, and you have the C above that—the chief C of the soprano voice. Go above that to 1024, you get an octave higher. You get an octave higher always by doubling the number of vibrations per second, and if you go on till you get up to about 5000 or 6000 or 10,000 periods per second, the note becomes so shrill that it ceases to excite the human ear and you do not hear it any longer. The highest note that can be perceived by the human ear seems to be something like 10,000 periods per second. I say "something like," because there is no very definite limit. Some ears cease to hear a note becoming shriller and shriller before other ears cease to hear it; and therefore I can only say in a very general way, that something like 10,000 periods per second, is about the shrillest note the human ear is adapted to hear. We may define musical notes, therefore, as changes of pressure of the air, regularly alternating in periods which lie between 20 and 10,000 per second.

---

[1] An Address at the Midland Institute, Birmingham, October 3, 1883, by Prof. Sir William Thomson, LL.D., F.R.S., president. Continued from p. 440.

Well now, are there vibrations of thirty or forty or fifty or a hundred thousand or a million of periods per second in air, in elastic solids, or in any matter affecting our sense? We have no evidence of the existence in matter of vibrations of very much greater frequency than 10,000 or 20,000 or 30,000 per second, but we have no reason to deny the possibility of such vibrations existing, and having a large function to perform in nature. But when we get to some degree of frequency that I cannot put figures upon, to something that may be measured in millions, if not in hundred-thousands of vibrations per second, we have not merely passed the limits of the human ear to hear, but we have passed the limits of matter, as known to us, to vibrate. Vibrations transmitted as waves through steel, or air, or water, cannot be more frequent than a certain number, which I cannot now put a figure to, but which, I say, may be reckoned in hundred-thousands or a few millions per second.

But now let us think of light. Light we know to be an influence on the retina of the eye, and through the retina on the optic nerve; an influence dependent on vibrations whose frequency is something between 400 million millions per second and 800 million millions per second. Now we have a vast gap between 400 per second, the sound of a rather high tenor voice, and 400 million millions per second, the number of vibrations corresponding to dull red light—the gravest red light of the prismatic spectrum. Take the middle of the spectrum—yellow light—the period of the vibrations there is in round numbers 500 million millions per second. In violet light we have 800 million millions per second. Beyond that we have something that the eye scarcely perceives—does not perceive at all perhaps—but which I believe it does perceive, though not vividly: we have the ultra-violet rays, known to us chiefly by their photographic effect, but known also by many other wonderful experiments, that within the last thirty years have enlarged our knowledge of light to a most marvellous degree. We have invisible rays of light made visible by letting them fall on a certain kind of glass, glass tinged with uranium—that yellowish green glass, sometimes called canary glass or chameleon glass. Uranium glass has a property rendering visible to us invisible rays. You may hold a piece of uranium glass in your hand, illuminated by this electric light, or by a candle, or by gas light, or hold it in the prismatic spectrum of white light, and you see it glowing according to the colour of the light which falls upon it; but place it in the spectrum beyond the visible violet end, where without it you see nothing, where a piece of chalk held up seems quite dark, and the uranium glass glows with a mysterious altered colour of a beautiful tint, revealing the presence of invisible rays, by converting them into rays of lower period, and so rendering them visible to the eye. The discovery of this property of uranium glass was made by Prof. Stokes, and the name of fluorescence from fluor spar, which he found to have the same property, was given to it. It has since been discovered that fluorescence and phosphorescence are continuous, being extremes of the same phenomenon. I suppose most persons here present know the luminous paint made from sulphides of calcium and other materials, which, after being steeped in light for a certain time, keep on for hours giving out light in the darkness. Persistence in emission of light after the removal of the source, which is the characteristic of those phosphorescent objects, is manifested also, as Edmund Becquerel has proved, by the uranium glass, and thus Stokes' discovery of fluorescence comes to be continuous with the old known phenomenon of phosphorescence, to which attention seems to have been first called scientifically by Robert Boyle about 200 years ago.

There are other rays, that we do not perceive in any of these ways, but that we do perceive by our sense of heat: heat rays as they are commonly called. But in truth all rays that we call light have heating effect. Radiant heat and light are one and indivisible. There are not two things, radiant heat and light: radiant heat is identical with light. Take a black hot kettle into a dark room, and look at it. You do not see it. Hold your face or your hand near it, and you perceive it by what Bunyan would have called Feel Gate; only now we apply the word feeling to other senses as well as Touch. You perceive it before you touch it. You perceive it with the back of your hand, or the front of your hand; you perceive it with your face, yes, and with your eye, but you do not see it. Well, now, must I justify the assertion that it is not light? You say it is not light, and it is not so to you, if you do not see it. There has been a good deal of logic-chopping about the words here; we seem to define in a vicious circle. We may begin by defining light—"It is light if you see it as light; it is not light if you do not see it." To save circumlocution, we shall take things in that way. Radiant heat is light if we see it, it is not light if we do not see it. It is not that there are two things; it is that radiant heat has differences of quality. There are qualities of radiant heat that we can see, and if we see them we call them light; there are qualities of radiant heat we cannot see, and if we cannot see them we do not call them light, but still call them radiant heat: and that on the whole seems to me to be the best logic for this subject.

By the bye, I don't see Logic among the studies of the Birmingham and Midland Institute. Logic is to language and grammar what mathematics is to common sense; logic is etherealised grammar. I hope the advanced student in grammar and Latin and Greek, who needs logic perhaps as much as, perhaps more than, most students of science and modern languages, will advance to logic, and consider logic as the science of using words, to lead him to know exactly what he means by them when he uses them. More ships have been wrecked through bad logic than by bad seamanship. When the captain writes down in his log—I don't mean a pun here, log has nothing to do with logic—the ship's place is so-and-so, he means that it is the most probable position—the position which, according to previous observations, he thinks is the most probable. After that, supposing no sights of sun or stars or land to be had, careful observation of speed and direction shows, by a simple reckoning (called technically the dead reckoning), where the ship is next day. But sailors too often forget that what they put down in the log was not the ship's place, but what to their then knowledge was the most probable position of the ship, and they keep running on as if it was the true position. They forget the meaning of the very words in which they have made their entry in the log, and through that bad logic more ships have been run on the rocks than by any other carelessness or bad seamanship. It is bad logic that leads to trusting to the dead reckoning, in running a course at sea; and it is that bad logic which is the cause of those terribly frequent wrecks; of steamers, otherwise well conducted, in cloudy but perfectly fine weather, running on rocks at the end of a long voyage. To enable you to understand precisely the meaning of your result when you make a note of anything about your own experience or experiments, and to understand precisely the meaning of what you write down, is the province of logic. To arrange your record in such a manner that if you look at it afterwards it will tell you what it is worth, and neither more nor less, is practical logic; and if you exercise that practical logic, you will find benefits that are too obvious if you only think of any scientific or practical subject with which you are familiar.

There is danger then of a bad use of words, and hence of bad reasoning upon them, in speaking of light and radiant heat; but if we distinctly define light as that which we consciously perceive as light—without attempting to define consciousness, because we cannot define consciousness any more than we can define free will—we shall be safe. There is no question that you see the thing; if you see it, it is light. Well now, when is radiant heat light? Radiant heat is light when its frequency of vibration is between 400 million millions per second and 800 million millions per second. When its frequency is less than 400 million millions per second it is not light; it is invisible "infra-red" radiant heat. When its frequency is more than 800 million millions per second, it is not light if we cannot see it; it is invisible ultra-violet radiation, truly radiant heat, but it is not so commonly called radiant heat because its heating effect is known rather theoretically than by sensory perception, or thermometric or thermoscopic indications. Observations which have been actually made by Langley and by Abney on radiant heat take us down about three octaves below violet, and we may hope to be brought considerably lower still by future observation. We know at present in all about four octaves—that is from one to two, two to four, four to eight, eight to sixteen, hundred million millions—of radiant heat. One octave of radiant heat is perceptible to the eye as light, the octave from 400 million millions to 800 million millions. I borrow the word octave from music, not in any mystic sense, nor as indicating any relation between harmony of colours and harmony of sound. No relation exists between harmony of sound and harmony of colours. I merely use the word "octave" as a brief expression for any range of frequencies lying within the ratio of one to two. If you double the frequency of a musical note, you raise it an octave: in that sense I use the word for the moment in respect to light, and in no other sense. Well now, think what a tremendous chasm there is between the 100 million millions per second, which is about the gravest hitherto discovered note of invisible radiant heat, and the 10,000 per second, the greatest number of vibrations in sound. This is an unknown province of science: the investigation of vibrations between those two limits is perhaps one of the most promising provinces of science for the future investigator.

In conclusion, I wish to bring before you the idea that all the senses are related to force. The sense of sound, we have seen, is merely a sense of very rapid changes of air pressure (which is force) on the drum of the ear. I have passed merely by name over the senses of taste and smell. I may say they are chemical senses. Taste common salt and taste sugar—you tell in a moment the difference. The perception of that difference is a perception of chemical quality. Well, there is a subtle molecular influence here, due to the touch of the object, on the tongue or the palate, and producing a sensation which is a very different thing from the ordinarily reckoned sense of touch, in the case now considered, telling only of roughness and of temperature. The most subtle of our senses perhaps is sight; next come smell and taste. Prof. Stokes recently told me that he would rather look upon taste and smell and sight as being continuous because they are all molecular—they all deal with properties of matter, not in the gross, but molecular actions of matter; he would rather group those three together than he would couple any of them with any of the other senses. It is not necessary, however, for us to reduce all the six senses to one, but I would just point out that they are all related to force. Chemical action is a force, tearing molecules apart, throwing or pushing them together: and our chemical sense or senses may therefore so far at least be regarded as concerned with force. That the senses of smell and taste are related to one another seems obvious; and if physiologists would pardon me, I would suggest that they may, without impropriety, be regarded as extremes of one sense. This at all events can be said of them, they can be compared—which cannot be said of any other two senses. You cannot say that the shape of a cube, or the roughness of a piece of loaf sugar or sandstone, is comparable with the temperature of hot water, or is like the sound of a trumpet, or that the sound of a trumpet is like scarlet, or like a rocket, or like a blue-light signal. There is no comparability between any of these perceptions. But if any one says, "That piece of cinnamon tastes like its smell," I think he will express something of general experience. The smell and the taste of pepper, nutmeg, cloves, cinnamon, vanilla, apples, strawberries, and other articles of food, particularly spices and fruits, have very marked qualities, in which the taste and the smell seem essentially comparable. It does seem to me, although anatomists distinguish between them, because the sensory organs concerned are different and because they have not discovered a continuity between these organs, we should not be philosophically wrong in saying that smell and taste are extremes of one sense—one kind of perceptivity—a sense of chemical quality materially presented to us.

Now sense of light and sense of heat are very different; but we cannot define the difference. You perceive the heat of a hot kettle—how? By its radiant heat against the face—that is one way. But there is another way, not by radiant heat, of which I shall speak later. You perceive by vision, but still in virtue of radiant heat, a hot body, if illuminated by light, or if hot enough to be self-luminous, red-hot or white-hot, you see it; you can both see a hot body, and perceive it by its heat, otherwise than by seeing it. Take a piece of red-hot cinder with the tongs, or a red-hot poker, and study it; carry it into a dark room, and look at it. You see it for a certain time; after a certain time you cease to see it, but you still perceive radiant heat from it. Well now there is radiant heat perceived by the eye and the face and the hands all the time; but it is perceived only by the sense of temperature, when the hot body ceases to be red-hot. There is then, to our senses, an absolute distinction in modes of perception between that which is continuous in the external nature of the thing, namely, radiant heat in its visible and invisible varieties. It operates upon our senses in a way that I cannot ask anatomists to admit to be one and the same in both cases. They cannot now, at all events, say that there is an absolute continuity between the retina of the eye in its perception of radiant heat as light, and the skin of the hand in its perception of radiant heat as heat. We may come to know more; it may yet appear that there is a continuity. Some of Darwin's sublime speculations may become realities to us; and we may come to recognise a cultivable retina all over the body. We have not done that yet, but Darwin's grand idea occurs as suggesting that there may be an absolute continuity between the perception of radiant heat by the retina of the eye and its perception by the tissues and nerves concerned in the mere sense of heat. We must be content in the meantime, however, to make a distinction between the senses of light and heat. And indeed it must be remarked that our sense of heat is not excited by radiant heat only, while it is only and essentially radiant heat that gives to the retina the sense of light. Hold your hand under a red-hot poker in a dark room: you perceive it to be hot solely by its radiant heat, and you see it also by its radiant heat. Now place the hand over it: you feel more of heat. Now, in fact, you perceive its heat in three ways—by contact with the heated air which has ascended from the poker, and by radiant heat felt by your sense of heat, and by radiant heat seen as light (the iron being still red-hot). But the sense of heat is the same throughout, and is a certain effect experienced by the tissue, whether it be caused by radiant heat, or by contact with heated particles of the air.

Lastly, there remains—and I am afraid I have already taxed your patience too long—the sense of force. I have been vehemently attacked for asserting this sixth sense. I need not go into the controversy; I need not explain to you the ground on which I have been attacked; I could not in fact, because in reading the attack I have not been able to understand it myself. The only tangible ground of attack, perhaps, was that a writer in New York published this theory in 1880. I had quoted Dr. Thomas Reid, without giving a date; his date chances to be 1780 or thereabouts. But physiologists have very strenuously resisted admitting that the sense of roughness is the same as that muscular sense which the metaphysicians who followed Dr. Thomas Reid in the University of Glasgow, taught. It was in the University of Glasgow that I learned the muscular sense, and I have not seen it very distinctly stated elsewhere. What is this "muscular sense"? I press upon the desk before me with my right hand, or I walk forward holding out my hand in the dark, and using this means to feel my way, as a blind man does constantly who finds where he is, and guides himself, by the sense of touch. I walk on until I perceive an obstruction by a sense of force in the palm of the hand. How and where do I perceive this sensation? Anatomists will tell you it is felt in the muscles of the arm. Here, then, is a force which I perceive in the muscles of the arm, and the corresponding perceptivity is properly enough called a muscular sense. But now take the tip of your finger and rub a piece of sandstone, or a piece of loaf sugar, or a smooth table. Take a piece of loaf sugar between your finger and thumb, and take a smooth glass between your finger and thumb. You perceive a difference. What is that difference? It is the sense of roughness and smoothness. Physiologists and anatomists have used the word "tactile" sense, to designate it. I confess that this does not convey much to my mind. "Tactile" is merely "of or belonging to touch," and in saying we perceive roughness and smoothness by a tactile sense, we are where we were. We are not enlightened by being told that there is a tactile sense as a department of our sense of touch. But I say the thing thought of is a sense of force. We cannot away with it; it is a sense of forces, of directions of forces, and of places of application of forces. If the places of application of the forces are the palms of the two hands, we perceive accordingly, and know that we perceive, in the muscles of the arms, effects of large pressures on the palms of the hands. But if the places of application are a hundred little areas on one finger, we still perceive the effect as force. We distinguish between a uniformly distributed force like the force of a piece of smooth glass, and forces distributed over ten or a hundred little areas. And this is the sense of smoothness and roughness. The sense of roughness is therefore a sense of forces, and of places of application of forces, just as the sense of forces in your two hands stretched out is the sense of forces in places at a distance of six feet apart. Whether the places be at a distance of six feet or at a distance of one hundredth of an inch, it is the sense of forces, and of places of application of forces, and of directions of forces, that we deal with in the sense of touch other than heat. Now anatomists and physiologists have a good right to distinguish between the kind of excitement of tissue in the finger, and the minute nerves of the skin and sub-skin of the finger, by which you perceive roughness and smoothness, in the one case; and of the muscles by which you perceive places of application very distant, in the other. But whether the forces be so near that anatomists cannot distinguish muscles, cannot point out muscles, resisting forces and balancing them—because, remember, when you take a piece of glass in your fingers every bit of pressure at every ten-thousandth of an inch pressed by the glass against the finger is a balanced force—or whether they be far asunder and obviously balanced by the muscles of the two arms, the thing perceived is the same in kind. Anatomists do not show us muscles balancing the individual forces experienced by the small areas of the finger itself, when we touch a piece of smooth glass, or the individual forces in the scores or hundreds of little areas experienced when we touch a piece of rough sugar or rough sandstone; and perhaps it is not by muscles smaller than the muscles of the finger as a whole that the multitudinousness is dealt with; or perhaps, on the other hand, these nerves and tissues are continuous in their qualities with muscles. I go beyond the range of my subject whenever I speak of muscles and nerves; but externally the sense of touch other than heat is the same in all cases—it is the sense of forces and of places of application of forces and of directions of forces. I hope now I have justified the sixth sense; and that you will excuse me for having taxed your patience so long in not having done it in fewer words.

ELECTRICAL STANDARDS[1]

THE Committee report that, in accordance with suggestions made at the last meeting of the British Association, arrangements have now been completed for testing resistance coils at the Cavendish Laboratory and issuing certificates of their value. These arrangements have been made by Lord Rayleigh and Mr. Glazebrook, and the report contains an account by the latter of the methods employed and the conditions under which the testing is undertaken, in order that those who use such coils may have a more exact estimate of the value of the test.

When a coil is to be tested, a suitable standard is chosen, and the two are placed in the water baths and left at least three or four hours—more usually over night. The comparison is then made in the ordinary manner by Prof. Carey Foster's method (*Journal of the Society of Telegraph Engineers*, 1874), and the coils again left for some time without being removed from the water. After this second interval another comparison is made. The temperatures of the water baths are taken at each comparison, and as a rule differ very slightly.

We thus have two values of the resistance of the coil to be tested at two slightly different temperatures.

The mean of these will be the resistance of the coil in question at the mean of the two temperatures.

We are thus able to issue a certificate in the following form:—"This is to certify that the coil No. *X* has been compared with the British Association Standards, and that its value at a temperature of *A*° C. is *P* B.A. Units or *P′* R. ohms; 1 B.A. Unit being ·9867 R. ohms." We further propose to stamp all coils in the future with this monogram and a reference number.

It will be noticed that nothing is said about the temperature coefficient of the coil or the temperature at which the coil is accurately 1 B.A. Unit. To determine this exactly is a somewhat long and troublesome operation, but at the same time it is one which every electrician, if he knows the value of the coil at one given temperature, can perform for himself with ordinary testing apparatus. It does not require the use of the standards. For many purposes the approximate value of the temperature coefficient obtained from a knowledge of the material of the coil will suffice; we may feel certain that any one requiring greater accuracy would be quite able, and would prefer, to make the measurement himself. We can state with the very highest exactness that the resistance of the coil *X* at a temperature *A*° C. is R. To obtain the temperature coefficient accurately requires an amount of labour which may be quite unnecessary for the purpose for which the coil is to be used.

In accordance with the resolution of the Committee, a fee of 1*l.* 1*s.* has been charged for testing single units, and of 1*l.* 11*s.* 6*d.* for others.

The only coils the testing of which is regularly undertaken are single units and multiples of single units by some powers of 10.

But though this is so, two standard ohms have been ordered, using for the value of the B.A. unit ·9867 ohms, and when they arrive and have been tested, it will be easy to determine the value of coils which do not differ much from a real ohm. At present, without these standards—the coils actually used in the recent experiments at the Cavendish Laboratory have a resistance of about ·1, 24, and 168 ohms—the operation is troublesome. The simplest accurate method seems to be to combine in multiple arc the real ohm, and one of the 100 B.A. unit standards, and to compare the combination with a single unit.

---

[1] Abstract of Report of the Committee, consisting of Prof. G. Carey Foster, Sir William Thomson, Prof. Ayrton, Mr. J. Perry, Prof. W. G. Adams, Lord Rayleigh, Prof. Jenkin, Dr. O. J. Lodge, Dr. John Hopkinson, Dr. A. Muirhead (Secretary), Mr. W. H. Preece, Mr. Herbert Taylor, Prof. Everett, Prof. Schuster, Sir W. Siemens, Dr. J. A. Fleming, Prof. G. F. Fitzgerald, Mr. R. T. Glazebrook, and Prof. Chrystal, appointed for the purpose of constructing and issuing practical Standards for use in Electrical Measurements.

ON THE MEASUREMENT OF ELECTRIC CURRENTS[1]

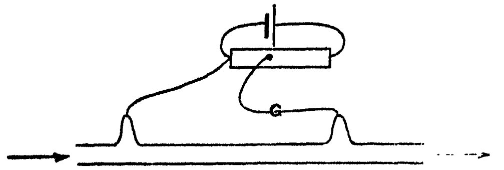
PERHAPS the simplest way of measuring a current of moderate intensity when once the electro-chemical equivalent of silver is known, is to determine the quantity of metal thrown down by the current in a given time in a silver voltameter. According to Kohlrausch the electro-chemical equivalent of silver is in C.G.S. measure $1\cdot136 \times 10^{-2}$, and according to Mascart, $1\cdot124 \times 10^{-2}$. Experiments conducted in the Cavendish Laboratory during the past year by a method of current weighing described in the British Association Report for 1882 have led to a lower number, viz. $1\cdot119 \times 10^{-2}$. At this rate the silver deposited per ampere per *hour* is 4·028 grams, and the method of measurement founded upon this number may be used with good effect when the strength of the current ranges from 1/20 ampere to perhaps 4 amperes. It requires, however, a pretty good balance, and some experience in chemical manipulation.

Another method, which gives good results and requires only apparatus familiar to the electrician, depends upon the use of a standard galvanic cell. The current from this cell is passed through a high resistance, such as 10,000 ohms, and a known fraction of the electromotive force is taken by touching this circuit at definite points. The current to be measured is caused to flow along a strip of sheet German silver, from which two tongues project. The difference of potential at these tongues is the product of the resistance included between them and of the current to be measured, and it is balanced by a fraction of the known electromotive force of the standard cell (see figure). With a sensitive galvanometer the balance may be adjusted to about 1/4000. The German silver strip must be large enough to avoid heating. The resistance between the tongues may be 1/200 ohm, and may be determined by a method similar to that of Matthiessen and Hockin (Maxwell's "Electricity," § 352). The proportions above mentioned are suitable for the measurement of such currents as 10 amperes.

---

[1] Abstract of a paper read at the Cambridge Philosophical Society.

Another method, available with the strong currents which are now common, depends upon Faraday's discovery of the rotation of the plane of polarisation by magnetic force. Gordon found 15°[1] as the rotation due to the reversal of a current of 4 amperes circulating about 1000 times round a column of bisulphide of carbon. With heavy glass, which is more convenient in ordinary use, the rotation is somewhat greater. With a coil of 100 windings we should obtain 15° with a current of 40 amperes; and this rotation may easily be tripled by causing the light to traverse the column three times, or, what is desirable with so strong a current, the thickness of the wire may be increased and the number of windings reduced. With the best optical arrangements the rotation can be determined to one or two minutes, but in an instrument intended for practical use such a degree of delicacy is not available. One difficulty arises from the depolarising properties of most specimens of heavy glass. Arrangements are in progress for a redetermination of the rotation in bisulphide of carbon.



RAYLEIGH

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—In spite of the large majority in favour of the preamble of the statute allowing women to enter for certain University Examinations, the statute was again opposed on March 11, on being brought up by Council after amendment. After a lengthy debate, the statute was carried by 107 against 72. The chief arguments used against the measure were based on the alleged unfairness to men in allowing women to compete under no restrictions of time and residence, and for portions only of any examination; and on the evil to the health of women which might arise from their competing with men. Mr. Pelham, of Exeter, pointed out that the statute was not one to confer degrees upon women, but to make Oxford an examining body for the various centres of female education in England, and enable it to confer certificates which would have a recognised value. Mr. Sedgwick read letters from the heads of Newnham and Girton, at Cambridge, showing that the health of the students was excellent.

SCIENTIFIC SERIALS

THE *American Journal of Science*, February.—Examination of Alfred R. Wallace's modification of the physical theory of secular changes of climate, by James Croll. While agreeing with much that has been advanced by Wallace in his "Island Life," in explanation of geological climate, the author fails to perceive that any of the arguments or considerations there adduced materially affect his own theory as advocated in "Climate and Time." He still holds that with the present distribution of land and water, without calling in the aid of any other geographical conditions than now obtain, the physical agencies detailed in "Climate and Time" are sufficient to account for all the phenomena of the Glacial epoch, including those intercalated warm periods, during which Greenland would probably be free from ice, and the Arctic regions enjoying a mild climate.—Communications from the United States Geological Survey, Rocky Mountain division, No. v.; on sanidine and topaz, &c., in the nevadite of Chalk Mountain, Colorado, by Whitman Cross. The sanidine crystals contain gas inclusions, but no fluids, and the topaz, elsewhere found only in granite, gneiss, or other metamorphic or crystalline schists, here occurs in an eruptive rock probably of early Tertiary age.—On the occurrence of the Lower Burlington limestone in New Mexico, by Frank Springer. The observations made by the author in 1882 in the Lake Valley Mining District, Southern New Mexico, have brought to light numerous facts confirming the views of the Burlington geologists regarding the distinct character of the upper and lower subcarboniferous groups in that district, but demonstrating that the Lower Burlington limestone has a much wider geographical range than had hitherto been suspected.—The Minnesota Valley in the Ice Age (concluded, with two maps), by Warren Upham. —Glacial drift in Montana and Dakota, by Charles A. White. The author, who had already determined the presence of true northern Glacial drift in the region about the Lower Yellowstone River, now traces the same drift much further west. His observations were mainly confined to the Missouri Valley, but also reached to the vicinity of the Great Paw Mountains, extending for over a thousand miles at intervals from the Great Falls of the Missouri to Bismarck in Dakota.—Phenomena of the Glacial and Champlain periods about the mouth of the Connecticut Valley, that is, in the New Haven region (with two plates), by James D. Dana. The author concludes that during the Ice period the Mill River channel was excavated or deepened by glacier action. This channel, as it widened southwards below the mouth of the Pine Marsh Creek, became partly obstructed by sand-bars, which increased as the flood made progress, and ultimately merged in the wide terrace formation of the New Haven plain.—Supplement to paper on the paramorphic origin of the hornblende of the crystalline rocks of the North-Western States, by R. D. Irving.—On herderite, a glucinum calcium phosphate and fluoride from Oxford County, Maine, by William Earl Hidden and James B. Mackintosh.—Note on the decay of rocks in Brazil, by Orville A. Derby.

Bulletin de l'Académie Royale de Belgique, December 1, 1883. —Note on the presence of erratic boulders on the Belgian lowlands, by M. E. Delvaux. From the blocks of Scandinavian granites found at Limburg, in East Flanders, at Wachtebeke, and other places, the author concludes that during the Ice Age glaciation extended over the whole of the Netherlands, Belgium, and the shallow or exposed lands now flooded by the North Sea, terminating on the plains of Norfolk and Suffolk.—On amygdaline and germination, by M. A. Jorissen.—On the scintillation of the stars, in connection with the constitution of their light as revealed by spectrum analysis, by M. Ch. Montigny. The author's spectroscopic studies lead to the conclusion that those stars sparkle most whose spectra present the fewest bands, scintillation being weakest in those whose spectra are marked by broad dark bands.—On the fossil remains of *Sphargis rupeliensis* discovered in the brick clay of the Waas district, by P. J. van Beneden.—Note on a new differential dilatometer and its application to the study of the expansion of alums under the action of heat (one illustration), by W. Spring.—Some experiments on thin liquid layers of glycerine prepared from the oleate of sodium, by J. Plateau.—On the false appearances of aurora borealis observed in Belgium during the month of November 1883, by F. Terby.—Note on the anatomy and histology of a *Turbellaria rhabdocelis* (three illustrations), by P. Francotte. —On the laws regulating the proprietary rights of authors of musical and dramatical works in Belgium, by M. Cattreux.—An historical study of the reformer Froment and his first wife, Marie d'Ennetières, by M. Jules Vuij.—On a Society of Lawyers that flourished in Brussels during a great part of the eighteenth century, by Louis Hymans.—Remarks on the present state of music in the chief cities of Central Europe, by X. van Elewyck. —Generalisation of a property of surfaces of the second order, by M. Jamet.—Appearance of the satellites of Jupiter during the night of October 14, 1883, by F. Terby.—Note on the parallax of the sun deduced from the micrometric observations made at the Belgian stations during the transit of Venus on December 6, 1882, by means of specially constructed heliometers, by J. C. Houzeau.—Contributions to the history of the ovum; indirect relation of the germinative vesicle to the periphery of the vitellus (twelve illustrations), by Ch. van Bambeke.—Remarks on the study of biology and natural history in Belgium, by M. Ed. van Beneden.—On the salient features of the beds of the great marine basins, by M. A. Renard.

Atti della R. Accademia dei Lincei, December 16, 1883.—Notice of G. Orano's treatise on "Habitual Criminals," by S. Ferri.—On the causes of the retirement of the Alpine glaciers, by Roberto Paolo. The author concludes that the glaciers were developed under a mean summer temperature lower than at present, and that they are retreating not so much through cosmic or telluric causes as through meteorological changes depending partly on the prolonged action of man on the earth.—On the molecular velocities of gaseous bodies (continued), by Arnoldo Violi.—Experimental studies on Thapsia resin, by Francesco Canzoneri.—Distribution of the spots, faculæ, eruptions, and protuberances on the surface of the sun, deduced from the observations made at the Observatory of the Collegio Romano during the year 1882, by Pietro Tacchini.—Official return of the archæological discoveries made at Este, Bologna, Rome, Bolsena, Albano, and some other parts of Italy during the November of 1883, by S. Barnabei.—Meteorological observations made at the Observatory of the Campidoglio during the month of November, 1883.

---

[1] January, 1884. In a note recently communicated to the Royal Society (*Proceedings*, November 15, 1883) Mr. Gordon points out that, owing to an error in reduction, the number given by him for the value of Verdet's constant is twice as great as it should be. The rotations above mentioned must therefore be halved, a correction which diminishes materially the prospect of constructing a useful instrument upon this principle.

January 6, 1884.—Notice of Prof. Carlo De Stefani's work on the "Lower Lias Formation of the Northern Alps," by S. Taramelli.—New determination of the optical characters of Christianite (anorthite) and Phillipsite (variegated copper ore), by Alfredo des Cloizeaux.—Note on the existence of two distinct optical axes in the Gismondine crystals (two illustrations), by the same author.—On the temperature corresponding to the Glacial period (continued), by Pietro Blaserna.—Some observations of the eighth satellite of Saturn, by E. Millosevich.—Meteorological observations made at the Observatory of the Campidoglio during the month of December, 1883.

Revue d'Anthropologie de Paris, No. 1, 1884, contains: Concluding part of Dr. P. Broca's "Description des Circonvolutions Cérébrales de l'Homme d'après le Cerveau Schématique," completed by Dr. Pozzi. The latter writer draws special attention to the third frontal circonvolution in man, which was first definitely shown by Broca to be the seat of the organ of speech. This function, in thirteen out of fourteen cases, is associated with the left frontal, and in one out of fourteen with the right frontal, as has been proved by loss of the faculty of speech, known as "aphasia," or, according to the writer, more correctly as "aphemia," which is due to lesions of that portion of the brain. Dr. Pozzi suggests that, in deference to the scientific importance of Broca's discovery, this special convolution should henceforth be distinguished by his name.—The continuation of M. Mathias Duval's lectures on "Le Transformisme," in which the writer treats specially of heredity and natural selection, drawing his materials, as in the earlier parts, almost exclusively from English sources.—"Les Cafres et plus spécialement les Zoulous," by Elie Reclus. This is the first of a series of papers intended by the author to elucidate the history of primitive peoples.

Rivista Scientifico-Industriale, Florence, December 15-31, 1883.—Account of the economic earthquake-warners constructed by the brothers Brassart of the Roman Central Meteorological Bureau (two illustrations), by E. Brassart.—De Tromelin's new aperiodical galvanometer.—On the electric resistance of porcelain, sulphur, and some other non-conducting substances.—On the measurement of electromotor forces.—On the determination of the work executed and absorbed by a dynamo.—Contribution to palæontological studies in Southern Italy, by Michele del Lupo.

Rendiconti del R. Istituto Lombardo, Milan, January 10, 1884.—On numbers irreducible by complex numbers (concluded), by Prof. C. Formenti.—Contribution to the physiology of the enteric juice, by Prof. L. Solera.—Clinical demonstration of a lymphatic infiltration of mechanical origin in the cornea; preliminary notice, by Dr. R. Rampoldi.—On the declaration of bankruptcy at the instance of the creditors, in the new Italian Commercial Code, by L. Gallavresi.—Attenuating and aggravating circumstances in the Criminal Code (concluded), by Prof. A. Buccellati.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, February 21.—"On an Explanation of Hall's Phenomenon." By Shelford Bidwell, M.A., LL.B.

Mr. E. H. Hall's papers, giving a full account of his well-known discovery, are printed in the *Philosophical Magazine* for March 1880, November 1880, September 1881, and May 1883. His original experiment was as follows:—A strip of gold leaf was cemented to a plate of glass and placed between the poles of an electromagnet, the plane of the glass being perpendicular to the magnetic lines of force. The current derived from a Bunsen cell was passed longitudinally through the gold, and, before the electromagnet was excited, two equipotential points were found by trial near opposite edges of the gold leaf, and about midway between the ends: when these points were connected with a galvanometer there was of course no deflection. A current from a powerful battery being passed through the coils of the magnet, it was found that a galvanometer deflection occurred, indicating a difference of potential between the two points, the direction of the current across the gold leaf being opposite to that in which the gold leaf itself would have moved across the lines of force had it been free to do so. On reversing the polarity of the magnet the direction of the transverse electromotive force was reversed; and when the magnet was demagnetised the two points reverted to their original equipotential condition.

Subsequent experiments showed that the direction of the effect differed according to the metal used. Thus with silver, tin, copper, brass, platinum, nickel, aluminium, and magnesium, the direction of the transverse electromotive force was found to be the same as in the case of gold: with iron, cobalt, and zinc the direction was reversed, and with lead there was no sensible effect in either direction.

Hall's results may be expressed by saying that the equipotential lines across the strip are rotated in a definite direction with respect to the lines of force. This effect was attributed by him to the direct action of the magnet on the current; and very great importance has been attached to the phenomenon in consequence of the opinion expressed by Prof. Rowland and others that it is connected with the magnetic rotation of the plane of polarisation of light, and thus furnishes additional evidence of an intimate relation between light and electricity.

A number of experiments made by the author convinced him, however, that no direct action of the kind supposed was ever produced, and he ultimately found that Hall's phenomenon might be completely explained by the joint action of mechanical strain and certain thermo-electric effects.

The strain is produced by electro-magnetic action. It will be convenient to refer to the metallic plate or strip (which for the purposes of this explanation may be assumed to be rectangular) as if it were an ordinary map, the two shorter sides being called respectively west and east, and the two longer north and south. Let the south pole of an electro-magnet be supposed to be beneath the strip, and let the strip be traversed by a current passing through it in a direction from west to east. Then the strip will tend to move across the lines of force in the direction from south to north. Since, however, it is not free to move bodily from its position, it will be strained, and the nature of the strain will be somewhat similar to that undergone by a horizontal beam of wood which is rigidly fixed at its two ends and supports a weight at the middle. Imagine the strip to be divided into two equal parts by a straight line joining the middle points of the west and east sides. Then in the upper or northern division the middle district will be stretched and the eastern and western districts will be compressed, while in the lower division the middle part will be compressed and the two ends will be stretched. If now a current is passing through the plate from west to east, the portion of the current which traverses the northern division will cross first from a district which is compressed to one which is stretched, and then from a district which is stretched to one which is compressed; while in the southern division the converse will be the case. And here the thermo-electric effects above referred to come into play.

Sir Wm. Thomson, in 1856, announced the fact that if a stretched copper wire is connected with an unstretched wire of the same material, and the junction heated, a thermo-electric current will flow from the stretched to the unstretched wire through the hot junction, while if the wires are of iron, the direction of the current is from unstretched to stretched. From this it might be inferred that a current would flow through the heated junction from an unstretched or free copper wire to a longitudinally compressed copper wire, and from a longitudinally compressed iron wire to a free iron wire; and experiment shows this to be the case. *A fortiori* therefore the direction of the current through the heated junction will be from stretched to compressed in the case of copper wire, and from compressed to stretched in the case of iron. If therefore a current is passed from a stretched portion of a wire to a compressed portion, heat will (according to the laws of the Peltier effect) be absorbed at the junction if the metal is copper and will be developed at the junction if the metal is iron. In passing from compressed to stretched portions the converse effects will occur.

It follows from the above considerations that if the metal plate (which is acted upon by a force from south to north and is traversed by a current from west to east) be of copper, heat will be developed in the western half of the northern division and absorbed in the eastern half; while heat will be absorbed in the western half of the southern division and developed in the eastern half. But the resistance of a metal increases with its temperature. The resistance of the north-western and south-eastern districts of the plate will therefore be greater, and that of the north-eastern and south-western districts smaller than before it was strained; and an equipotential line through the centre of the plate, which would originally have been parallel to the west and east sides, will now be inclined to them, being apparently rotated in a counter-clockwise direction.

If the plate were of iron instead of copper, the Peltier effects would clearly be reversed, and the equipotential line would be rotated in the opposite direction.

The peculiar thermo-electric effects of copper, and iron discovered by Thomson are thus seen to be sufficient to account for Hall's phenomenon in the case of those metals. It became exceedingly interesting to ascertain whether the above explanation admitted of general application, and the author therefore proceeded to repeat Thomson's experiments upon all the metals mentioned by Hall. The results are given in the following table, where those metals which in Hall's experiments behave like gold are distinguished as negative, and those which behave like iron as positive :—

Metals	Forms used	Direction of current	Hall's effect
Copper	Wire and foil	S to U[1]	Negative
Iron	Wire and sheet ; annealed	U to S	Positive
Brass	Wire, commercial	S to U	Negative
Zinc	Wire and foil	U to S	Positive
Nickel	Wire	S to U	Negative
Platinum	Wire and foil	S to U	Negative
Gold	Foil, purity 99·9 per cent.	S to U	Negative
	Wire, commercially pure	*U to S*	
	Jeweller's 18 carat wire and sheet	S to U	
	Jeweller's 15 carat sheet	S to U	
Silver	Wire and foil	S to U	Negative
Aluminium	*Wire and foil, pure*	*U to S*	*Negative ?*
Cobalt	Rod : 8 mm. diameter	U to S	Positive
Magnesium	Ribbon	S to U	Negative
Tin	Foil	S to U	Negative
Lead	Foil (assay)	No current	Nil

It will be seen that in every case, excepting that of aluminium and one out of five specimens of gold there is perfect correspondence between the direction of the thermo-electric current and the sign of Hall's effect. With regard to the aluminium, a piece of the foil was mounted on glass, and Hall's experiment performed with it. As was anticipated, the sign of the "rotational coefficient" was found to be positive like that of iron, zinc, and cobalt. Either, therefore, Mr. Hall fell into some error, or the aluminium with which he worked differed in some respect from that used by the author. The anomalous specimen of gold, being in the form of wire, could not be submitted to the same test. It probably contained some disturbing impurity.

It is submitted that the considerations and experiments above detailed render it abundantly evident that the phenomenon described by Mr. Hall involves no new law of nature, but is merely a consequence of certain thermo-electric effects which had been observed nearly thirty years ago.

"Some Relations of Chemical Corrosion to Voltaic Current." By G. Gore, F.R.S., LL.D.

The author states that the chief object of this research was to ascertain the amounts of voltaic current produced by the chemical corrosion of known weights of various metals in different liquids, and to throw some light upon the conditions which determine the entire conversion of potential molecular energy into external (*i e.* available) electric current. The metals used were magnesium, zinc, cadmium, tin, lead, aluminium, iron, nickel, copper, and silver; some of them being also used in an amalgamated state. The liquids employed were solutions of nitric, hydrofluoric, hydrochloric, sulphuric, fluosilicic, and acetic acids; and potassic hydrate and cyanide, also of different degrees of strength.

The chief numerical results are given in a series of ten tables, a table for each metal. Each table contains the electromotive of the current, the loss and rate of loss of the corroded metal, and of a comparison sheet not producing a current; and the percentage of current obtained in ninety-seven different cases.

The results show that the proportion of loss of the positive plate by "local action" to that by corrosion producing external current varied greatly in different cases, viz. from 1·3 to 95·25 per cent. In no case was the whole of the metal dissolved by "local action," nor did the whole of the corrosion produce external current. In about 6 per cent. of the cases the comparison plate was more corroded than the one which was used to produce a current. Whilst also the contact of a negative metal with the corroding plate usually increased the total corrosion, it commonly decreased the corrosion due to "local action."

The proportion of corrosion attended by external current to that due to "local action," varied with the kind of metal and of liquid; with cadmium it averaged 75·63, and with copper 30·33 percent. of the total corrosion; with solution of potassic cyanide it averaged 63·27, and with dilute nitric acid 31·14 per cent. It varied also with other conditions; and the kind of metal had more influence than that of the liquid. Amalgamation of the metal also had distinct effects upon the proportion, but opposite in different cases. The rate of total corrosion of the positive plate appeared to be related to the degree of electromotive force of the current. The chief cause of the great variation in the proportion of corrosion by "local action" to that producing external current was probably a variation of electric conduction resistance.

March 6.—"Magnetic Polarity and Neutrality." By Prof. D. E. Hughes, F.R.S.

The author, citing the researches of Page, Marianini, Wertheim, Joule, Wiedemann, De la Rive, Weber, Beetz, and Maxwell, together with his own published researches, demonstrating that the molecules of magnetic bodies, such as iron, have inherent polarity, and that all the known effects of magnetism can be explained by the demonstrable rotation of the molecules whenever a change of polarity occurs, now gives a new series of experiments verified by several independent methods, in which he shows that the penetration of the apparent polarity diminishes rapidly from the exterior to the interior of a bar, due to the frictional resistance of its molecules. In rotation, as when the rod or bar is vibrated whilst under the exciting influence, the penetration is four times greater than previously. In all cases, however, there is no reversal of polarity in the interior whilst under the influence of its exciting cause. The instant this is withdrawn neutrality takes place in soft iron, or a partial return to the same state even in the hardest of steel.

The author has discovered that this neutrality is not caused by a mixing of the fluids as assumed by Coulomb, or a heterogeneous arrangement of the molecules as assumed by Ampère and all other theories up to the present time, but that a reaction takes place between the outside or strongest polarity with that of the weaker inside, completely reversing it to a remarkable extent.

A bar of iron under the influence of its exciting cause may be represented by three series of letters, the centre representing the inside of a bar, thus— $\begin{array}{ccc} N & N & N \\ S & S & S \end{array}$, but when this influence is withdrawn we should have— $\begin{array}{ccc} N & S & N \\ S & N & S \end{array}$. And if the inner reversed polarity exactly balanced the exterior the sum of both would be zero, and consequent neutrality.

The paper describes the methods employed, and gives diagrams of these curves. In certain cases the exterior becomes reversed, as shown by magnetising a soft strip of steel half a millimetre thick, and then reducing it to a nearly perfect neutral state, either by mechanical vibrations, or by heating the strip to red heat. That the outside is reversed is shown by dissolving the exterior in dilute nitric acid, when its previous polarity reappears.

---

[1] S means stretched; U means unstretched.

The author cites several methods by means of which an apparent neutrality is shown to be the result of internal reaction, and that in all cases, even in the most permanent magnet, there is a portion of it reversed to its apparent polarity.

The author shows the importance of the knowledge of this fact in the construction of electro-magnets, whenever we desire to have the maximum of effect whilst under the influence of a current with a minimum of remaining magnetism when the influence ceases.

This is shown by experiments upon bars of similar length but of different thickness, solid bars having far greater effect than tubular ones. Experiments were made on electro-deposited iron of varying thickness, showing the remarkable retentive power of extremely thin coatings of soft iron.

The result is given of a series of researches not yet completed (the details of which will be published in a future paper) upon the saturating point of soft iron and steel. The author has found that the atmosphere as well as all gaseous matter has precisely a similar curve of magnetic rise from neutrality to its magnetic saturation, and that bismuth as well as all so-called diamagnetic bodies obey the same law of saturation. Consequently he assumes that all matter is strongly magnetic, the widest limit yet found, from bismuth to soft Swedish iron, being only forty times greater for the iron.

An explanation is given of the well-known disappearance of magnetism at yellow red heat, in which the author assumes, from observed effects of violent mechanical vibrations, that this disappearance is due to a violent molecular oscillation destroying its symmetrical arrangement of polarity.

The author concludes by saying, "Whatever theory we adopt as an explanation of evident magnetism, it will be found that neutrality occurring after the cessation of an external inducing force upon a bar of iron or steel is the result of symmetrically opposed polar forces, producing apparent waves of opposite polarity, or reactions between the exterior and interior of a bar of iron."

Linnean Society, March 6.—Sir J. Lubbock, Bart., president, in the chair.—Dr. A. B. Shepherd and Mr. Jas. Dallas were elected Fellows, and Mr. W. Hodgson an Associate of the Society.—The President announced the receipt of an intimation from the Foreign Office (through the Science and Art Department) of an International Ornithological Congress to be held in Vienna in the beginning of April.—Mr. J. Britten exhibited specimens of *Lithospermum purpureo cæruleum*, illustrating points in the life-history of the plant as described by Mr. J. W. White in the *Journal of Botany*.—Mr. F. O. Bower drew attention to a figure published in the *Gardener's Chronicle* representing a case of proliferation of the so-called "double needle" of *Sciadopitys verticillata*. He alluded to the various views as to the morphological value of the "double needle," and concluded that the one first propounded by Prof. A. Dickson, afterwards discussed adversely by Von Mohl, but favourably by Goebel, appears most in accordance with the history of its development.—Dr. M. Masters showed and made remarks on an example of bud variation of *Pinus silvestris*.—There was exhibited for Mr. T. E. Gunn a stuffed specimen of a male variety of the common moorhen (*Gallinula chloropus*), shot near Norwich last spring.—Mr. A. W. Bennett drew attention to specimens under the microscope of species of *Ptilota* and *Callithamnion* which demonstrated the continuity of the protoplasm.—Prof. Cobbold gave a verbal account of a communication from Dr. P. Manson of Hong Kong, in which the author furnishes fresh evidence as to the *rôle* of the mosquito considered as the intermediary host of *Filaria sanguinis-hominis*. Dr. Manson has verified his previous observations in the most complete manner, and he now recognises and describes six well-marked stages of the Filariæ whilst they are dwelling within the body of the insect. In the discussion following, Dr. T. R. Lewis confirmed Manson's statements in many particulars.—The Secretary read an abstract of a paper on the Indian species of *Cyperus*, with remarks on some others that specially illustrate the subdivisions of the genus. The author divides this memoir into three sections: (1) a descriptive account of each part of a *Cyperus*, viz. the culm, inflorescence, &c., comparing these successively in all the Indian species; (2) contains a discussion of some difficult species and disputed genera; (3) is a systematic arrangement with descriptions of the Indian species, with short citations of some non-Indian species that more particularly illustrate the subdivisions and groups.—Prof. St. G. Mivart read a paper on the relations between instinct and other vital processes. In this he contended that instinct cannot be divided by a very hard and fast line from such vital processes as reflex action, processes of repair after injuries, and the process of development of the individual; and that these latter were more readily explained as activities especially instinctive, than that instinct could be explained by reflex action or by lapsed intelligence. The vital processes referred to were also shown to have an important bearing on the question of the origin of species.—Then followed a paper, notes on Afghanistan algæ, by Dr. J. Schaarschmidt, founded on material derived from Surgeon-Major Aitchison's collection of plants made during the Afghanistan Expedition in 1880.

Zoological Society, March 4.—E. W. H. Holdsworth, F.Z.S., in the chair.—Mr. Howard Saunders, F.Z.S., exhibited and made remarks on specimens of two Gulls (*Xema sabini* and *Larus philadelphia*) in the breeding-plumage, both killed in Scotland. Mr. Saunders also made some observations upon the specimen of *Larus atricilla* in the British Museum, said to be the one killed by Montagu at Winchelsea, and came to the conclusion that the bird in question was not Montagu's specimen. Mr. Saunders likewise exhibited a specimen of *Puffinus griseus* killed off the Yorkshire coast.—A letter was read from Dr. Ch. W. Lütken, Foreign Member, calling attention to a specimen of an Echidna in the Zoological Museum of Copenhagen, which seemed to be different from the ordinary *Tachyglossus aculeatus*, and which Dr. Lütken was of opinion might possibly be referable to the lately-described *T. lawesi* of New Guinea.—Mr. J. E. Harting, F.Z.S., exhibited and made observations on some antlers of roe deer from Dorsetshire and Scotland.—Mr. W. R. Ogilvie Grant read a paper on the fishes of the genera *Sicydium* and *Lentipes* (belonging to the family Gobiidæ), in which an attempt was made to arrange the species of *Sicydium* into smaller groups, the members of which were found to be allied together by convenient and distinctive characters. Five new species of *Sicydium* were described.—A communication was read from Mr. F. Moore, F.Z.S., on some new Asiatic Diurnal Lepidoptera, chiefly from specimens in the Calcutta Museum.—A communication was read from the Count T. Salvadori, C.M.Z.S., containing some critical remarks on an African Duck, *Anas capensis*, Gmelin.

Chemical Society, March 6.—Dr. W. H. Perkin, president, in the chair.—It was announced that a ballot for the election of Fellows would take place at the next meeting (March 20).—The following papers were read:—Studies on sulphonic acids, No. i.; on the hydrolysis of sulphonic acids, and on the recovery of benzenes from their sulphonic acids, by Drs. H. E. Armstrong and A. K. Miller. By passing steam through a solution of the sulphonic acids or the sulponates in their own weight of sulphuric acid, the authors find that all the benzenes can be recovered. No decomposition of any of the benzenes tried takes place, and an almost theoretical yield is obtained. The method has been of great value in separating the hydrocarbons obtained from camphor.—On a relation between the critical temperature of bodies and their thermal expansions as liquids, by T. E. Thorpe and A. W. Rücker. By combining the simple expression recently published by Mendeléeff for the expansion of liquids with some of the conclusions arrived at by Van der Waals, the authors arrive at the result that the density of a liquid is very nearly proportional to the number obtained by subtracting its absolute temperature from twice its absolute critical temperature.—Remarks on the densities of members of homologous series, by Dr. W. H. Perkin. The author has plotted curves in the usual way, taking the number of carbon atoms as abscissæ, and a scale of numbers embracing those of the densities at 20° C. as ordinates. The bodies examined consisted chiefly of very carefully purified acids and ethers of the fatty series. It is obvious from the curves that the densities of the homologous acids and ethers follow a regular law.—Note on some experiments made at the Munster Agricultural School to determine the value of ensilage as a milk- and butter-producing food. Cows were fed on ensilage for a week and on mixed food for a week, and the author has analysed the milk and weighed the butter produced. The results in the two experiments are almost identical, so that ensilage is not inferior to ordinary food.—Note on the behaviour of the nitrogen of coal during destructive distillation and a comparison of the amount of nitrogen left in cokes of various origin, by Watson Smith.—On a hitherto unnoticed constituent of tobacco, by T. J. Savery. The author, having noticed in tobacco a substance which strongly reduced Fehling's solution, investigated the subject, and separated a body closely resembling caffetannic acid, and which he proposes to call tabacotannic acid.

Geological Society, February 20.—Prof. T. G. Bonney, F.R.S., president, in the chair.—Thomas Lionel Bates, G. J. Williams, and Alfred Prentice Young were elected Fellows of the Society.—The following communications were read:—On a recent exposure of the shelly patches in the Boulder-clay at Bridlington, by G. W. Lamplugh, communicated by Dr. J. Gwyn Jeffreys, F.R.S.—On the so-called *Spongia paradoxica*, S. Woodward, from the Red and White Chalk of Hunstanton, by Prof. T. McKenny Hughes, F.G.S.—Further notes on rock-fragments from the South of Scotland embedded in the low-level Boulder-clay of Lancashire, by T. Mellard Reade, C.E., F.G.S.—Ripple-marks in drift, by T. Mellard Reade, C.E., F.G.S.

CAMBRIDGE

Philosophical Society, February 25.—The following were elected Fellows of the Society:—Mr. A. R. Forsyth, B.A., Trinity College, Mr. W. J. Ibbetson, B.A., Clare College.—The following communications were made to the Society:—On the sums of the divisors of a number, by Mr. J. W. L. Glaisher.—On primitive roots of prime numbers and their residues, by Mr. A. R. Forsyth.—A comparison of Maxwell's equations of the electro-magnetic field with those of Helmboltz and Lorentz, by Mr. R. T. Glazebrook. The author pointed out that the main difference between the two theories turned on the fact that while Maxwell considers the electric displacement throughout the field, Helmholtz deals with the electric moment of each element of volume supposing that by the action of the inducing force opposite electricities are driven to opposite ends of each element. Maxwell's displacement corresponds to the induction in the magnetic field, Helmholtz's polarisation to the induced magnetisation. The existence of a normal wave was discussed, and it was shown that Maxwell's equations without the solenoidal condition $\frac{df}{dx} + \frac{dg}{dy} + \frac{dh}{dz} = 0$, lead to the same result as those of Helmholtz, at any rate in the case in which a plane wave is traversing the medium. It was further pointed out that in the case in which the induction is due to the presence of electricity at rest outside the portion of the field considered, the above solenoidal condition must hold.

EDINBURGH

Royal Society, February 4.—The Right Hon. Lord Moncreiff, president, in the chair.—The President gave a review of the hundred years' history of the Society, a full report of which appeared in our issue of February 14 (p. 368).—The Abbé Renard and Mr. John Murray communicated notes on the microscopical characters, the chemical composition, and distribution of volcanic and cosmic dust; and also a paper on the nomenclature, origin, and distribution of deep-sea deposits. Dust obtained by melting snow from Ben Nevis was not volcanic in character.—The Abbé Renard gave a note on a large crystal of calc-spar found by Prof. Tait in Lough Corrib.

DUBLIN

Royal Society, January 21.—Physical and Experimental Science Section.—G. F. Fitzgerald, F.R.S., in the chair.—Prof. W. N. Hartley, F.R.S.E., read a paper on a simple method of observing faint lines with diffraction spectroscopes. The author states that he works in a darkened room, the goniometer of the spectroscope being illuminated by a shaded lamp which stands to right of the telescope. The grating is movable, while the collimator and telescope are fixed in such a position as to include as small an angle between them as possible. The telescope being to the right of the collimator, a small gas jet is placed upon the left, the rays of which proceed to the grating and are reflected into the field of the telescope. By the adjustment of this light the field may be illuminated in any colour of the spectrum, and by selecting that tint which is complementary to the colour of the lines to be measured, they are sure to stand out apparently in relief on a bright ground.—Howard Grubb, M.E., F.R.S., read a paper on a new form of equatorial telescope. The author referred to an instrument of his construction which has been at work in Cork Observatory for the last two years, in which the eyepiece is placed in a fixed position in the interior of a building. The success of this instrument induced the author to attempt to carry out the same principle on a larger scale, the difficulty to be overcome being that of producing a perfect plane of sufficient size. The author described a form of instrument which, by a combination of a dialytic telescope and his siderostatic form of mounting, would admit of its being of the largest dimensions without the necessity for employing very large reflectors, as in the case of the new French instrument described in NATURE, November 8, 1883 (p. 36). Mr. Grubb claimed that the form of instrument now described possesses all the chief advantages of the French form, while the difficulties of manufacture would be one-ninth, and the cost about the same as the ordinary construction, including dome. Another important advantage claimed is that the difficulty of construction is not increased in the same proportion as in the French form, and therefore Mr. Grubb's arrangement would be applicable to instruments of the largest size.—Greenwood Pim, F.L.S., communicated a paper on the rendering by photography of light and dark colours in their natural values, in the course of which he pointed out that while the ordinary bromide gelatine plates at present so extensively employed rendered a blue of low illuminating power almost white and a yellow of high illumination very dark, by using the isochromatic plates patented by Messrs. Attout-Tailfer and John Clayton of Paris these colours were reproduced in shades corresponding to the illuminating power. Numerous prints from ordinary and from isochromatic plates of ribbons, coloured fabrics, coloured drawings of flowers, &c., were exhibited, clearly showing the superiority of the latter plates when blue and yellow colours had to be photographed; thus avoiding over-exposing the blue in order to bring out the detail of the yellow portion. These isochromatic plates are prepared with eosine in presence of an alkali, usually ammonia, and appear to owe their property more to the chemical action than to the physical action of its red colour; for a screen of eosined collodion interposed between a band of coloured ribbons and the sensitive plate, so as to cover part and leave part uncovered, had but little effect, all that could be noticed being a general slowing action, and not more in the blue than in the yellow.

Natural Science Section.—Rev. Maxwell Close, M.A., in the chair.—Rev. S. Haughton, F.R.S., read a paper entitled "Remarks on the unusual sunrises and sunsets that characterised the close of the year 1883." The older writers on astronomy, such as Brinkley and Maddy, state that on the average twilight lasts until the sun is 18° below the horizon. From this it has been computed that the height of the twilight-producing atmosphere is—

40 miles	on hypothesis	of one	reflection,
12 ,,	,,	two reflections,	
5 ,,	,,	three	,,
3 ,,	,,	four	,,

Herschel and Newcomb make no statement whatever as to the duration of twilight. Chambers (in his compilation) says that the average depression of the sun is 18°, which is reduced to 16° or 17° in the tropics, but in England a depression ranging from 17° to 21° is required to put an end to the twilight phenomena. Dr. Ball informs me that Prof. Schmidt, of Athens, gives for that place 15° 51′, and also that Liais (Paris) fixes the first twilight arc to set at 10° 41′, and the second at 18° 18′. In the following observations I calculate the zenith distance of the sun at the close of the phenomena by the well-known formula—

$$\cos z = \alpha + \beta \cos h,$$

where

z = sun's zenith distance,
h = sun's hour angle,
$\alpha = \sin \lambda \sin \delta$,
$\beta = \cos \lambda \cos \delta$,
λ = latitude of place of observation,
δ = declination of sun.

Observation I.—Mr. Bishop, observing at Honolulu, found the phenomenal sunsets to commence on September 5, 1883, and to last up to 7.25 p.m.

$$\text{Here } \lambda = 22°,$$
$$\delta = 6° 16'.$$

This gives the sun's place 18° 22′ below the horizon. This indicates twilight phenomena intensified by some unusual cause, but does not denote an extension of twilight reflection into regions of the air higher than the time-honoured traditional 40 miles. The epoch of the main eruption of Krakatoa has been fixed by Gen. Strachey at August 27 9.32 a.m. If the explosion of Krakatoa on August 27 was the cause of the brilliant sunset at Honolulu on September 5, the result is nothing short of miraculous! The Editor of NATURE writes on December 20 (p. 174), with an enthusiastic glow worthy of the twilights: "The extraordinary fact now comes out that before even the lower currents had time to carry the volcanic products to a region so near the eruption as India, an upper current from the east had taken them in a straight line *viâ* the Seychelles, Cape Coast Castle, Trinidad, and Panama, to Honolulu, in fact very nearly back again to the Straits of Sunda!" [The note of admiration is not mine]. It is worth our while to calculate the rate at which this wonderful journey of volcanic dust was performed. The actual distance is 255° of a great circle, and the time of journey nine days, from which I calculate the speed of the train to have been eighty-two miles per hour! This is absolutely incredible, and becomes still more so when we know that the phenomena observed at Honolulu were unusual twilight phenomena, but had no connection whatever with reflection from the upper regions of the air. In point of fact, my calculation of the sun's position disproves the presence of dust or any reflecting substance in the upper air. Observation II. Dunsink Observatory (a letter received from Dr. R. S. Ball, F.R.S., January 7, 1884):—"Sunday evening, December 30, was exceptionally fine, and the sunset was so well seen, that the moon, though only twenty-seven hours old, was well seen by Cathcart and myself from the roof of the Observatory. We estimated that the twilight lasted certainly for two hours after sunset, and that for ten minutes longer there was still enough light in the western sky to distinguish it from other parts of the horizon. At two hours the sun's zenith distance is 15° 56′; at two hours and ten minutes it is 16° 51′. The first figure coincides almost exactly with the 15° 51′ given by that most skilful observer Schmidt (*vide Astron. Nach*, No. 1495), of Athens, as the zenith distance at the end of astronomical twilight. The 18° which the text-books state to be the limit, seems to be a survival from Kepler, who had it from Ptolemy. There seems to be rather a dearth of careful observations on the subject, at least I can find but few good references to it in Houzeau's *Astronomy*. The only one of this century there contained besides Schmidt is Liais' (*Comptes Rendus*, t. xlviii. p. 110); he says that the first 'arc crépusculaire' sets at 11° 42′, and the second at 18° 18′. It appears to me that on the whole the truth lies nearer to 16° than to any other figure." Observation III. (a letter received from Mr. R. S. Graves, Kingstown, Co. Dublin, December 26, 1883):—"I was on Kingstown Pier yesterday evening (25th inst.), and as the after-glow of sunset looked so beautiful behind the hill, I lingered on the pier, looking at the wonderful brightness and beauty of the whole west sky. The red glow continued to throw *distinct* light on the harbour's shipping till 5.20; from that time, however, the light faded very fast, and at 5.30 it was black night, although the sky was still very red. After this hour the light-giving power seemed to have gone. I see the sun set at 3.53 p.m. (Dublin almanac). The lights in Kingstown presented a very curious appearance: looking at the bright red above the hill, then the hill, and under the hill the hundreds of lights looked just like one of those fancy foreign pictures with pinholes stuck in everywhere to represent the lights. I wish you could have seen the whole scene." N.B. The sun was 14° 15 below horizon at close of phenomena. Observation IV. (a letter received from a correspondent in Old Derrig, Co. Carlow, December 31, 1883):—". . . I have, of course seen a good deal of the after-glow. Some evenings the appearance is like the glare of limelight at a theatre, the effect on grass or garden very strange. With back to west each blade of grass is like fire, a bit of straw like a red-hot needle; but facing the light, it is all lurid light and shade. Last night sun set by almanac at 3.47; here the sun disappears twenty and twenty-five minutes before, owing to hills. At 4.30 the glow was splendid; at 5.10 I could see seconds-hand of watch 23 minutes after sunset, or nearly 1¾ hour after sun had vanished from us. A planet from 4.30 to 5.10 was in the glow, and from 5 and 5.30 was bright emerald green." N.B. The sun was 15° 15′ below horizon at close of phenomena.—Prof. W. R. McNab, M.D., read a paper entitled: "Note on the botanical topographical divisions of Ireland." The districts adopted by the authors of the "Cybele Hibernica" not being readily comparable with the divisions into provinces, vice-provinces, and vice-counties, as defined by Watson, it is proposed to treat the "districts" as equivalent to provinces, and to arrange thirty-six vice-counties under the twelve provinces. The divisions Dr. McNab thus proposes to adopt in the "Cybele Hibernica" collection at Glasnevin, Dublin, are the following:—Province I. West Munster.—Vice-counties: 1. Kerry. 2. S. Cork. II. East Munster.—(3) N. Cork; (4) Waterford; (5) S. Tipperary. III. West Leinster.—(6) Kilkenny; (7) Carlow; (8) Queen's County. IV. East Leinster.—(9) Waterford; (10) Wicklow. V. North Leinster.—(11) Kildare; (12) Dublin; (13) Meath; (14) Louth. VI. West Shannon.—(15) Limerick; (16) Clare; (17) East Galway. VII. East Shannon.—(18) North Tipperary; (19) King's County; (20) Westmeath; (21) Longford. VIII. West Connaught.—(22) West Galway; (23) West Mayo. IX. East Connaught.—(24) East Mayo; (25) Sligo; (26) Leitrim; (27) Roscommon. X. South Ulster.—(28) Fermanagh; (29) Cavan; (30) Monaghan; (31) Tyrone; (32) Armagh. XI. West Ulster.—(33) Donegal, and City of Londonderry. XII. East Ulster.—(34) Down; (35) Antrim; (36) Derry.—Prof. A. C. Haddon communicated a paper on an apparatus for demonstrating systems of classification, &c.—The apparatus, which was exhibited last March, consists of a series of glass plates placed horizontally one over the other, leaving a small space between each plate. On these plates oblong blocks of wood rest on which are printed the names of the forms whose affinities it is desired to indicate, thus constituting a classification in *three dimensions of space.* This apparatus is especially useful in palæontology.

PARIS

Academy of Sciences, March 3.—M. Rolland in the chair.—Researches on explosive gaseous mixtures, by MM. Berthelot and Vieille. The results are here tabulated of 250 experiments made with forty-two distinct explosive compounds, including not only mixtures of oxygen and hydrogen, the oxide of carbon and formene, pure or mixed with nitrogen, but also mixtures including cyanogen, acetylene, ethylene, methyl, methylic ether, and common vapour of ether. Studies were also made of mixtures of oxygen with two combustible gases together, such as the oxide of carbon and hydrogen, as well as combinations of the protoxide of nitrogen mixed with hydrogen, with the oxide of carbon, with cyanogen, and the bioxide of nitrogen mixed with cyanogen. The main object of the experiments was to determine the amount of pressure developed at the moment of explosion, the temperature produced, and the specific heats of the gases at various temperatures, and especially those of the compound gases.—On a recent note of M. D. André, by Prof. Sylvester. It is shown that M. André's theorem is a direct consequence of the generalisation given by the author to Newton's theorem ("Universal Arithmetic," part 2, chap. ii.) on the imaginary roots of equations.—Remarks on the maps of Madagascar from the Middle Ages to the present time, by M. Alf. Grandidier. The author, who identifies Ptolemy's Menuthias with Madagascar, shows that this island was known to the Greek and Arab geographers long before its rediscovery by the Portuguese in 1500 (not in 1506 as is usually supposed).—On the principle of separate watertight compartments in ship-building, and on the first men-of-war constructed on this principle, by M. Bertin.—New experiments showing how Nobili's electro-chemical rings may be imitated by means of a continuous stream of water falling from a cylindrical tube vertically on a horizontal sheet of black glass moistened all over, by M. C. Decharme.—Description of a new process of generating steam, by M. Bordone.—Theorem by means of which it may be ascertained that certain algebraic equations have no positive root, by M. Désiré André.—Note on hyperfuchsian functions, by M. E. Picard.—On the groups of finite order contained in the group of undeterminative and reversible substitutions of the second order, that is, the quadratic substitutions of Cremona, by M. Autonne.—On linear equations of the second order with partial differences, by M. R. Liouville.—Note on the oxychloride of barium, by M. G. André.—On a new group of nitrous compounds, by M. R. Engel.—On the oxidation of menthol by means of the permanganate of potassium, by M. G. Arth.—On two campholurethanes with an isomerous relation analogous to that presented by M. Pasteur's right and left tartaric acids, by M. Haller.—Experiments on the toxic or medicinal substances which modify hæmoglobin, and especially on those that convert it into methæmoglobin, by M. G. Hayem.—On the conditions favourable to the development of root-suckers in plants, by M. E. Mer.—Analysis of the mineral substances friedelite, discovered by M. Bertrand, and pyrosmalite, found at Dannemora in Sweden, by M. Alex. Gorgeu.—Note on the existence of manganese in a state of complete diffusion in the blue marbles of Carrara, Paros, and the Pyrenees, by M. Dieulafait.—On the coincidence of the transformations observed in the Pons-Brooks comet with its passage across currents of a cosmic character, by M. Chapel.—Notice of two Chinese works on elementary and analytical chemistry presented to the Academy by M. Billequin of the Imperial College, Pekin.

Berlin

Physical Society, February 8.—Prof. Lampe referred to two recent works on mechanics, one by Herr Streintz, the other by Herr Mach, and brought forward certain problems, which were there dealt with at full length.—Prof. Schwalbe described a peculiar ice-formation he had observed in the Harz towards the end of December last. Under a temperature of from + 2° to + 3° C. by day and − 1° to − 2° C. by night, he perceived, on a road covered with gravel and withered leaves, swellings of the surface at various spots, which, on closer inspection, proved to be ice-protuberances rising from the ground and pushing up its topmost stratum. On the unfrozen earth stood separate, diminutive ice-columns of from three to four centimetres in height, each supporting at its upper extremity a little stone or a withered leaf which it had loosened from the ground and in the course of growth had lifted upwards. Similar swellings were found by Prof. Schwalbe on rotten twigs lying on the ground. In these the rind over a large surface was pushed from the wood by ice-excrescences of soft, brilliant, asbestine appearance, and uncommonly delicate to the touch. They adhered in large numbers to the body of the wood, and reached as great a length as one decimetre. Prof. Schwalbe brought some of these withered and rotten twigs with him to Berlin, and it was in his power to produce on them at any time the phenomenon just described. For this purpose all that was needed was thoroughly to moisten the twig, in such a manner, however, that no water dropped off, and then to let it cool slowly in a cold preparation. Ice-excrescences also appeared of themselves on twigs lying in the garden whenever the temperature fell below 0° C. in the night. In reference to the explanation of this phenomenon, Prof. Schwalbe favoured the view of Le Conte, who had described the matter thirty years ago, and considered it as an instance of capillary action. In the process of slow cooling, the water in the pores became frozen into a small capillary tube, which sucked the water up, and this in turn becoming congealed shot continually further upwards. In this way the little stone or the withered leaf lying on the road, or the rind on the rotten twig, was pushed constantly further away from the substratum, and lifted upwards.

Physiological Society, February 15.—In continuation of the address delivered by him at the last sitting of the Society, Dr. J. Munk set forth the further course of his investigations into the resorption, formation, and deposition of fats in the animal body. After, by feeding a dog on rape-seed oil, he had demonstrated that heterogeneous fats were absorbed and deposited in the animal body, he passed to the question in what manner was the resorption effected. It was universally assumed that the fats in the intestinal canal were emulged, and, as emulsion, entered through the intestinal villi into the chyle vessels. In order to the production of an emulsion it was now first of all necessary that the fat should become fluid at the temperature of the body; and second, that the intestinal contents should be alkaline. As was, however, well known, there were fats which did not melt unless at a temperature of over 40° to 50° C., that is, they could not become fluid at the temperature of the body—mutton suet, for example, which was therefore incapable of being emulged in the intestinal canal. Still less so were the sebacic acids of mutton, which could be only melted at higher temperatures. It had therefore to be experimentally proved whether such fats generally were resorbed. Dr. Munk had a year ago briefly related to the Society an experiment directed to this end, in which he fed a dog with mutton suet. It had yielded a positive result. The fat taken from the body of the dog which had been fed on mutton suet was essentially distinct from the normal fat of a dog, both by its whiter colour and by its greater consistence. On chemical examination, too, it was confirmed that the dog had deposited mutton suet in its body. The experiments now in question, which the speaker described at greater length, were of such a kind that a dog was brought to a state of equilibrium in respect to nitrogen, that is, to such a state that just as much nitrogen was secreted from the body as was supplied it with the food. At certain epochs along with the albumen, either lard or mutton suet, or the sebacic acids of mutton, were administered for a number of days, and during that time careful analyses were made of the evacuations. By these analyses, besides the above-mentioned fact of the deposition of mutton suet in the canine body, it was established that the lard was almost completely used up, only 2 per cent. having been lost to the body in the evacuations, while of the mutton suet about 94 per cent. was absorbed in the intestinal canal, and even of the sebacic acids of mutton 86 to 87 per cent. was taken up. In the last case the quantity of nitrogen secreted was somewhat greater than the quantity received, so that a part of the alimentary albumen was decomposed. Mutton suet, or the sebacic acids of mutton, might therefore be used for feeding; in the excrements a larger quantity of free sebacic acids and of soaps along with neutral fat was always found, a fact which indicated a splitting of the neutral alimentary fats in the intestine. The existence of such a splitting of the neutral fats was also confirmed by the demonstration that the contents of the small intestine never showed alkaline reaction, but reacted either in an acid or neutral manner. This could not be referred to any extensive transition of the contents of the stomach, for the small intestine was found to be always very lax and almost empty, if an excitement of stronger peristaltic movements were carefully avoided during the experiments. A process of emulsion on the part of the mutton suet, which from its consistence offered great difficulties, must therefore, even on account of the reaction of the intestinal contents, be excluded from the problem, and Dr. Munk was of opinion that the demonstrated splitting of the fats must play a very important part in the absorption, the nature and manner of which would have to be studied by further investigations. Lately, microscopical demonstrations had been given by other observers that lymphatic corpuscles strayed towards the free intestinal surface, and there supplied themselves with alimentary substances, laden with which they again strayed back. Such a mechanical absorption was, in Dr. Munk's opinion, highly probable in cases in which the fat was not liquefied by the temperature of the body, as, for example, in the case of feeding on mutton suet.—Dr. Benda described microscopic preparations which he made from tuberculous kidneys, and which he exhibited to the members of the Society for their inspection.

Christiania

Society of Science, February 1.—Dr. Collet described the *Beryx borealis*, a remarkable deep-sea fish, and the northern representative of the genus *Berycidæ*, so common in the Chalk period, and its relation to *Beryx decadactylus* of Madeira and Japan.—Prof. Lochmann mentioned a case of poisoning by gas, and referred to the influence of subterranean air on the human organism.—Prof. Lie presented a paper on the common theory of differential equations.—Dr. Kjær described two species of moss, *Hylocomium squarrosum* and *Climacium dendroides*, which were discovered in the clay in the hill in which the famous Norse Viking ship was found near Sandefjord in 1880.

THURSDAY, MARCH 20, 1884

A BIOLOGICAL LABORATORY ON THE ENGLISH COAST

ARRANGEMENTS have been made for a meeting in the rooms of the Royal Society at half-past four, on Monday, March 31, the object of which is to found a Society having for its purpose the establishment and maintenance of a well-equipped laboratory at a suitable point on the English coast, similar to, if not quite so extensive as, Dr. Dohrn's Zoological Station at Naples.

The value of such an institution to the progress of zoological science, and the simple necessity which exists for the thorough and detailed knowledge only to be gained by the constant work of a well-supported laboratory devoted to the complete exploration of a definite area of sea-bottom, if any reasonable action is to be taken in regulating and improving British sea fisheries, have been set forth at various times in these pages during the past year in connection with the conferences held at the Fisheries Exhibition.

English naturalists have at length determined to do their best to bring about the foundation of the desired laboratory. A large sum of money will be needed in order to secure a site and erect the necessary buildings, besides the provision of an annual income. The Society will be able to raise these funds and to administer them in a more satisfactory way than would be possible were the matter taken in hand by a few private individuals only. The laboratory, when once set going, together with its boats and fishermen, will be used for the purpose of carrying on investigations by any naturalists who are members of the Society, and may desire from time to time to avail themselves of its resources. Its work will therefore be chiefly carried on by volunteers, and it is quite certain that there are a very large number of thoroughly competent naturalists who are only waiting for the opportunity thus afforded. At present such men are to be found scattered here and there on our coasts, making shift to carry on observations without laboratory, boats, or any efficient appliances. Eventually it will no doubt be possible to place a qualified observer in charge of the laboratory. The laboratory will also be available for special investigations, for which a public body or other authority may have employed the services of a naturalist.

Apart from the conveniences which it can afford and the value of the moral effect of combined action even in scientific investigation—the continuous working of a number of naturalists at one spot has a most important reaction upon their work. In proportion as a particular area becomes thoroughly familiar in this way, it becomes easy to obtain special animals and plants for study which were at first regarded as rare, or were altogether unknown in the locality. The thorough and long-continued operations of such a laboratory have naturally enough the value of systematised work as compared with the casual dippings and exploratory incursions of the isolated naturalist who spends a month in one year at this place and a month in another year at another place.

Already in Scotland, on the Firth of Forth, close to Edinburgh—through the admirable energy of Mr. John Murray, the director of the *Challenger* Expedition publications—a small laboratory has been set up, and funds obtained for carrying on its work by the engagement of young naturalists to investigate special problems. The English laboratory will be erected at a point as rich as possible in respect of its marine fauna, and at the same time in proximity to important fishing grounds. No locality has yet been decided upon, but both Torquay and Weymouth have been suggested as presenting the desired combination. Everything depends on the amount of pecuniary support which the Society will be able to obtain. A great work may be done if sufficient funds are forthcoming; a smaller work will be accomplished with smaller funds, and carried on in the firm expectation of gaining increased means of activity as results are produced justifying the enterprise.

But as a matter of fact, no tentative method of procedure is needed. It is quite certain, from the experience obtained in other countries, that a properly provided observatory—with good working-rooms, large and small tanks, sea-water pump, a steam launch and well-trained fishermen and permanent staff—can turn out results which are numerous and valuable in proportion to the completeness of the arrangements and the experience of the permanent staff. France was the first country to start such marine laboratories or observatories. At present there are several in operation on the French coast—viz. at Roscoff, at Concarneau, at Villefranche, and near Cette. Italy boasts of the great international laboratory founded and carried on with wonderful perseverance and success by Dr. Dohrn at Naples. An idea of the cost of a really first-rate institution of the kind may be gathered from the fact that the palatial building in the Villa Nazionale at Naples with its fittings and fishing-boats represents a capital of 20,000*l.*, whilst the annual expenditure is over 4000*l.* Austria has such a laboratory at Trieste, maintained by the Imperial Government. Among the most successful of such laboratories have been those established on the eastern coast of the United States. That at Beaufort, directed by the Johns Hopkins University, has furnished an extraordinary amount of interesting results through the activity of Mr. Brooks and the young naturalists of the United States who make use of it. That erected by Prof. Alexander Agassiz at Newport (Maine) is no less satisfactory as an evidence of the utility of such institutions. Since the foundation of these laboratories (within the past decade) our knowledge of marine organisms has increased at an enormous rate: without them we should have gone on in the casual, uncertain way which necessarily arose from the fact that every naturalist, before the foundation of these laboratories, had to establish his own little workshop for the summer and to make a fresh start in an unexplored locality, or in one explored only by the efforts of himself alone.

The meeting on March 31 promises to be one of great influence. Prof. Huxley, P.R.S., is to preside. Prof. Flower, Prof. Moseley, Prof. Milnes Marshall, Sir Lyon Playfair, Mr. W. S. Caine, M.P. (one of the Commission on Trawling), Prof. Michael Foster, Prof. Ray Lankester, Dr. Albert Günther, Dr. W. B. Carpenter, Mr. Gwyn Jeffreys, Dr. P. L. Sclater, Mr. Frank Crisp, Sir John

Lubbock, and other gentlemen, have signified their intention of being present and supporting the resolutions which are to be submitted to the meeting.

We beg to refer those of our readers who are interested in this subject to the articles published during the past year in NATURE, and to the arguments advanced in support of the proposal to found such a laboratory, together with a sketch of the relation of zoological science to the well-being of British fisheries, in the address on the Scientific Results of the Fisheries Exhibition delivered by Prof. Ray Lankester at the conference on July 19, and published by the Exhibition Committee.

THE UNITY OF NATURE

The Unity of Nature. By the Duke of Argyll. (London: Strahan, 1884.)

THIS book is in our judgment a dreary failure. Although in the mere matter of style it is a well written popular exposition of what we may call the comfortable way of looking at things, in all matters of deeper importance it is utterly barren. Throughout its five or six hundred pages there is no single original observation in science, nor any single original thought in anything that deserves to be called philosophy. Moreover, if regarded only as an exposition, the first chapters are tedious on account of the redundant manner in which elementary science is explained, while the later chapters, in which the author's views on various philosophical questions are unfolded, display a feebleness of thought and argument which renders them even more tedious than the earlier ones. In short, the successive essays strongly remind us of a series of Scottish sermons. There is everywhere a narrow consistency in the doctrine, which is presented in a rhetorical precision of style; but the discussion never seems to get below the surface, while even surface difficulties are either unperceived or intentionally avoided. On this account the discussion itself tends to illustrate the principle of "unity" with which it is concerned; it begins, continues, and ends in a monotone. No matter how fearfully out of tune this may be with any of the notes struck by the greatest men of our time, the Duke of Argyll, like a Highland piper, is deaf to every other music, and drowns all else in the one continuous drone of his own particular instrument.

The pages of a scientific journal are not suited to an examination in any detail of the parts of the book to which these general remarks apply. We shall, therefore, proceed to examine the more purely scientific strands which are woven into the texture of the work. In this connection the chief topic which meets us is that of "Animal Instinct in Relation to the Mind of Man." Here the main question which is dealt with—that as to the mode of origin and development of instincts—appears to us most inefficiently treated. The object of the writer is to argue that the phenomena of instinct point directly to the design of a Creator, who correlates instinct with structure and environment. So far, of course, every evolutionist, who is also a theist, may go. But, in order to enforce this view, the Duke proceeds to argue that the phenomena in question are of so mysterious a nature that it is not possible to point to any causes of a proximate or physical kind which may reasonably be supposed to produce them. Now it would be easy to show—were this the place to show it—that the writer has here adopted a weak position even as an apologist; but, to consider the matter only from the side of science, surely it shows some grave want either of judgment or of consideration to make the kind of statements of which the following may be taken as fair examples:—

> "I can therefore see no light in this new explanation to account for the existence of instincts which are certainly antecedent to all individual experience—the explanation, namely, that they are due to the experience of progenitors 'organised in the race.' It involves assumptions contrary to the analogies of nature, and at variance with the fundamental facts, which are the best, and indeed the only, basis of the theory of evolution. There is no probability—there is hardly any possibility—in the supposition that experience has had, in past times, some connection with instinct which it has ceased to have in the present day. . . . There was a time when animal life, and with it animal instincts, began to be. But we have no reason whatever to suppose that the nature of instinct then or since has ever been different from its nature now. On the contrary, as we have in nature examples of it in infinite variety, from the very lowest to the very highest forms of organisation, and as the same phenomena are everywhere repeated, we have the best reason to conclude that, in the past, animal instinct has ever been what we now see it to be—congenital, innate, and wholly independent of experience."

Such passages as these scarcely admit of comment, because all that can be said about them is that the writer has either never read, or has completely forgotten, the whole of the literature to which he alludes. No evolutionist has ever entertained the suicidal "supposition that experience has had, in past times, some connection with instinct which it has ceased to have in the present day;" and the conclusion that in the absence of so absurd a supposition the only alternative is to regard instinct as always having been wholly independent of experience is a conclusion which stands in direct opposition to all that constitutes "evolution" a "theory." Of course no one is bound to accept this theory; it may be rejected, or it may be left unmentioned; but it is futile to set up a nonsensical form of words, and then to call the absurdity the "theory of evolution."

And these are no mere chance expressions, which, if standing alone, might be indicative only of carelessness. The whole of the dissertation on instinct is pervaded by a similar misapprehension, or want of apprehension, of the fundamental ideas of the newer philosophy which the writer appears to suppose that he is considering. Thus, he fails to perceive that the doctrine of natural selection has any bearing upon the subject, while, with reference to the factor of what Mr. Darwin called "inherited habit," he says:—

> "If the habits and powers which are now purely innate and instinctive were once less innate and more deliberate, then it will follow that the earlier faculties of animals have been higher, and that the later faculties are the lower in the scale of intelligence. This is hardly consistent with the accepted idea of evolution," &c.

Comment is needless. We shall, therefore, notice only one other point with reference to the essay on instinct, and this is the difficulty which is thus manufactured to meet the experience theory.

> "Did there ever exist in any former period of the world what, so far as I know, does certainly not exist now—any animal with dispositions to enter on a new career, thought of and imagined for the first time by itself, unconnected with any organs already fitted for and appropriate to the purpose? . . . The questions raised when a young dipper, which had never before seen the water, dives and swims with perfect ease, are questions which the theory of organised experience does not even tend to solve; on the contrary, it is a theory which leaves these questions precisely where they were, except in so far as it may tend to obscure them by obvious confusions of thought."

Here one would have thought that the writer need not have gone further than the instance which he himself gives to have found evidence of the growth of an instinct by the accumulation of hereditary experience or habit, and as yet unconnected with the "organs already fitted for and appropriate to the purpose." For the dipper belongs to a non-aquatic family of birds, and therefore has no organs specially adapted to its aquatic instincts. In particular it has no webs to its feet; and therefore, so far as the structure and affinities of the bird can in themselves argue anything, they speak most distinctly in favour of the view that the species must have developed aquatic instincts while not yet having had time to develop the "appropriate organs." It would be no answer to say that this *species* does not need these organs; else why are they needed by all the *families* of birds which present the same instincts? Or, conversely, can it be said that these same organs, *i.e.* webbed feet, stand in any special correlation with the existing instincts of the upland geese, which, being terrestrial in their habits (though aquatic in their affinities), never use them for swimming or diving? Short of historical or palæontological knowledge (which in the case of instinct is of course impossible), we could have no stronger evidence of transmutation than is afforded by these two complementary cases, in one of which the absence of a structure points to the recent acquisition of the instinct, while in the other the presence of this structure points to the former existence of the instinct now obsolete. Analogous cases occur in the species of ground-parrots and tree-frogs which, while retaining their ancestral structures adapted to climbing, have nevertheless entirely lost their arboreal instincts.

Moreover, a strange want of thought is shown by the remark that, so far as the writer knows, "there certainly does not exist now any animal with dispositions to enter on a new career, thought of and imagined for the first time by itself." It is enough to quote the complete change in the instincts of nidification which has been observed to take place in the house-sparrow, and in several species of swallow, since these birds first had the opportunity of building on houses; or the more recent and perhaps more remarkable case of the mountain parrot, which has been observed to manifest a "progressive development of change in habits from the simple tastes of a honey-eater to the savageness of a tearer of flesh." Many similar instances might be given, and, as showing that they are not uncommon, I may remark that a very instructive one is published by Dr. Rae in a recent number of this journal.

So much, then, for the Duke of Argyll's views on instinct. Scarcely less unsatisfactory are his views on rudimentary organs. The explanation which he adduces to account for these structures is, not that they are remnants of organs useful in the past, but that they are prophesies of organs which, when more fully developed, are to be of use in the future. We have no space to criticise at any length this wholly untenable inversion of Mr. Darwin's teaching; but we think it will be enough to notice the singularly unfortunate instance which the Duke selects to illustrate his theory. This instance is that of the whales, and he says that Mr. Darwin's views of the rudimentary organs here to be met with "obliges us to suppose that the ancestors of the whales were once terrestrial quadrupeds, and in that case we start with the conception of hind limbs, and of the quadrupedal mammal, fully formed and perfectly developed. Whereas, if we accept the possibility of useless organs being the beginnings and rudiments of structures which are there because the germ has always within it the tendency to produce them, then we catch sight of an idea which has the double advantage of going nearer to the origin of species, and of being in harmony with the analogy of natural operations as we see them now." Is not this enough? When we remember the eloquence, as it were, with which the whole organisation of the Cetacea tells us of their having been originally, like other mammals, terrestrial, it seems that the Duke could have chosen no worse example whereby to illustrate his hypothesis.

Passing now to the long discussion of the question whether savages should be regarded as the product of evolution from lower levels of human life, or of degradation from higher levels, we may say in general terms that by adopting the latter hypothesis as applying to all savages, the Duke sets himself in opposition to the theory of evolution as a whole. Moreover, he does not appear to have reflected that the question is not one which can be investigated or decided, as it were, in the lump. It is quite likely that some savages have fallen from a higher to a lower level of savagery; it by no means follows that all savages have done the same. Further, if we were to suppose that they did, from what level of civilised or of uncivilised life are we to suppose that they all started? This hypothesis, as a general explanation of the savage state of man is, indeed, as incoherent as it is obsolete; yet it is not more so than certain other views upon the savage state to which this writer gives expression. Thus, his chief contention is that savage man shows himself to be, as it were, out of joint with the rest of Nature, or, as he expresses it, an "evident departure" from the unity or order of Nature. Perhaps it is enough to say of a doctrine which from a scientific point of view is so peculiar, that it ought to have prevented the author from styling his book "The Unity of Nature."

We have no space left to consider the only other topic that calls for consideration in these columns, viz. the essay on the Moral Sense. The whole treatment of this subject appears to us most feeble. It is also most inaccurate, as the following quotation will suffice to show:—

"It has been laid down that evolution, in its most perfect conception, would be such that the development of every creature would be compatible with the equal development of every other. In such a system it is said there would be no 'struggle for existence—no harmful competition, no mutual devouring—no death' (Herbert Spencer, 'Data of Ethics,' chap. ii. pp. 18, 19). The inspired imaginings of the Jewish prophets of some future time when the lion shall lie down with the lamb, and the ideas which have clustered round the Christian heaven, are more probably the real origin of this conception than any theory of evolution founded on the facts and laws of nature."

It is needless to say that no more ridiculous travesty than this could well be imagined, or that no such absurdity as that which professes to be formally quoted from Mr. Spencer is to be found either under the reference given or in any other part of his writings. In short, this "most perfect conception" of evolution is a pure invention, which reads almost as if it were intended to misinform the uninformed. We do not, however, suppose that such is the case. This extreme of inaccuracy we take to have been reached by the habit of drawing upon "inner consciousness," until not only the whole sense and substance of other writings are perverted, but even the most pure and delicious nonsense is seen by "the mind's eye" to occur in particular words on a particular page of some other book.

If space permitted or need required, we could point out other inaccuracies, and even still greater absurdities, both in this chapter and elsewhere; but we have doubtless already said more than enough to show that "The Unity of Nature" can scarcely be considered a successful work from a scientific point of view.

GEORGE J. ROMANES

OUR BOOK SHELF

The Electrician's Directory, with Handbook for 1884. 67 pp. (London: *Electrician* Office, 1884.)

THIS work, now in the second year of publication, contains much information of use to electric and telegraphic engineers. Amongst its contents are comprised a list of new electric companies, a list of provisional orders granted by Parliament for electric lighting, a list of the "British Cable Fleet," a list of British railways and railway officials, a fairly complete directory of the professions and trades connected with electricity; also a large amount of statistical information about different kinds of dynamo machines, electric lamps, and telegraph tariffs, much of which will doubtless be out of date in twelve months' time. There is also an obituary of electricians deceased in 1883, a table by Mr. Geipel of the cost of electric conductors as calculated by Sir W. Thomson's formula, and a set of tables by Mr. Crawley for corrections of measurements in horse-power and in watts. These two sets of tables are the only portion of the work claiming independent scientific value. We object entirely to Mr. Crawley's gratuitous remark in the prefatory paragraph of his section that the accepted system of electric units was "really foisted upon electricians by men devoted more to theoretic than to practical work." Nothing could be further from the truth than to accuse Mr. Latimer Clark, Sir Charles Bright, who originated the system, and Sir William Thomson, who did so much to perfect it, of not being practical workers. As a matter of fact, *ohms*, *volts*, *farads*, and *webers* were used by practical electricians for years before they found their way into the text-books written by the theorists.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

On a "Magnetic Sense"

SIR WILLIAM THOMSON, in his presidential address at the Midland Institute, which is reported in NATURE for March 6 (p. 438), draws attention to the marvellous fact that hitherto we have no evidence to show that even the most powerful electromagnets can produce the slightest effect upon a living vegetable or animal body. But Sir William "thinks it possible that an exceedingly powerful magnetic effect may produce a sensation that we cannot compare with heat, or force, or any other sensation," and hence he cannot admit that the investigation of this question is completed,—for although the two eminent experimenters named by Sir W. Thomson felt nothing when they put their heads between the poles of a powerful electromagnet, it does not follow that, therefore, every member of the human race would feel nothing.

May I be permitted to point out that some slight evidence already exists in the direction sought by Sir W. Thomson? Scattered in different publications there are numerous statements made by different observers in different countries during the present century, which, if trustworthy, indicate that upon certain human organisms a powerful magnet does produce a very distinct and often profound effect. Unfortunately, with the exception of the careful and excellent observations made by Dr. W. H. Stone, who tried Charcot's experiments on a patient of his at St. Thomas's Hospital, the observations referred to are singularly wanting in precision of statement and in a due recognition of the precautions needful in order to avoid fallacious or ambiguous results from illusions of the senses.

This being the case, an attempt is being made by the Society for Psychical Research to ascertain—by direct and careful experiment, extending over a wide range of individuals—whether any trustworthy evidence really exists on behalf of a distinct magnetic sense. The sectional Committee of that Society intrusted with this and cognate work has published a preliminary report,[1] which contains a fragment of evidence pointing in the direction of the existence of a magnetic sense in certain individuals. Three persons have been found by the Committee, who, when their heads were placed near the poles of a powerful electromagnet, could tell by their sensations when the magnet was excited or not. One of these "sensitives" told the investigating Committee accurately twenty-one times running whether the current was "on" or "off" from a peculiar and unpleasant sensation he alleges that he experienced across his forehead. Every precaution that suggested itself was taken to prevent the subjects gaining any information through the ordinary channels of sensation of what was being done at the contact-breaker placed in another room. But I am sure the Committee will gratefully welcome any criticism of their procedure or suggestions for future experiment which Sir William Thomson may feel inclined to give. The honorary secretary of the Committee is Mr. W. H. Coffin, Cornwall Gardens, S.W.

Two or three months ago one of the gentlemen who appeared to have this magnetic sense was in Dublin, and I took the opportunity of repeating with care in my own laboratory the experiments previously made at the Society's rooms in London. The result satisfied me that this individual did in general experience a peculiar sensation, which he describes as unpleasant, when his head was within the field of a powerful magnet. Nevertheless the keenness of his magnetic sense, if such it be, varied considerably on different days, and sometimes he stated that he could detect little or no sensory effect. Usually the effect was felt most strongly when the forehead was in the line joining the two poles; but one day, when he was suffering from facial neuralgia, he found that his face was the most sensitive part, and complained of a sudden increase of pain whenever the magnet was excited, his face being near the poles. Sufferers from neuralgia among the students of science may therefore have a new and useful career before them, in the pursuit of which their increased torture will, it is to be hoped, be vanquished by a far stronger intellectual joy.

---

[1] *Proceedings of the Society for Psychical Research*, Part 3. (Trübner and Co.)

The peculiar and unpleasant sensation which the magnet appeared to produce on the subject just referred to was described as slowly rising to a maximum in fifteen or twenty seconds after the current had been sent round the coils of the electromagnet. In like manner the effect seemed to die down slowly after the contact was broken. Unknown to the subject, the circuit was closed and opened several times, and the magnetism correspondingly evoked or dissipated, the result being that there was a fairly accurate correspondence between the physical and the psychical effect. The faint molecular crepitation which accompanies the magnetisation of iron, and can be heard when the ear is very near the magnet, is, however, very apt to mislead the imagination. To avoid this, the subject was placed at a distance where this faint sound could not be heard, and he was then requested to walk up to the electromagnet, and, judging only from his sensations, to state if the current were "on" or "off." The experiment was made twelve times successively, and he was correct in ten out of the twelve trials. He had no means of seeing or hearing the contact-breaker; of course, it is possible for a trickster, using a concealed compass-needle, to be able to impose on a careless experimenter, but care was taken, and I have not the least reason to doubt the entire *bonâ fides* of the subject of this experiment. Obviously the foregoing observation is but of little value unless corroborated by a far more extensive series of experiments, conducted with the most stringent precautions to avoid the creation of illusory effects.

I have tried experiments with large helices encircling the limbs and head, and animated by powerful currents, but have not observed any peculiar sensory effect in my own case, though I am inclined to think the headache which I have often experienced when working with a large magnet may not be altogether an accidental coincidence. Meanwhile experiments are in progress in my laboratory to ascertain, if possible, whether any sensory effect is produced upon lower organisms. I hardly anticipate any affirmative results, but it seemed worth making a systematic investigation from minute structures up to man. Sir W. Thomson's address will, I hope, stimulate other workers in this field.

W. F. BARRETT

Royal College of Science, Dublin, March 11

Instinct

I WRITE one more letter on this subject, in order to observe that I do not think the only remaining difference between Mr. Lloyd Morgan and myself is so great as it may be apt to appear. In my books I have been careful to point out the peculiar disabilities under which the science of comparative psychology labours from its necessarily ejective character. But while in Mr. Morgan's view these disabilities are so great as to render any science of comparative psychology impossible, in my view they are not quite so great. I quite agree with the quotation which he gives from Prof. Huxley on the crayfish; but this does not amount to saying that no science of comparative psychology is possible. We may still, for instance, feel perfectly certain that a dog is a more intelligent animal than a crayfish, and in this we have a purely scientific proposition.

The difference, therefore, between Mr. Morgan and myself is more apparent than real, and depends upon what we mean by "a science." This is the question that must be answered before we can proceed to consider the question raised by him, viz. "Is a science of comparative psychology possible?" In my estimation the possibility of a science is furnished wherever there is material to investigate. The more vague the material, the less exact must be the science, and on this account, no doubt, comparative psychology is the least exact of all the sciences. But so long as its subject-matter admits of any investigation at all, so long, it seems to me, comparative psychology is a science.

GEORGE J. ROMANES

The Remarkable Sunsets

WITH reference to the theory that the red sunsets are due to volcanic dust in the air, I think that the following extract from a letter which has been forwarded to me is of considerable interest. The writer is Mr. Frederick Spofforth, and his letter is dated January 29, from Collaroy, 150 miles from Sydney. It will be observed that the corroboration which he gives to the theory in question is the more striking from the fact of its being so completely unconscious.

GEORGE J. ROMANES

"A most peculiar sight this summer are the sunsets. The sun always goes down as red as can be, and half the night there is the same roseate hue, which lasts till past midnight. Many causes are given for it, but nearly all differ.

"Another curious thing is the enormous amount of dust—even up here, where you see nothing but trees as far as the horizon on all sides. Some days the whole landscape will be covered in dust, and where the dust comes from nobody can tell. It is always worst in the early morning."

Right-sidedness

MR. LE CONTE (NATURE, xxix. p. 452) seems rather to complicate than to simplify this question. If the right side of his body shows more dexterity than the left, surely it is his left eye that should share this excellence, if we are to suppose that this difference in dexterity depends upon any central origin. A person paralysed on the left side of the body loses sight—if sight be lost at all—in the right eye, and *vice versâ*. Further, I am right-handed, and use an eyeglass in my left eye; yet, though the right eye is the weaker, I use it for a telescope or microscope by unconscious preference. On the other hand, most persons who use a single eyeglass wear it in the right eye. I may have adopted the left for ease in adjusting the glass, so that my right hand might be free. When I am reading, if I put my hand in front of my left eye, I am conscious of some muscular alteration; if I obscure my right eye, I notice nothing but a slight diminution of the sense of light, white objects seeming less white to my right eye than to my left. And this effect is just as noticeable when I wear spectacles as when I am reading without them; so that my myopia is not the cause of the difference.

In discussing right-sidedness—whether we regard the decussation of the nerves in the medulla oblongata or not—we must not forget that prize-fighters normally strike with the left hand, using the right as a guard or to deliver the second blow; perhaps this is to gain the advantage of the greater strength of the right leg. Moreover, the habit among Western nations of writing from left to right appears to argue that right-handedness is the rule among them: but Orientals reverse the process, so that the majority of mankind must be left-handed. What do the anthropologists say to this?

Mr. Charles Reade, writing in the *Daily Telegraph* some years ago, argued that if the habitual use of the right hand led to a greater development of the left side of the brain, a further acquired use of the left hand would aid the development of the right cerebral hemisphere, and so increase the general power of the brain. But is there any evidence to show that ambidextrous people, left-handed apparently by nature, and right-handed from habit, have any general mental advantage over their fellows? I think not.

HENRY T. WHARTON

39, St. George's Road, Kilburn, March 17

IN my own experience (I can with confidence only give that) I differ almost wholly from that of Mr. Joseph Le Conte, as expressed in NATURE (p. 452). In my case strength and dexterity of arm do not *in everything* go together. For instance, although strongly left-handed, I learnt to write with the right hand and shoot from the right shoulder, and could do either very indifferently indeed if attempted with the left hand or arm. I perhaps may call myself with truth a rather handy man, improved upon by living for many years in places where tradesmen were not to be had. In all connected with pencil, pen, ink, and paper, such as printing, chart-making, my left hand, although strongest, was clumsy, whereas my right showed considerable skill, as was exhibited once in rather a ludicrous manner by the Hydrographer of the Admiralty mistaking my pen-and-ink chart of some seven hundred miles of Arctic discovery for an engraving of the same. My left leg is the stronger, yet I use it in kicking and in other ways requiring dexterity; *e.g.* when very many years younger I could perform the many curious movements or steps of some of our Scottish dances with much more accuracy and ease with the left foot than with the right. I fear the subject-matter of this note may be scarcely considered a valid excuse for so much self-notice.

Ravens in the United States

ON p. 336 of NATURE for February 7, Manhattan asks a question about "ravens." I do not propose to answer his question, but to state a fact. I was raised from boyhood to manhood in Tioga Co., Penn., and in my boyhood days, when the primeval forests were broken only by the recent settler's small patch scattered here and there along the valleys, the raven was as common as the crow; nor could the one ever be mistaken for the other. Before I had attained the years of manhood, however, the raven had become a *rara avis*, while the crow, on the contrary, had become vastly more abundant. The bald-eagle, and the fish-hawk, too, were then very often seen, now seldom or never. Other birds could be added to the list if desirable. The question, *why?* is not so easily disposed of as it is to state the fact. Should one be disposed to answer by saying *the rifle*, it would be pertinent to reply that the rifle was just as active against the crow, the common hen-hawk, and the crow-blackbird, as it was against the raven, the fish-hawk, and the bald-eagle; but these latter birds have all disappeared, while, in spite of the rifle, the former have increased. We must look deeper for the cause. IRA SAYLES

Washington, D.C., March 3

In answer to the query of your correspondent "Manhattan," who writes from New York, under date of Jan. 11, concerning the prevalence of ravens in the United States, I would like to remark that ravens quite replace the crow in Nevada. I have never seen them here in the east. Mr. Ridgway who was with me in 1867-68 could give you much valuable information in regard to their habits and range. W. W. BAILEY

Brown University, Providence, R.I. (U.S.A.), March 1

Thread-twisting

IN NATURE, January 31 (p. 305), I read some remarks by Prof. E. B. Tylor on a "rude method of making thread by rolling palm or grass fibre into a twist with the palm of the hand on the thigh," which Prof. Tylor regards as a "savage art" of old native tribes of Guiana, who were thigh-twisters. I have often seen shoemakers when at work prepare their threads by twisting them on the thigh with the palm of the hand. May this practice be one which has survived from a barbarous period? J. S.

Truro, March 14

BICYCLES AND TRICYCLES IN THEORY AND IN PRACTICE [1]

WHEN I was honoured by the invitation to give this discourse on bicycles and tricycles, I felt that many might think the subject to be trivial, altogether unworthy of the attention of reasonable or scientific people, and totally unfit to be treated seriously before so highly cultured an audience as usually assembles in this Institution. On the other hand, I felt myself that this view was entirely a mistaken one, that the subject is one of real and growing importance, one of great scientific interest, and, above all, one of the most delightful to deal with that a lecturer could wish to have suggested to him.

It is quite unnecessary for me to bring forward statistics to show how great a hold this so-called new method of locomotion has taken upon people of all classes: the streets of London, the roads and lanes in all parts of the country, testify more forcibly than any words of mine can do to what enormous numbers there are who now make use of cycles of one sort or other for pleasure or for the purposes of business.

Not only has the newly developing trade brought prosperity to towns whose manufactures were dying a natural death, but the requirements of cyclists have given rise to a series of minor industries, themselves of great importance. Riders of bicycles and tricycles come along so silently that instruments of warning have been devised. There are bells that jingle, bells that ring, whistles, bugles, and a fiendish horn which will utter anything from a gentle remonstrance to a wild, unearthly shriek. Lamps, tyres, saddles, seats, springs, &c., are made in unending variety; these form the endless subject of animated conversation in which the cyclist so frequently indulges. Cyclometers or instruments for measuring the distance run are also much used. Some show the number of revolutions made by the wheel, from which the distance can be found by a simple calculation; others indicate the distance in miles. There is on the table a home-made one of mine with a luminous face which at the end of every mile gives the rider a word of encouragement; it now indicates that a mile is nearly complete; in another turn or two you will all hear it speak.

Cyclists have a literature of their own. There are about a dozen papers wholly or largely devoted to the sport. They can even insure themselves and their machines against injury by accident in a company of their own.

The greatest and by far the most important growth is the Cyclists' Touring Club, a gigantic club to which every right-minded rider in the country belongs. This club has done more to make touring practically enjoyable than could have been thought possible when it began its labours. Railway companies have with few exceptions consented to take cycles at a fixed and reasonable rate; in almost every town in the country an agreement has been made with the leading, or at any rate a first-class, hotel, in virtue of which the touring member may be sure of meeting with courtesy and attention for himself and with clean quarters and an intelligent groom for his horse, instead of finding himself as hitherto a strange being in a strange place at the mercy of some indifferent or exorbitant landlord. In consequence of this, thousands now spend their holidays riding over and admiring the beauties of our own country instead of being dragged with a party of tourists through the streets and buildings of a foreign town. Of the delightful nature of a cycling tour I can speak from grateful experience; last autumn alone I travelled nearly 1500 miles, meeting on my way with almost every variety of beauty that the scenery of this country affords. Wherever I went I felt the beneficial influence of the C.T.C., as the touring club is called. At all the hotels—our headquarters—at which I stopped, I found the most sanguine wishes of the club amply fulfilled, our wants understood and provided for.

The C.T.C. have also done a great service in providing us with a uniform which has been proved to be as near perfection as possible. They have also designed a ladies' cycling dress, which can be seen in the library.

Though touring in the country is the perfection of our art, town riding has its advantages. I, in common with a fair number, ride daily to and from my work no matter what the weather may be: rain, snow, wind, or hail, cycling affords the pleasantest means of crossing London. Instead of waiting in draughty railway stations, of catching cold outside or being stewed inside omnibuses, or of being smoked in the Underground Railway, we, the regular cyclists, look forward to our daily ride with pleasure, for the healthy exercise, the continuous necessity of watching the traffic and avoiding ever-approaching danger, form between them a relief from mental worry or business anxiety which we alone can appreciate.

Of the dangers of the streets I have little to say: the regulation of the traffic by the police, and the consideration of drivers, though they are not in general too fond of us, make danger in the quarter from which it might be expected very remote. Our chief difficulty is due to the irregular and utterly unaccountable movements of pedestrians, whose carelessness keeps us in a continual state of anxiety.

There remains one point of the utmost importance on which I would say a few words, I refer to the effect of cycling on our general health. About a year ago there appeared in the *Lancet* an article condemning in no measured terms the evils likely to result from the development of this new craze, in which, as far as I remember, it was stated that we are now sowing the seeds of a series of new diseases, the symptoms of which will only appear possibly in years to come. I would not for a moment question the accuracy of opinion held by any professional man; whether this is or is not the case I cannot tell; however, I may mention that the only symptoms which I have so far discovered in myself are an improved appetite, increased weight, and a general robustness to which I was formerly a perfect stranger. Having, I trust, succeeded in showing that the advantages offered to riders are sufficient to account for the rapid development of cycling, that it is in fact no mere temporary craze, I shall now proceed to consider the theory and construction of the various machines at present known.

---

[1] Lecture delivered by C. Vernon Boys, A R.S.M., at the Royal Institution, March 7.

From the hobby-horse to the bone-shaker, and from the bone-shaker to the bicycle, the steps are so simple and obvious that it is quite unnecessary for me to trace them. It is also needless for me to describe the modern bicycle: every one must be familiar with it, every one must have seen the ridiculous zigzag of the beginner, and have admired the graceful gliding of an accomplished rider. Of the theory of the balance little need be said; anything supported in a mere line, in unstable equilibrium as it is called, must fall one way or the other. The machine and rider would of necessity capsize if some action of recovery were not possible. To whichever side the machine shows any inclination, to that side the rider instinctively directs it. By this means the tendency to fall to one side is balanced by the property of the rider to continue moving in a straight line, and so to go over on the other side. This action of recovery is always overdone, so that a second turn in the opposite direction must follow. Hence the extraordinary path traced by the beginner. Even with the most skilful rider, though he appears to travel in a perfectly straight line, a slightly sinuous course is essential, as the highly characteristic track left on the road indicates. If anything should happen to check this slightly serpentine motion, as, for instance, occurs when the driving-wheel drops in the groove of a tram-line, the balance at once becomes impossible, and the rider is compelled to dismount.

The extraordinary stability of the bicycle at a high speed depends largely on the gyroscopic action of the wheels. On the table is a top supported in a ring which is free to move how it pleases. So long as the top is spinning the ring is as rigid as a block; on stopping it, the freedom of the support is at once apparent.

It is a marvel to many how anything so light, how anything so delicate, can carry the weight or can travel at the speed so common without utterly collapsing. The wheels especially attract attention. In a hoop no one part can be pushed in unless some other part can go out. A bicycle wheel is a hoop in which every part is prevented from going out by the tension of the spokes. To give the wheel lateral stability, the spokes are carried not to the centre, but to the two ends of the hub, thus lying on two cones. Such a wheel is abundantly strong in its own plane: it can withstand the jars and shocks of a bad road without a groan, but once subject it to serious side strain, such as I can with ease put upon it with a jerk of my wrists, and the wheel will crumple up like an umbrella in a storm. Till this year there has been no change in the principle of construction, though in detail many improvements have been carried out and are largely adopted. By the use of hollow rims a stiffer and lighter wheel can be made; thick-ended, crossed and laced spokes are employed, and other details modified. Essentially, however, the "spider" wheel as a structure is the same as it was when first introduced. Suddenly two radical changes are presented to us. Mr. Otto, whose great work I shall describe in its proper place, has devised a wheel on a new system, in which the spokes that form the structure lie in the plane of the rim, in which position they are best able to withstand direct shocks. Such a wheel would be unstable, but requires very little to keep it true. Delicate spokes, not screwed up very tight, are therefore placed on either side, so that a side-strain is met by the whole strength of the spokes on one side, which are not as hitherto weakened by the pull of the spokes on the other. On this system much narrower wheels can be made than was possible before. The other change, due to the same inventor, is still more striking. He has found, contrary to the opinion of every one, that wheels, either of his narrow type or of the usual form, can be made and will remain true when the spokes are made elastic by being bent into a wavy or slightly spiral form. If only these wheels will stand the test of time—and I see no reason why they should not—one of the greatest discomforts and possible causes of injury from which the cyclist suffers—the vibration and jolting due to a bad road—will have been removed.

The bearings in a bicycle are perhaps more to be admired than any single part. Instead of allowing the axle to slide round in its bearings, hard steel rollers or balls are introduced, so that the parts which are pressed together roll over and do not slide upon one another. Any one who has trodden on a roller or a marble must have found in a possibly unpleasant manner the great difference between rolling and sliding friction. I can now give for the first time the result of an experiment only completed this morning, which shows the extraordinary perfection to which this class of work has attained. I have observed how much a new set of balls which I obtained direct from the well-known maker, Mr. Bown, has lost in weight in travelling 1000 miles in my machine. Every 200 miles I cleaned and weighed the balls with all the care and accuracy that the resources of a physical laboratory will permit. The set of twelve, when new, weighed 25·80400 grm. After 1000 miles, they weighed 25·80088 grm., the loss being 3·12 mgrm., which is equal to 1/20·8 grain, that is, in running 1000 miles, each ball lost 1/250 grain. This corresponds to a wear of only 1/158,000 inch off the surface. At this rate of wear—3·12 mgrm. per 1000 miles—the balls would lose only 1/34·3 of their weight in travelling as far as from here to the moon.

The twelve balls, after the first 200 miles, each weighed in grammes as follows. The loss of each in running 600 miles is appended:—

Weight in grm.	Loss in 600 miles	Weight in grm.	Loss in 600 miles
2·16605	·00050	2·14725	·00020
2·16180	·00025	2·14725	·00020
2·15550	·00035	2·14700	·00020
2·15480	·00015	2·14500	·00020
2·15000	·00015	2·14280	·00025
2·14730	·00015	2·13875	·00020

I did not weigh each ball on the first and last occasion. However, the wonderfully uniform wear in the intermediate 600 miles speaks well for the equal hardness of the balls.

The wear of the dozen during each journey of 200 miles was as follows:—

Miles	Wear in grm.
0—200	·00055
200—400	·00070
400—600	·00055
600—800	·00075
800—1000	·00062

I have given the results of these experiments at length, for I do not think that accurate and systematic observations of the kind have been made before.

We may consider, then, that the balls are practically indestructible. Knowing this, Mr. Trigwell has applied the ball-bearing to the construction of the "head" of the bicycle, not so much with the view of diminishing the friction there, but of preventing wear in a place where any shake is highly objectionable. One of his ball-heads is on the table.

The frame of the bicycle, consisting merely of the fork and backbone, is made of thin steel tube, the type of all that is light and strong. Indiarubber, besides being used for the tyres of all machines, has been worked into every part of the structure to diminish, so far as is possible, that perpetual and wearying vibration of which all bicyclists so bitterly complain. The number of improvements in every detail is so great that any attempt to enumerate them is out of the question. Suffice it to say that the modern bicycle is the perfection of all that is perfect; as a machine for racing, as a machine for hurrying over good and level roads nothing can approach it. Unfortunately, however, there is ever present danger, and danger of the most objectionable sort, for the most skilful rider knows too well that should he strike a stone of even an ordinary size he must expect to be pitched over the handles, and come with a crash to the ground. It is true that in general no harm is done, but such a fall may bring any one to a sudden and horrible end.

Many have attempted, while still retaining the advantages of the bicycle, to make these involuntary headers impossible by modifying in some way its construction. One of the earliest attempts in this direction is well named the "Extraordinary." On it the rider is placed much further behind the main wheel, but can still employ his weight to advantage, as the treadles are placed below him and are connected by levers with the cranks. In another safety bicycle a third wheel is carried in front, just above the ground, so as to resist at once any tendency to tilt forward. In another type much smaller wheels are employed, and the feet, now nearer the ground, are connected with the cranks, by levers in the "Facile," or by a hanging pedal in the "Sun and Planet." There is a bicycle with two large wheels—one in front of the other—which two can ride, which should be both safe and rapid.

By far the most curious and utterly unintelligible of all machines of the bicycle type is Mr. Burstow's "Centre-cycle." So incomprehensible did this machine seem to me that I took the trouble one afternoon last week to ride to Horsham to see it in its native place. A careful examination has convinced me that it is not only correct in its design, but that it is in many respects the most wonderful cycle at present made. There is on the table a model Plympton skate. When this is level, it runs straight; when inclined either way, it wheels around in a manner that was so familiar a few years ago. The four wheels of the Centre-cycle are a counterpart of the four wheels of the skate; when the frame leans either way, they turn in an appropriate manner, or, conversely, when they turn, the machine leans in the proper direction. It might be thought that a thing with five wheels is more nearly allied to a tricycle than to a bicycle; but this is not so, for the Centre-cycle, when ridden skilfully, has rarely more than one wheel on the ground; the leaning to one side in turning a corner (tricycles unfortunately must remain upright), and the general action is essentially that of a bicycle. The great peculiarity of this machine is the power that the rider possesses of raising or lowering any wheel he likes. Now that I have mounted it you will see that I can rest on one, three, four, or five wheels as I please. In consequence of this power of lifting the wheels, a rider can travel over an umbrella without touching it, lifting the wheels as they approach, and dropping them as they pass, after the manner of a caterpillar.

Whatever difficulty I may have had in doing justice to the bicycle, the corresponding difficulty in the case of tricycles is far greater. The number of makers and the variety of their work is so great that it would be sheer madness on my part to attempt to describe all that has been done. Those who wish to see the great variety of detail which chiefly constitutes the difference between one make and another must go to one of the exhibitions of these things which are now so common.

All I shall attempt will be an explanation of the leading principles which are involved in the design of a tricycle. For this purpose it will be necessary for me to mention occasionally some particular machine; but in justice to the hundreds to which I cannot even refer, I wish it to be understood that those named, though typical, are not of necessity better than any other.

Till a few years ago the bicycle was the only velocipede which was worthy of the name. Inventive genius and mechanical skill have given rise to a series of machines on three wheels on which any one can at once sit at ease, and which require but little skill in their management. Men who do not care to risk their necks at the giddy height of the bicyclist, ladies to whom the ordinary bicycle presents difficults which they cannot well surmount, each find in the tricycle the means of obtaining healthy and pleasant exercise, and of enjoying to a certain extent the advantages which the bicycle affords. Thanks to the perfection of the modern tricycle, cycling has become one of the most popular institutions of the day.

It is first necessary to know what combinations of three wheels will, and what will not, roll freely round a curve. The few possible arrangements determine the general forms which a tricycle can take. A wheel can only travel in its own direction; no side motion is possible without the application of considerable force, entailing strain and friction of a most injurious kind. In any combination, then, of three wheels, each must be able, in spite of the united action of the other two, to move in its own direction. There is on the table a model in which the three wheels can take every possible position. To begin with, two large ones are placed opposite to, but independent of, one another, and parallel, and a small one, parallel to the others, is mounted between them at one end. This arrangement rolls along in a straight line with perfect freedom; on twisting the plane of the third wheel it is also free to roll round a curve whether the little wheel is before or behind. If I shift the position of one of the large wheels so that, though still parallel to, it is no longer opposite, the other, then, though they can freely move in a straight line, they can by no possibility be induced to roll round a curve. It is clear, then, that two wheels that are parallel cannot be employed in a tricycle unless they are opposite one another. The only class of people who frequently appear to be familiar with this fact are nursemaids, who always tip up the front of a perambulator in turning a corner.

If one wheel is in front of and another behind a third, the combination can only roll round a curve when the front and rear wheel are turned to proportionate extents in opposite directions. The model is so arranged now; if either of the little wheels is not turned to exactly the right amount, they can no longer roll, they can only be dragged round a curve. It is not sufficient that two parallel wheels should be opposite one another, they must be able to turn at different speeds. I have now the two large wheels keyed on the same axle, so that they must of necessity turn together; this combination is ready enough to go straight, but no amount of encouragement by the steering wheel will induce it to go in any other direction.

Bearing these facts in mind, it will not be difficult to follow the development of the tricycle. It would seem impossible in the first arrangement (that with two wheels opposite one another, and a third, or steering wheel, before or behind between them) to drive both sides, for the wheels must be able to turn at different speeds; let therefore one be free to go as it pleases, if the other only is driven, we have at once a very common form of tricycle, in which one wheel drives, one steers, and one is idle.

Machines of this class have many defects. The feeble steering power, combined with their unsymmetrical driving, render them altogether untrustworthy. If any power is applied to the driver, which can only have its share of the weight upon it, it slips on the ground; if the machine is quickly stopped, owing to the small weight on the steering wheel, it is apt to swing round and upset; nevertheless, those who are content with pottering about on our wood pavement and gravel roads find this class of machine answer their purpose, and owing to their cheapness and simplicity they do not care to get a better.

The second arrangement of the model, in which riders must have recognised the Coventry Rotary, is free from most of the defects of the form just described; there is more weight on the driver, but not enough to prevent its being made to slip round; there are two steering wheels a long way apart, with plenty of weight upon them, so that the guiding power in this type of tricycle is all that can be desired.

Let me now return to the first arrangement, in which two parallel wheels are opposite one another. If by any possibility both wheels could be driven, and yet be free to go at different speeds, then there being so large a weight on the drivers they could not be made to slip; the driving being symmetrical, most of the twisting strain would be taken off the steering wheel, and still the machine would be capable of rolling round a curve with perfect freedom.

All the methods of solving the problem of double driving come under two heads, one depending on the action of a clutch and the other on differential or balance gear.

The clutch action being the simplest, I shall describe that first. In going round a corner the inner wheel must lag behind, or the outer wheel must run ahead of the other; as either wheel may be inner or outer according to the direction of the curve, each must be able to lag behind or each must be able to run ahead. If both were able to lag behind, the machine could not be driven forward, and it would be of little use; if both were able to run ahead, the machine could not be driven backwards—a matter of small importance. There is on the table a large working model, showing how a four-sided wheel is free to revolve in a ring, but is instantly seized when turned the other way, owing to a jambing action on one or more of four rollers. The four-sided wheel then can be employed to drive the ring one way but not the other. One of these "clutches" or "friction grips" is placed at each end of the crank shaft in the "Cheylesmore" tricycle, and a chain round the ring of each drives the corresponding wheel. The machine named is a rear-steerer; the clutch is also employed in some front-steerers.

The other method of double driving depends on the use of the well-known gear of three bevel wheels or of some equivalent mechanism. If the axle of the middle of the three wheels is turned round the common axle of the other two, the applied force is divided between those two wheels, yet the pair are free to move relatively. Let then the chain drive a wheel carrying the middle bevel, and let the side bevels be connected with the two drivers. Whatever happens, the power of the rider will be equally divided between them, yet the machine will be free to roll round a curve.

There are a great number of devices which are exactly equivalent to this the simplest of all, which is known as Starley's gear. There is on the table a beautiful model of the gear used in the Sparkbrook tricycle, which has been lent me by the makers of that machine, Bown's differential gear, and some others; but time will not allow me to describe them. There is one gear, however, which presents many peculiarities, which I have devised, and which may be of interest. A large working model is on the table. Between the conical edges of two wheels which are connected to the drivers lie a series of balls, outside which is a ring with sloping recesses. If the ring be turned by a chain or otherwise, the balls jamb in the recesses as the rollers do in the clutch gear. Nevertheless they are free to turn about a radial axis, and so allow the two driven cone wheels independent motion. The bursting strain on the ring and the side thrust on the cones acting on rolling balls balance one another. With this gear the rider can cause the balls to jamb one way or both ways, and so have or avoid the "free pedal" as he pleases.

In almost all good designs of front-steering tricycles the power applied to the cranks is transmitted to a differential gear by a chain. The crank and connecting rod have also been used to transmit the power, but then the clutch is necessary.

There is, however, another type of tricycle, in which the use of cranks is avoided, among which may be mentioned the "Omnicycle," the "Merlin," and that highly ingenious machine, the rowing tricycle. On the table there is the Omnicycle gear. In all these the power is applied direct to the circumference of a wheel or sector, and so dead points are avoided, which is a point in their favour when meeting with much resistance. On the other hand, the sudden starting and stopping of the feet in the two former machines and of the body in the latter make this type utterly unsuitable for obtaining anything more than a moderate speed. In the Omnicycle ingenious expanding drums are employed, so that the power may be applied with different degrees of leverage according to circumstances.

There remains one type of tricycle which, for rapid running, surpasses many: I refer to what is known as the Humber pattern. So excellent is this form in this respect that the leading manufacturers have, by turning out machines on the same lines, paid the original makers a compliment which is not altogether appreciated. This pattern departs less from the ordinary bicycle than any other; it is one, in fact, in which, instead of one, there are two great wheels, giving width to the machine, between which the power is divided by the usual differential gear.

Having spoken of the differential gear and the clutch, I had better show the comparative advantages and disadvantages of the two methods of double driving. With the differential gear the same force is always applied to each wheel, so in turning a corner the outer one, which travels furthest, has most work expended upon it (work = force × distance). In this respect the differential gear is superior. On the other hand, when one wheel meets with much resistance from mud or stones, and the other with hardly any, the latter has still half the strength of the rider spent upon it, which is clearly a mistake. With a clutch-driven machine running straight, the wheels take such a share of the rider's power as is proportional to the resistance they individually meet. When the machine is describing a curve, that is generally, only the inner wheel is driven, and the machine is for the time only a single driver, with the driver on the wrong side.

I must now describe some devices which are attracting much attention at the present time, the speed and power gears. Let us suppose there are two machines with wheels of different sizes, but in other respects alike. Then each turn will take the larger wheeled machine further than the smaller. In going up a hill the larger wheel will take its machine up a greater height than the other in one revolution, which involves more work and therefore more strength. If on the large wheel the chain pulley were increased in size, then for the same speed of the treadles it would not turn so quickly, it would not take the machine so far up the hill as before, it would in fact be equivalent to a smaller wheel, so that less strength than before would be necessary. This diminution of speed, though of great advantage when climbing a hill, is the reverse on the level, for then very rapid pedalling would be necessary to maintain even a moderate speed. To obtain the advantage of high wheels or high gearing on the level and at the same time low wheels or low gearing on the hills, some highly ingenious devices are employed. On the table is a well-known one of these, the "Crypto-dynamic," which by a simple movement changes the relative speed of wheel and treadle. Time will not permit me to describe the details of this arrangement, but it contains an epicyclic gear which is or is not in action according as the rider desires power or speed. There are several other devices having the same object, some depending on an epicyclic gear in a pulley, others on the use of two chains, only one of which is active at a time. These arrangements have the further advantage of enabling the rider to disconnect the treadles from the wheels whenever he pleases.

Tricycles on which two, three, or a whole family can go out for a ride together, involve few new principles, and I shall not for this reason have a word to say about them.

There remains one machine forming a class by itself, more distinct from all others than they are from one another. It is not a bicycle in the ordinary sense of the word; it is not a tricycle, for it has only two wheels. This machine is, from a scientific and therefore from your point of view, more to be admired than any other. It is called, after its inventor, the "Otto." The Otto bicycle and the Otto gas-engine will be lasting memorials to the ingenuity of the brothers who invented them.

No machine appears so simple, but is so difficult to understand as this. Tricyclists who have been in the habit of managing any machine at once, are surprised to find in this something which is utterly beyond them. They cannot sit upon it for an instant, for so soon as they are let alone it politely turns them off. When at length, after much coaxing, they can induce it to let them remain upon it, they find it goes the way they do not want. Riding the Otto, like any other accomplishment, must be learnt. Some seem at home on it in half an hour, others take a week or more. It is not surprising that that quick perception, in which ladies have so much the advantage of men, enables them to quickly overcome the apparently insurmountable difficulties which this machine presents to the beginner.

The rider when seated is above the axle of two large equal wheels; being then apparently in unstable equilibrium, he would of necessity fall forwards or backwards if some movement of recovery were not possible. The Otto rider maintains his balance in the same way as the pedestrian. If he is too far forward, pressure on the front foot will push him back; if too backward in position, pressure on the rear foot will urge him forward. That this must be so is clear, for, whatever turning power he applies to the wheels, action and reaction being equal and opposite, they will produce an equal turning effect upon him. The steering of this machine is quite peculiar. In the ordinary way both wheels are driven by steel bands at the same speed; so long as this is the case, the Otto of necessity runs straight ahead. When the rider desires to turn, he loosens one of the bands, which causes the corresponding wheel to be free; if then he touches it with the brake or drives the other wheel on, it will lag behind, and the machine will turn. It is even possible to make one wheel go forwards and one backwards at the same time, when the machine will spin like a top within a circle a yard in diameter.

There being no third wheel the whole weight is on the drivers, the whole weight is on the steerers; the frame, which is free to swing, compels the rider to take that position which is most advantageous, making him upright when climbing a hill, and comfortably seated when on the level. Owing to a curious oscillation of the frame which occurs in hill climbing, the dead points are eliminated, so the rider need not waste his strength at a position where labour is of no avail.

Though it has been impossible for me to do more than indicate in the most imperfect manner how numerous and beautiful are the principles and devices employed in the construction of cycles, I trust I have disappointed those who were shocked and horrified that so trivial a subject should be treated seriously in this Institution.

DANGERS FROM FLIES

IN a note communicated to the *Gazzetta degli Ospitali* for August 1883, and republished in the current number of the *Archives Italiennes de Biologie* (tome iv. fasc. ii.), Dr. B. Grassi calls attention to the fact that flies are winged agents in the diffusion of infectious maladies, epidemics, and even parasitic diseases. During the summer season, when flies occur in swarms, it seems impossible to prevent them from settling on any and every object. In these countries, though sometimes troublesome, they are scarcely ever so numerous as in the warmer climates of the Continent, and even in these latter they are not often to be found such plagues as they are in Egypt; but in all these countries alike they may be seen to alight on all moist substances without distinction. It may be the expectorations of a phthisical or the ejecta of a typhoid patient that have last attracted these inquiring diptera; but, irrespective of the material they may have been investigating, their next visit may be to the moist lips or eyes of a human being. Their feet, their mouth, and the pectoral portion of their bodies will have all come in contact with the infective mass, and will all in turn be more or less cleansed of it by the moisture of the freshly visited mucous membranes. But this danger has already been known and recognised, and it seems scarcely doubtful that in Egypt ophthalmia is constantly carried to the eyes of the infant natives by such winged visitors. Dr. Grassi calls our attention to even greater danger, and this from the ejecta of the flies themselves. Every housekeeper knows how the bright surface of a mirror or the gilt moulding of a picture-frame can be covered over with the little flecks left by these flies,—no English words occur to us to translate therewith the phrase "les méfaits des mouches." The following experiences of Dr. Grassi relate to these:—At Rovellasca, between his laboratory, which is on a first floor, and his kitchen, which is on the ground floor, there lies a courtyard, with a distance between the windows of the two rooms of about ten metres. On a plate on the table of his laboratory he placed a large number of the eggs of a human parasite (Trichocephalus). After a few hours he found, on some white sheets of paper hanging in the kitchen, the well-known spots produced by the excreta of the flies, and on a microscopical examination of these spots, several eggs of the parasite were found in them. Some flies coming into the kitchen were now caught, and their intestinal tract was found quite filled with an enormous mass of fœcal matter, in which the presence of eggs of Trichocephali were detected. As it was practically impossible to keep all alimentary substances from contact with these flies, it follows that the chances of Dr. Grassi and his family being infected with Trichocephali were very great. As a matter of fact, the experiment was tried with non-segmented eggs of this worm. Another experiment was in the same direction. Dr. Grassi took the ripe segments of a *Tænia solium* (which had been in spirits of wine) and broke them up in water, so that a great number of the tapeworm's eggs remained suspended in the fluid. The flies came to the mixture, attracted by the sugar, and in about half an hour the ova of the tapeworms were to be found in their intestines and in the spots. Had these eggs been in a recent and living state, they would doubtless have been just as easily transported. To those who care to try these experiments, it [is suggested that lycopod powder mixed with sugar and water is a good material, as the lycopod spores are easily detected.

It is self-evident that if the mouth-apparatus of the fly will admit of the introduction of such objects as have been above noted, that there will be no difficulty in its admitting scores of the spores of many parasitic fungi, and above all of those belonging to the Schizomycetes, the possible cause of so much disease. Already has Dr. Grassi detected in fly excrement the spores of *Oidium lactis*, and the spores of a Botrytis, this latter taken from the bodies of silkworms dead of muscardine.

There arises, of course, the question of how far the active digestion in the intestines of the flies may not destroy the vitality of germs or spores thus taken in, but it would seem probable that in many instances the larger bodies swallowed may not serve as objects for assimilation, but may be got rid of as foreign bodies, and it will be borne in mind that the flies themselves fall victims to the growth of a parasitic fungus (*Empusa muscæ*, Cohn), which is probably taken first into their own stomachs.

Dr. Grassi promises to publish the results of his experiments in fuller detail. Judging of their interest by this abstract, they will well deserve to be followed up, and though in these countries our modern sanitary arrangements do not tend to the development of such immense swarms of flies as are so constantly to be met with in Italy, still the dangers to be apprehended from them there are possibly, though in a less degree, to be encountered here, and the investigation of the fact is easy to any one possessing a fairly average microscope and the power of catching a fly.

E. P. W.

EDINBURGH MARINE STATION

At the half-yearly meeting of the Scottish Meteorological Society held on Monday last, Mr. Murray submitted a statement on the work done by the Fisheries Committee. This included preliminary reports from the Rev. A. M. Norman on the invertebrate fauna of the Scottish fresh-water lochs; Prof. Herdman's report of his researches connected with the fisheries of Loch Fyne, and similar reports from Messrs. Hoyle and Beddard from Peterhead and Eyemouth. After reading several interesting extracts from these reports, which will shortly appear in the Society's *Journal*, he then stated that the marine station at Granton would be formally opened for scientific work about the 10th of next month by Prof. Haeckel of Jena. The floating laboratory, which has been named the *Ark*, was successfully launched on Saturday last, and it has accommodation for seven biologists. The steam yacht of thirty tons, which is to be called the *Medusa*, is to be launched on the 26th inst. at Glasgow, and will be at the station ten days thereafter. The Station will then be possessed of the three most important requisites, viz. the floating laboratory, with abundance of sea water; a steam vessel fitted with all modern appliances for sounding, dredging, and other biological and physical investigations; and lastly, a most complete library in marine biology and physics. Mr. J. T. Cunningham, B.A. Oxon., Fellow of University College, Oxford, has been appointed Naturalist in charge of the Station; Mr. Hugh Robert Mill, B.Sc., who holds a Research Fellowship in the University of Edinburgh, is to carry on physical and meteorological investigations under the superintendence of Prof. Tait; Mr. Alexander Turbyne, fisherman, Keeper; Mr. William Bell, late Royal Navy, Engineer; and it is hoped the arrangements will shortly be made that will enable a botanist and geologist to carry on systematic work at the Station. The captain of the yacht will be appointed next week.

British and foreign naturalists are invited to make use of the resources of the Station free of charge, and those who desire to do so are requested to communicate with Mr. John Murray, *Challenger* Office, Edinburgh, stating the kind of work they propose to undertake and the length of time they will probably remain. Efforts are now being made to provide living accommodation for the naturalists and others who may be working at the Station. Immediately after the meeting Mr. Murray received anonymously a donation of 100*l.* towards the further equipment of the Station. We wish every success to this undertaking, and, from the liberal spirit shown in placing at the service of scientific men the unique facilities afforded by the Station for the prosecution of inquiries of the highest practical importance, we have every confidence that the public will not be slow in seeing that the funds required for its efficient maintenance are forthcoming.

THE DEEP-SEA FISHES OF THE "TALISMAN"

Among the many wonderful animal forms collected during the voyage of the *Talisman* none surpass the fishes in interest. In the exhibition, now open at the Jardin des Plantes, Paris, of the various specimens collected during this voyage, the collection of fishes holds a chief place. During the cruises of the *Travailleur*, owing to the apparatus employed, the capture of a fish was a rare event, but by the employment of a kind of drag-net on board the *Talisman* the number both of species and individuals taken was quite surprising. Once, on July 29, in 16° 52′ N. lat. and 27° 50′ W. long., in one haul of the drag-net no less than 1031 fishes were taken from a depth of 450 metres. The chief surface fish noted in M. Filhol's very interesting papers, which are in course of publication in our French contemporary *La Nature* (to the editor of which journal we are indebted for the illustrations accompanying this notice), were the well-known shark (*Charcharias glaucus*), very common between the Senegal coast and the Cape de Verde Islands; its strange attendant fish, the so-called pilot fish (*Naucrates ductor*), and the very curious and odd-looking fish of the Sargassum Sea, *Antennarius marmoratus*. It is noted that not only were the pilot fishes never molested by the sharks but that they constantly swam around them, sometimes even they were seen placing themselves against the shark's sides between their pectoral fins. Many observations were made on the strange Antennarius, the colour of whose body so closely approaches to that of the alga amidst which it lives that it enables these fish to approach almost unseen, and so quite easily take their prey. It is not, however, altogether unworthy of remark that this prey, consisting for the most part of small crustacea and mollusks, is also of the same general shade of colour as the mass of the weed, so that the assuming of this uniform dull tinge of colour must mean a heightened danger to some of these forms of life.

The great interest, however, of the fish captures of the *Talisman* centres in the remarkable forms taken from the depths of the sea, which were both considerable in the number of individuals and in the newness of the forms. The question of whether certain fish inhabit certain zones of depths was closely considered, and is answered in the affirmative. These zones are of very considerable depth, varying from 600 to over 3650 metres, and in bringing up specimens from such areas of great pressure these suffer immensely through the phenomena caused by the rapid decompression of the air, the more remarkable effects being dilatation of the swim bladder, the eyes being squeezed out of their orbits, and the scales clothing the body are shed. In some cases even the fish's body has become smashed into pieces. Notwithstanding all these phenomena, the area in depth of the distribution of many of the deep-sea fish is very considerable. Thus *Alepocephalus rostratus* is met with between a depth of 868 and that of 3650 metres; *Scopelus maderensis*, between

FIG. 1.—*Macrurus globiceps*, Vaill.

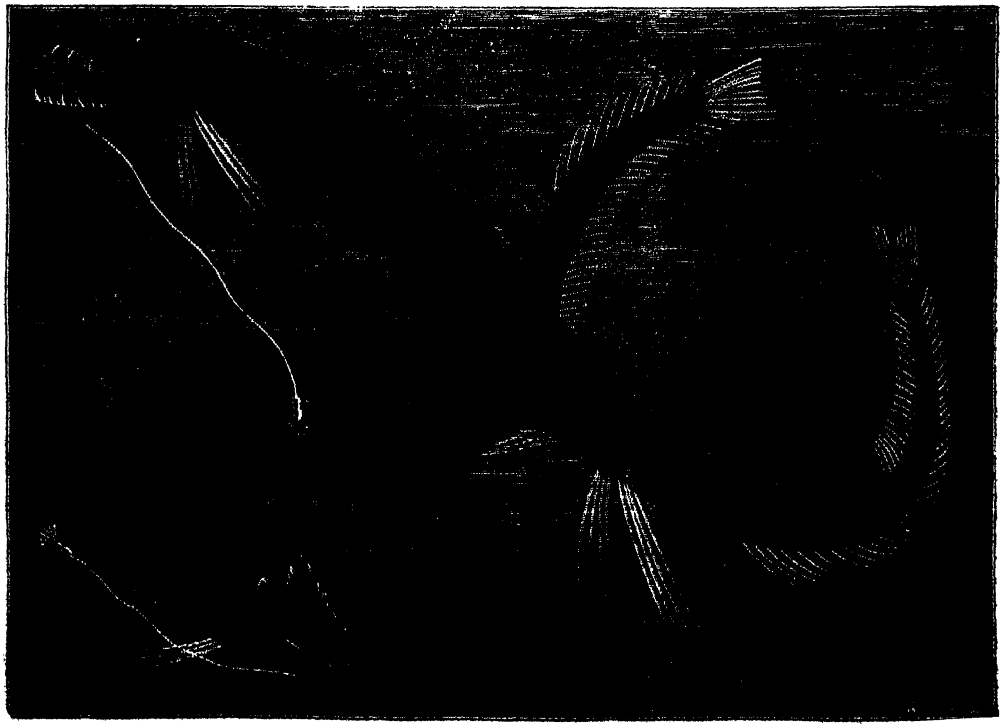

FIG. 2.—*Eustomias obscurus*, Vaill.

depths of 1090 and 3655 metres; *Lepidoderma macrops*, between 1153 and 3655 metres; and *Macrurus affinis*, between 590 and 2220 metres. The explanation would seem to be not only that the organisation of these fishes is such as enables them to support the enormous pressures at the greater depths of the ocean, but that in the course of their movements of ascent and descent they proceed very slowly so as gradually to get accustomed to the alterations in pressure. These fishes are all flesh eaters, with well developed dental systems; the absence of light prevents the growth of marine algæ in these depths, and as a general rule all the fish found below 150 metres are of necessity predatory. These deep-sea fishes, as Dr. Günther reminds us, do not belong to any peculiar order, but are chiefly modified forms of surface types; some of these modifications being no doubt very extreme, but serving as indications not only of the struggle for existence, but also of the plasticness of the forms to adapt themselves to the extreme conditions under which they live. The most remarkable phenomena in connection with their deep-sea life is doubtless the tremendous pressure which has to be borne. No one seems to doubt but that these deep-sea forms live as active a life as surface forms, indeed their very appearance seems to indicate a swiftness and energy of movement not to be surpassed by surface swimmers; and we may believe that the abyssal pressure has a great deal to do with keeping their feebly calcareous bones and delicate muscular system compact and in a condition for effective use. The placid state of the water at these depths must also be borne in mind—no storms affect them, and the extraordinary attenuation of some organs may be directly ascribed to this phenomenon. Thus *Macrurus globiceps* (Fig. 1), which forms one of a family of deep-sea Ganoids, known as living at depths of from 600 to 2200 metres, and occurring in considerable variety and great numbers over all our oceans, is a new species, described by M. L. Vaillant as found at a depth of between 1500 and 3000 metres. Its body, globular in front, will be seen to be very greatly attenuated behind.

In some of the deep-sea fishes peculiar organs, unknown for the most part among surface fishes, are to be found; these are sometimes "more or less numerous, round, showing mother-of-pearl coloured bodies embedded in the skin"; in some fish these are to be met with on the head, or near the eyes, or along the sides and back. Dr. Günther informs us that of these strange bodies the following hypotheses are possible: (1) all these different organs are accessory eyes; (2) only those having a lens-like body in their interior are sensory, those with gland-like structure are not sensory but are phosphorescent; and (3) all are producers of light. Many serious objections can be urged against the first view. Some of the fish with immense eyes have these bodies, others without eyes want them, while as to glandular bodies being sense organs this is not yet scientifically realisable. One seems therefore justified in adopting the middle hypothesis, and though on first thought it seems strange that fish with large eyes should have accessory eyes, yet Dr. Günther's supposition may be the true one—that there are light producers behind the lenses, and that these latter may act the part of "bull's-eyes" in a lantern. This form of "light organ" might constitute a very deadly trap for prey, one moment shining it might attract the curiosity of some simple fish, then extinguished the simple fish would fall an easy prey.

Long filamentous organs are to be met with showing apparently a brilliant type of phosphorescence. Among the many curious forms of development of these tactile organs to be met with, one of the most singular is that to be seen on a fish referred by M. L. Vaillant to a new genus and species found at a depth of 2700 metres, and represented in the annexed woodcut (Fig. 2). In this form (*Eustomias obscurus*) the tactile organ takes the appearance of a long filament, which is placed underneath the lower jaw, and which ends in an inflated and rayed knob-like phosphorescent mass.

Another peculiarity now well known in deep-sea fishes is the enormous development of the mouth and stomach of these fish. In the genus Melanocetus and in Chiasmodus the capacity of the stomach is such that it can contain prey twice the size of the fish which swallowed it, and perhaps the largest gape of jaws known is that of *Eurypharynx pelecanoides*. The greatest depth at which a fish was taken during the cruise of the *Talisman* was 4255 metres; the fish was *Bythytes crassus*: but it will be remembered that during the *Challenger* Expedition a specimen of *Bathyopis ferox* was taken at a depth of 5000 metres.

We hope again to have the opportunity of referring to other of the deep-sea forms taken by the *Talisman*.

ANCIENT JAPAN[1]

THIS volume contains a literal translation of the oldest Japanese book in existence, accompanied by introductions, notes, and appendices, and is beyond doubt the most learned and remarkable work which European scholarship has yet produced from Japan. Of the many important propositions on the early history of the Japanese race established by it we shall have to speak later on; but of the work itself it may be said now that the translator claims it to be "the earliest authentic connected literary product of that large division of the human race which has been variously denominated Turanian, Scythian, and Altaïc, and it even precedes by at least a century the most ancient extant literary compositions of non-Aryan India." Indeed more than this may be said; for if the claim of Accadian to be an Altaïc language be not substantiated, not only the archaic literature of Japan (to which the *Kojiki* belongs), but also its classical literature, precedes by several centuries the earliest extant documents of any other Altaïc tongue. This alone would render the work an object of much interest, but it derives additional importance from its contents as well as from the period at which it was written. It is the earliest record of the language, customs, mythology, and history of ancient Japan, and soon after the date of its compilation, as Mr. Chamberlain points out, most of the salient features of distinctive Japanese nationality were buried under a superincumbent mass of Chinese culture; it is therefore to these "Records" and one or two other ancient works that the investigator must look if he would not be misled at every step into attributing originality to modern customs and ideas which have simply been borrowed wholesale from the neighbouring continent. It appears beyond doubt that, though the work existed in tradition for some years before that period, it was not committed to writing till the year 712 of our era, and from it a picture can be formed of the Japanese of that remote epoch. It is to the sections devoted by the translator to the manners and customs of the early Japanese and their political and social ideas that we propose to direct special attention now.

As pictured, then, in these "Records," the Japanese of the mythical era had emerged from the Stone Age and from the savage state. They were acquainted with the use of iron for weapons of the chase, such as arrows, swords, knives; but there is a curious silence about ordinary implements, such as axes and saws, though they had the fire-drill, pestle and mortar, wedge, and shuttle for weaving. The art of sailing appears to have been quite unknown, but boats for use on the inland lakes are mentioned. As would naturally be expected, the population was scattered along the seashore and on the banks of the larger rivers, while house and temple building are the subjects of frequent reference. The Japanese of the present day appear to have inherited their habits of great personal cleanliness from their early forefathers, for we read more than once of bathing, and bathing-women are said to have been specially attached to an imperial infant. Among the religious practices, too, was that of lustration. A custom of the early Japanese, which is still found existing in the island of Hachijô, off the east coast, was that of a woman before childbirth erecting with her own hands a one-roomed hut without windows, into which she was expected to retire and give birth to her child. In Hachijô formerly a woman was driven out from the village under these circumstances to a hut on the mountain side, which she was not permitted to leave under any circumstances whatever before the birth of the infant; but in later times the custom was so far relaxed that the hut was allowed to be put up within the homestead. Each sovereign on his accession, also, had a new palace erected for him; but these so-called "palaces" were nothing more than ordinary wood huts. Although cave-dwellers are referred to in the "Records," it appears that at the date to which the work refers they had quite passed away. The principal food was fish and the flesh of wild animals. Rice is mentioned in such a manner that there can be no doubt of its cultivation from immemorial antiquity; *saké*, the native rice-beer, is also referred to. In dress the mythical Japanese appear to have reached a high level, and we find many garments specialised, such as skirts, trousers, girdles, veils, and hats; while it is interesting to note that although jewellery forms no part of the attire of the modern Japanese, their ancestors adorned themselves with necklaces, bracelets, and other articles formed from stones considered precious. They appear to have had a tolerably extensive acquaintance with the animal and vegetable kingdoms, but the tea-plant was evidently not yet introduced among them. Iron, which was used from time immemorial, was the only metal they knew; and their acquaintance with colours was confined to black, blue (including green), red, white, and piebald (of horses). In the Japan of to-day the different degrees of relationship are distinguished in much the same way as in Europe, except that brothers and sisters, instead of being considered as mutually related in the same manner, are divided into two categories, elder and younger, in accordance with the Chinese usage. But the ancient Japanese had a complicated system of nomenclature, which appears to have perplexed native commentators themselves, the foundation of which was a subordination of the younger to the elder born, modified by a subordination of the females to the males. A distinction also appears to have been drawn between the chief and secondary wives, and the wife is constantly spoken of as "younger sister." It appears that consanguinity, however close, was no bar to marriage, as we hear of unions with half-sisters, step-mothers, and aunts. When the Chinese ethical code was imported, these gradually disappeared, but not, it is said, without political troubles. Exogamy did not exist, and there appear to have been no artificial impediments in the way of marriage. On death the hut of the deceased was abandoned; and there was a tradition of an earlier custom of burying alive some of the retainers in the neighbourhood of a royal tomb. This is the only trace of human sacrifice to be found in the records of the Japanese race, and there is also a total absence of any trace of slavery. They were unacquainted with any of the arts by which their descendants are best known; they had neither tea, fans, lacquer, or porcelain. They knew nothing of vehicles, money, or the computation of time. They were ignorant of writing, and of course had no books.

---

[1] *Transactions of the Asiatic Society of Japan*, vol. x. Supplement. Translation of the "Kojiki" or "Records of Ancient Matters." By Basil Hall Chamberlain. Yokohama, 1883.

This brings us to another interesting part of the subject, viz. the antiquity claimed by native writers for their monarchy, and the reliability of their early chronology. There is no break in their history between the fabulous and the real, and the continuity of their mythology and history is a tenet of the native commentators. They hold the age of the gods to have ceased and that of their human kings to have commenced at an era corresponding with 660 B.C., and the then ruler of Japan is claimed as the first of an unbroken line of sovereigns extending down to the Mikado of to-day. All the earlier European writers on Japan have accepted 660 B.C. as the commencement of historical Japan; the Mikado himself has claimed this long descent; frequently in official publications we find this accepted as the Japanese year 1.[1] In native chronologies we find the names of a series of Emperors who have reigned from that time. This antiquity, though as yesterday compared to that of the Chinese, is highly respectable if correct, but unfortunately there is nothing whatever to support it. For, in the words of Mr. Chamberlain, this era, this accession of the first emperor, "is confidently placed thirteen or fourteen centuries before the first history which records it was written, nine centuries before (at the earliest computation) the art of writing was introduced into the country, and on the sole authority of books teeming with miraculous legends." Another scholar, who made the chronology of Japan a special study, and who has published a valuable monograph on that subject, the late Mr. Bramsen, does not scruple to say that "the whole system of fictitious dates applied in the first histories of Japan is one of the greatest literary frauds ever perpetrated, from which we may infer how little trust can be placed in the early Japanese historical works." In short it appears that, for all historical purposes, Japan is a newer country than England by several centuries. Another proposition for which native scholars have always strenuously contended will also have to be abandoned. It is usual to say that early Japanese civilisation was a purely indigenous product, and that even a certain form of writing called "letters of the Divine Age" existed long before there was any contact with China. European scholars have always been doubtful about this divine alphabet, and it is now beyond doubt that they are the invention, or adaptation from Corea, of a later age; but it is also certain from these "Records" that, "at the very earliest period to which the twilight of legend stretches back, Chinese influence had already begun to make itself felt in these islands, communicating to the inhabitants both implements and ideas." It would occupy too much space here to exhibit the evidences of this. One must suffice. "Curved jewels," *magatama* as they are called, figure largely in the Japanese mythology as ornaments of the early Japanese. These are generally made of jade, or a jade-like stone, and Prof. Milne shows that no such mineral has ever been discovered in Japan. Further proofs of Chinese influence are found in the nature of the myths, the existence of the intoxicant *saké*, the language, &c. The religion of the early Japanese appears to have been merely "a bundle of miscellaneous superstitions," not an organised system. We find no body of dogmas, or code of morals, authoritatively enforced by a sacred book. The gods of their mythology were of course the object of worship; conciliatory offerings of a miscellaneous kind were made to them. Purification by water is the sacred rite of which we hear most. Trial by hot water also existed; compacts, too, resembling our oaths, were entered into with a god. Priests are mentioned, but the impression conveyed is that in early times they did not exist as a separate class. In his "History of Civilisation," Buckle attributes some of the superstition of the inhabitants of Spain and Italy to the occurrence of earthquakes and other volcanic phenomena; but in Japan there is "no testimony to any effect produced on the imagination by the earthquakes from which the Japanese islanders suffer such constant alarms." Nor is there any tradition of a deluge, which is the more remarkable as Noah's deluge has recently been claimed as a myth of Altaïc origin. "Yet here we have the oldest of *undoubtedly* Altaïc nations without any legend of the kind." There is no such thing as star-worship, nor are there any fancies such as the imagination of other races has connected with them.

---

[1] In an interview with the Japanese Minister in London, published in the *Pall Mall Gazette* of February 26, His Excellency is reported to have attributed the ardent attachment of the Japanese to his country to two facts, one that Japan has been unconquered for 2500 years, the other that for the same period it has been governed by the same dynasty. "No other State can point to such a record," said Mr. Mori, "and it is but natural that we should feel a pride in our country," &c., &c. The Minister, as will be seen, would have to deduct nearly fifteen hundred years from his major premiss before he touched the solid ground of fact.

Much, very much, more might be written on this deeply interesting volume. Although more than a thousand years of Japanese history must be cut away, "the Japanese mythology is the oldest existing product of the Altaïc mind." When to this are added the facts that here we have the *ipsissima verba* (for the translation is literal) of the Japanese compiler of eleven centuries ago, that it is the first complete translation of an archaic Japanese work, that it is the first work in which an attempt is boldly made to separate Japanese history from myths, and to fix the commencement of the historical era, and that it contains abundant illustrations of the manner and ideas of this primitive race as recorded by themselves, we have said enough to attract a wide circle of students. Besides the very valuable preliminary discussions, the text is abundantly annotated by the translator, who has for this purpose made use of the works of the numerous native commentators and editors of the work.

NOTES

THE gold and silver Rumford Medals have been presented by the American Academy of Arts and Sciences to Prof. Rowland of Baltimore for his researches on heat and light.

WE are sure that every field-naturalist and working geologist will be grateful to Prof. Bryce for introducing into Parliament his Bill "to secure access to mountains and moorlands in Scotland." Since the substitution of deer for sheep and cattle on the Scottish moors and mountains, great restrictions have been placed on access to these favourite haunts of the lover of nature, so that in some districts the tourist and collector are faced by the trespassers' board in all directions. We have no wish whatever to infringe the rights of private property, but surely the great landed proprietors of Scotland can afford to be generous to those whose noblest game is a rare butterfly, an Alpine flower, or a chip from the rocky escarpment of a hill. Already some of the most valuable hunting grounds of science have been shut up, and in the present condition of things we may soon hear of such natural phenomena as the Parallel Roads of Glenroy being rendered inaccessible, and the traveller confined to the dusty highways. The Bill embodies every possible precaution against the abuse of the access craved, and we strongly advise the members of the many natural history societies and field clubs all over the country to use every legitimate means to obtain for it Parliamentary sanction. We need scarcely point out how greatly interested in the provisions of the Bill are all artists and the great army of tourists.

SIR J. H. LEFROY, we are glad to learn, has accepted the presidency of the Geographical Section at the Montreal meeting of the British Association.

SIGNOR QUINTINO SELLA, whose death on March 15 is announced, was president of the R. Accademia dei Lincei.

WE regret to learn of the death of Dr. Behm, the eminent geographer of Gotha, the editor of the *Geographische Mittheilungen*, the *Geographisches Jahrbuch*, and, along with Prof. Wagner, of the well-known "Bevölkerung der Erde."

WE are glad to notice the hearty manner in which the *Times* recognises the necessity for scientific education among all classes. In an excellent leading article on the Technical Institute, it maintains that the old rule-of-thumb methods will no longer suffice, and that science and organised knowledge are bound to invade industry as they have already invaded almost every branch of human endeavour.

THERE can be no doubt of the great scientific value of a bathymetrical survey of the Scottish lochs, about which Lord Balfour of Burleigh asked a question in the House of Lords on Tuesday, and concerning which there has been a correspondence between the Royal Society of Edinburgh and the Government. No one wishes to retard the completion of the English Survey for the purpose of this special undertaking; but this is not necessary, as, without going to any great expense, Government might easily employ other existing agencies in carrying out the work.

SIR RICHARD OWEN was on Saturday presented with a framed and illuminated address by the Geologists' Association, on the occasion of his retirement from the post of Director-General of the Natural History Department of the British Museum. A large audience assembled in the lecture-hall at South Kensington to witness the ceremony. The address was presented by Dr. Henry Hicks, F.G.S., who said that in his retirement Sir Richard Owen would take with him the good wishes and warm interest of all who appreciated his scientific work, and his great personal kindness in communicating its results to others. Sir Richard Owen, in reply, said that, of all the recognitions which he had recently received of his years of service in the State museums, none would be more valued by him than that testimonial from his fellow workers in those walks of natural science in which he had been for over half a century more or less occupied. He would value the address amongst the rarest of his treasures, and he trusted that its contemplation would stimulate his sons and grandsons, particularly the latter, to walk in their grandfather's footsteps. He returned his grateful thanks, and wished the members and all present every happiness.

IT is intended at the forthcoming celebration of the tercentenary of Edinburgh University to confer the degree of LL.D. on sixty-nine gentlemen, among whom are Prof. Cayley, Mr. Archibald Geikie, Prof. Helmholtz, Sir John Lubbock, Sir Henry Maine, and Prof. Haeckel.

AT its last private sitting the Academy of Sciences of Paris debated the question of the sale of the Observatory grounds in order to find the funds required for the erection of a *succursale* in the vicinity of Paris. The matter was postponed for fifteen days, after a long and interesting discussion. The majority of the Academy is of opinion that it would be desirable to grant the credits required for the erection of a new establishment; but many members are against the sale of any parcel of ground. They contend that the present position of the Observatory must not be deteriorated under any pretence whatever. MM. Wolf and Janssen delivered addresses defending the *statu quo*.

THE convention for the protection of cables has been signed in Paris by the plenipotentiaries of the following nations:—Germany, Argentine Republic, Austria-Hungary, Belgium, Brazil, Costa Rica, Denmark, San Domingo, Spain, United States of America, United States of Colombia, France, Great Britain, Greece, Guatemala, Italy, Netherlands, Persia, Portugal, Roumania, Salvador, Sweden, Norway, Turkey, and Uruguay. The protocol has been left open for acceptation by the other countries. This is the final step towards the accomplishment of the work originated at the Congress of Electricians in Paris.

THE exhibition of the submarine objects at the Museum of Paris was closed on March 15, but will be opened on a larger scale on the occasion of the session of the Délégués des Sociétés Savantes, which will take place as usual in the Easter holidays.

THE number of members of the French Alpine Club is yearly increasing, and the financial position of the Society is very prosperous indeed. The general sitting of the Paris section took place on March 10. M. Janssen delivered an address on the sun. The discourse was illustrated by projections exhibiting all the phenomena connected with the eclipse of 1883, as observed by him on Caroline Island. It is the first time these pictures have been presented to the public, and they have been very successful.

AMONGST the latest publications in the domain of electricity we notice "Das Elektrische Potential," by A. Serpieri; "Die Elektrische Kraftübertragung," by Jos. Popper; and "Die Atmosphärische Elecktricität," by Prof. Palmieri. Hartleben of Vienna is the publisher of all the works mentioned.

M. PERRIER presented on Monday to the Academy of Sciences of Paris six sheets of the map of Tunisia, which the French military geographers are executing on the scale of 1 : 100,000. The mapping of the whole country from Algeria to the Tripolitan territory will be published in a few weeks. The publication, which will contain twenty-one sheets, will be completed this year. This great work will have required only four years to accomplish. The maps are lithographed, and will be ultimately engraved.

WE have already mentioned a publication issued by the Direction of Schools at Tiflis, in which the teachers of the Caucasus have the opportunity of publishing descriptions of the interesting but little known districts where they are compelled to stay, often deprived of any intercourse with the civilised world. We have now received the third volume of this publication, which contains several valuable papers. The chief of them is the first part of an interesting memoir, by M. Lavroff, on Ossetia and Ossetians, with a map. In this first part the author describes the country, its orography and hydrography, climate, flora, and fauna, leaving the purely ethnographical part for a second memoir. M. Gadovsky contributes valuable notes on the newly-annexed province of Kars: its geography, population, tenure of land, and the occupations of the inhabitants. The second part of this volume is devoted to the rich folk-lore of the Cossacks, Tartars, and Circassians, in which the ethnographer will find rich materials.

IN the "Untersuchungen aus dem botanischen Institut zu Tübingen" F. Schwarz discusses the structure and functions of the root-hairs of flowering plants. He finds that in maize the surface of a hairy root is 5·5 times greater than that of a root not covered with hairs; in the pea 12·4 times greater. The intimate contact of the root-hairs with particles of soil is effected by the conversion into mucilage of the outermost layer of the wall of the hair; the inner layer of the membrane is stained blue, the outer layer yellowish brown by zinc chloriodide. The greatest development of root-hairs accompanies the greatest energy of growth of the root. A medium degree of moisture is most favourable for their formation; with plants growing in water they are often altogether suppressed. Nutation promotes their production, especially at the point of curvature. Contact with dry solid bodies has no effect on their production. They are always formed in acropetal succession. They have not in most cases the same form in the same species, being considerably affected by conditions of growth. In many plants the root-hairs are branched.

THE annual prize of 25,000 francs, instituted by the King of the Belgians, will for 1885 be granted to the author of the best work on the means of popularising the study of geography and developing it in the different educational establishments. Foreigners may compete equally with Belgians. The works of the competitors must be sent to the Minister of the Interior before January 1, 1885.

WE understand that Messrs. Sanderson and Co. are about to issue a small volume on tall-chimney climbing and lightning-rod testing.

CAPT. A. E. BARLOW, Commander of the P. and O. steamer *Paramatta*, writes as follows to the *Times*:—"An unusual phenomenon was observed during the recent voyage of the P. and O. steamer *Paramatta* to Sydney, New South Wales, which may be of interest to some of your readers. On December 11 and the following day, about lat. 10° S. and long. 92° E., the surface of the sea was covered with lava and pumice, some being as fine as sawdust and of a yellowish colour, but several patches of large extent were passed through with masses of pumice from the size of a cocoanut to that of a hogshead; this extended over 5° of latitude, and probably much more of longitude, as the densest patches all ran in an easterly and westerly direction. The largest specimen of pumice which I picked up was about ten inches in diameter, and appeared only to have been a few days in the water, as there was no deposit on it. This would lead to the conclusion that a submarine upheaval must have taken place long after the great eruption of Krakatoa, in the Strait of Sunda, our nearest approach to which was over 800 miles. On the homeward voyage on February 1 the same phenomenon was observed, but in a much less degree, in lat. 4° S., long. 88° E., showing that the mass had drifted to the west-north-west about 500 miles in six weeks."

UNDER the title of "New Commercial Plants and Drugs, No. 7," Mr. Thos. Christy has recently issued a continuation of his notes on useful plants which come before him in the course of commerce. The demand for economic plants of every description has of late years considerably increased amongst planters not only in our own colonies but also in other parts of the world in consequence of the general desire for the greater dissemination of staple articles of cultivation that are acknowledged sources of revenue, and also the introduction of new staples where from long cultivation or the ravages of disease the older and better known plants have ceased to be remunerative. The circulation amongst planters and colonists generally of such books as this is calculated to do a great deal of good even if it were only to let them know of the existence and properties of certain plants, for while there are many that have a knowledge of useful plants, there are also others who are content to go on growing the same crops that they have always been accustomed to, and though we may not expect full details of the uses of the plants enumerated, nor botanical descriptions of the plants themselves, sufficient is given in all cases to put the reader on the right track for further information. In some of the subjects, however, very voluminous abstracts are given from some of the best journals in which special articles have appeared. It will suffice to say that the present number of "New Commercial Plants and Drugs" contains very interesting articles on the Cacao (*Theobroma cacao*) and its preparation, the Siam benzoin tree, pepper and nutmeg cultivation, Liberian coffee, and numerous other economic plants of very varied uses.

THE Eleventh Annual Report of the National Health Society shows that the Society has carried on its work during the past year in a most practical manner. Hundreds of lectures on sanitary subjects have been delivered, not only all over the poorer parts of London, but in provincial towns, to large audiences of working men and women, classes of girls, district visitors, and others engaged in work amongst the poor. The Society is much encouraged by the practical results of the lectures on keeping the house healthy, rearing of infants, prevention of the spread of infectious diseases, preparation of food and kindred subjects, knowledge of which is so much needed in our crowded neighbourhoods. The questions of poisonous dyes in domestic fabrics, of smoke abatement, of dust collection, and the prevention of cholera have been investigated and reported upon by special committees appointed for the purpose. The Health Exhibition held by the Society last June was commented upon, and the Secretary stated that more than 100 members had joined the Society during the past year.

THE great interest manifested in the International Health Exhibition is shown by the fact that application has been made, by British exhibitors alone, for space five times as great as that actually at the disposal of the Executive Council. Information has recently been received that the French Government has appointed a Commission; and Italy—owing in a great measure to the individual exertions of a member of the Executive Council—will, it is hoped, take an active part. A portion of the Educational Section of the Exhibition will be located in the Central Institute of the City of London Technical Guilds, the handsome building in course of erection in the Exhibition Road, which has been kindly placed at the disposal of the Executive Council. The Royal Albert Hall with its musical attractions will now form an integral part of the Exhibition; and the Aquarium, a popular feature of the late Fisheries Exhibition, will continue as an important part of the Health Exhibition. In the Dress Section the most popular exhibit will probably prove to be a series which is being prepared illustrative of English dress of all ranks of life, from the time of the Conquest to George IV. An International Congress on Education will be held, and conferences and lectures will conduce to the elucidation of the subjects of the Exhibition. It is also proposed to have a library and reading-room in connection with the Exhibition, which will be open to all visitors, under proper regulations, while the Exhibition is open. The library will consist of books on various subjects comprised in the classification of the Exhibition, both English and foreign. Application has been addressed to foreign and colonial Governments, asking them for copies of reports and statistics on sanitary and educational matters, and a circular is being sent out to authors and publishers requesting them to contribute works of a similar character.

AT a meeting of the Society of Telegraph Engineers held on the 13th inst., a short paper, "Notes on a Train Lighting Experiment," was read by Mr. W. H. Massey of Twyford, who strongly advocated the use of a small engine and dynamo-machine placed on each locomotive for working incandescent lamps, by means of which railway carriages would be much better lighted than at present for less than is paid for gas. An interesting discussion took place, and the meeting was adjourned to the 27th inst., when Mr. Massey is expected to reply.

THE March number of *Petermann's Mittheilungen* contains a letter from Dr. Junker dated Sami, 6½° N. lat., 25° E. long., December 8, 1882, in which he gives a brief statement of the results of his journeys in the Upper Welle and Bomokandi, with notes on the various tribes that inhabit the region. Dr. Junker did some further exploring work to the south-west of his station in 1883; but his numerous cases of collections have been lost in a fire which consumed the building where they were stored.

THE additions to the Zoological Society's Gardens during the past week include a Squirrel Monkey (*Chrysothrix sciurea*) from Guiana, presented by Mrs. Dundas; a Leopard (*Felis pardus*) from Africa, presented by Mr. S. Cresswell; a West Indian Rail (*Aramides cayennensis*) from South America, presented by Mrs. Edward Hairby; a Kestrel (*Tinnunculus alaudarius*), British, presented by Mr. F. E. Baum; a Common Viper (*Vipera berus*), British, presented by Mr. W. H. B. Pain; two Mute Swans (*Cygnus olor*), European, four Redshanks (*Totanus calidris*), British, purchased.

PHYSICAL NOTES

PROF. J. H. POYNTING has published in the *Proceedings of the Birmingham Philosophical Society* a note on a method of calculating the velocity of propagation of waves of longitudinal and transverse disturbances by the rate of transfer of energy. The paper discusses the two cases by the method originally propounded by Lord Rayleigh.

WE have received from Madame Plateau copies of three posthumous memoirs by her late husband, the lamented Prof. J. Plateau. Their titles are: "Quelques Expériences sur les lames liquides minces (deuxième note)"; "Sur l'Observations des Mouvements très rapides"; and "Bibliographie analytique des Principaux Phénomènes subjectifs de la Vision." The first of these *brochures* relates to the preservation of the glyceric fluid, to certain appearances in very thin films, and on the constitution of foam. In the second the writer contrasts four methods: the rotating mirror, the stroboscopic method, the intermittent illumination by electric sparks, and the process of multiple instantaneous photography. The third is a supplement for the years 1880–1882 to the well-known bibliography compiled by the deceased *savant*.

WE have also received the first instalment of vol. i. of the *Bulletin de la Société Internationale des Électriciens* (January 1, 1884), containing the laws of the new society, a list of founders, and one of the members already enrolled, now numbering about 1200, of whom only a few are Englishmen.

PROF. QUINCKE has lately read before the Berlin Academy a paper on the measurement of magnetic forces by hydrostatic pressure. He has examined the magnetic inductive capacity, or, as he calls it, the "di-magnetic constant" of a number of liquids, by observing their rise in an open-air manometer when subjected to a field of powerful, but known, intensity, the observed change of pressure being proportional to the square of the intensity of the field and to the difference between the magnetic inductive capacity of the substance and that of the air. A number of tables are given, with copious numerical data. The di-magnetic constant of such liquids as ether, alcohol, turpentine, nitric acid, bisulphide of carbon, glycerine, water, &c., showed small negative values; whilst the values were positive, and in many cases much more considerable for solutions of chloride of iron, chloride of manganese, sulphate of nickel, and of cobalt, and for solutions of magnetic salts in general.

A SLIGHT mistake occurred in a note on p. 276, in which Bunsen's estimation that in three years 5·135 cubic centimetres of carbonic dioxide was absorbed by a square metre of glass was stated as the absorption of one square centimetre.

THE CHEMICAL WORK OF WÖHLER[1]

IT seems fitting that these walls, which have vibrated in sympathy with that brilliant eulogy of Liebig which Prof. Hofmann pronounced some nine years ago should hear something of him whose life-long association with Liebig has exercised an undying influence on the development of scientific thought. The names of Frederick Wöhler and Justus Liebig will be linked together throughout all time. The work which they did in common makes an epoch in the history of chemistry. No truer indication of the singular strength and beauty of their relations could be given than is contained in a letter from Liebig to Wöhler, written on the last day of the year 1871. "I cannot let the year pass away," writes Liebig to Wöhler, "without giving thee one more sign of my existence, and again expressing my heartfelt wishes for thy welfare and the welfare of those that are dear to thee. We shall not for long be able to send each other New-Years' greetings, yet, when we are dead and mouldering, the ties which have united us in life will still hold us together in the memory of men as a not too frequent example of faithful workers who, without envy or jealousy, have zealously laboured in the same field, linked together in the closest friendship."

---

[1] A lecture delivered at the Royal Institution on Friday evening, February 15, 1884, by Prof. Thorpe, F.R.S.

And yet, bound as they were in the ties of a friendship the purity and warmth of which were but characteristic of the men, and although each influenced the other's walk and work in life to a degree which it is almost impossible to gauge, such was the strength of their individuality and such the force of their genius that, without a doubt, either would have been a great figure in the history of science if the other had not existed.

The conditions under which minds of the highest type arise and develop have on more than one occasion engaged the attention of this audience. Although there were circumstances in Wöhler's surroundings which in early life may have influenced the bent of his mind, it is not easy to see whence sprang that passionate love of nature which was so strikingly exhibited in the man. His father, August Anton Wöhler, was formerly an equerry in the service of the Elector William II. of Hesse; he afterwards came to live at Frankfort, and became a leading citizen of that town. His wise liberality and public spirit are commemorated in the Wöhler Foundation and Wöhler School, institutions known to every Frankforter. His mother was connected by marriage with the minister of Eschersheim, a village near Frankfort, and it was in the minister's house that Frederick Wöhler first saw the light, on July 31, 1800. Even in early youth his passion for experimenting and collecting manifested itself, to the neglect not unfrequently of the lessons of the gymnasium; indeed it would appear that during his school career Wöhler was not characterised by either special diligence or knowledge. The bent of his mind towards natural science was directed by Dr. Buch, a retired physician who had devoted himself to the study of chemistry and physics; and it was in the kitchen of his patron's house that he prepared the then newly-discovered element selenium, of which an account was afterwards sent by Dr. Buch to Gilbert's *Annalen*, with Wöhler's name at the head of it. The elder Wöhler appears to have been a man of considerable artistic feeling, and under his direction the son was taught sketching and otherwise educated in that perception of natural beauty which comes out so strikingly in his after life; and he was encouraged to make himself familiar with the literature which the genius of Schiller and Goethe has ennobled. He had, moreover, to thank his father for that love of physical exercise and passion for outdoor life which reacted so beneficially upon his development, and contributed so largely to the uniformly good health which he enjoyed to within a few days of his death. Mainly, it would seem, because his father had been there before him, Wöhler, in his twentieth year, entered the University of Marburg. It was his own and the family's wish that he should study medicine, and he accordingly put his name down for the lectures of Bünger on Anatomy, Gerling on Physics and Mathematics, and Wenderoth on Botany. He found time also to attend Ullmann's classes on Mineralogy; and although he declined to hear Wurzer's lectures on Chemistry, he by no means neglected that science. He transformed his living-room into a laboratory, and to the great, and perhaps not undeserved, disgust of his landlady, occupied himself with the preparation and study of the properties of prussic acid, thiocyanic acid, and other cyanogen compounds. He discovered at that time, without knowing that Sir Humphry Davy had anticipated him, the beautifully crystalline but intensely poisonous iodide of cyanogen; and in the little paper on cyanogen compounds which his good friend Dr. Buch communicated to Gilbert's *Annalen* for him we have the first description of the remarkable behaviour of mercuric thiocyanate on heating, which has astonished and amused us in the so-called "Pharaoh's Serpent."

Wöhler, attracted by the fame of Leopold Gmelin, left Marburg for Heidelberg. His main idea was to hear the lectures of that distinguished man, but Gmelin declared this to be unnecessary and a waste of time. Wöhler in fact never attended any systematic lectures on chemistry; he had access, however, to the old cloisters which at that time constituted the Heidelberg laboratory, and there began the work on cyanic acid which some four or five years later was destined to culminate in the great discovery of the synthesis of urea. His association, at this time, with Tiedemann, who was engaged in physiological chemical investigation with Gmelin, had also considerable influence in determining the direction of much of his future work, whilst its immediate effect was the publication in Tiedemann's *Zeitschrift für Physiologie* of the results of an inquiry into the transformation experienced by various substances, organic and inorganic, in their passage through the organism. In 1823 Wöhler obtained his degree, when, on Gmelin's advice, he determined to follow his master's example, and abandon medicine for chemistry. At that time the great Swedish chemist Berzelius was at the summit of his fame: his masterly analytical skill, no less than his labours towards the development of chemical theory, had made him supreme among the chemists of Europe, and to Stockholm therefore, Wöhler, acting on the advice of Gmelin, determined to go. He was warmly welcomed by Berzelius, on whom his communications to Gilbert's *Annalen* had made a favourable impression, and with the offer of a place in the private laboratory of the illustrious Swede, Wöhler set out for the Scandinavian capital. Of his experiences with Berzelius his pupil has left us a delightful account. It is valuable not only as a charming character-sketch of the great teacher, but also from the side-light it throws upon the nature and disposition of Wöhler and himself. It is interesting, too, as an account of the mode in which Berzelius worked and taught, and as showing how the typical laboratory of that time contrasted with the temples which have since been reared by the disciples of Hermes.

"With a beating heart," says Wöhler, "I stood before Berzelius's door and rang the bell. It was opened by a well-clad, portly, vigorous-looking man. It was Berzelius himself. . . . As he led me into his laboratory I was as in a dream, doubting if I could really be in the classical place which was the object of my aspirations. . . . I was at that time the only one in the laboratory: before me were Mitscherlich and Heinrich and Gustav Rose: after me came Magnus. The laboratory consisted of two ordinary rooms furnished in the simplest possible way; there were no furnaces nor draught places; neither gas nor water service. In one of the rooms were two common deal tables; on one of these worked Berzelius, the other was intended for me. On the walls were a few cupboards for the reagents; in the middle was a mercury trough, whilst the glass-blower's lamp stood on the hearth. In addition was a sink, consisting of an earthenware cistern and tap, standing over a wooden tub, where the despotic Anna, the cook, had daily to clean the apparatus. In the other room were the balances, and some cupboards containing instruments: close to was a small workshop fitted with a lathe. In the neighbouring kitchen, in which Anna prepared the meals, was a small but seldom-used furnace and the never-cool sand-bath."

Wöhler's first exercises were in mineral analysis, in order that he might become acquainted with Berzelius's special methods and manipulative procedure. At that time he prepared, among other products, some new compounds of tungsten, notably the beautifully crystallised monoxychloride and the tungsten sodium-bronze ($Na_2W_3O_9$), which some twenty-five years later was introduced into the arts as a bronze powder. It was, however, with his investigation on cyanic acid that both he and Berzelius were mainly interested. In Berzelius's opinion the existence of this body was of importance from the light it seemed to him to throw upon the validity of the new chlorine theory. "I was surprised," says Wöhler, "to hear him, the hitherto steadfast upholder of the old notion, now always talk of *chlorine* instead of oxidised hydrochloric acid. Once, when Anna, in cleaning some vessel, remarked that it smelt strongly of oxymuriatic acid, Berzelius said, 'Hearest thou, Anna, thou must no longer speak of oxidised muriatic acid; thou must call it *chlorine*: that is better.'" With what feelings would Davy have listened to that colloquy between the Swedish philosopher and his factotum! Chlorine was discovered by Berzelius's illustrious countryman, Scheele, but its true nature was first demonstrated in the laboratory of the Royal Institution.

A couple of months were now spent in travel with Berzelius, in company with the two Brongniarts, Alexander the geologist and Adolph the botanist, during which they explored the greater portion of the geologically interesting parts of Southern Sweden and Norway, and collected rich stores of those wonderful minerals for which Scandinavia is famous. Scandinavia is no less famous for salmon and trout, and it was on his return from a fishing expedition in Norway that the travellers met with Davy, who, as readers of "Salmonia" know, handled his rod with great zest and zeal. Wöhler, who as a boy had learned the story from his friend Dr. Buch, of the isolation of the alkaline metals by Davy, and who, aided by his little sister, whose business it was to blow the bellows, had toiled, not unsuccessfully, to make potassium in the kitchen fire, was presented to the famous chemist.

On the return to Stockholm, Wöhler took leave of Berzelius and prepared to return to Germany. Of his association with this great man Wöhler had ever the kindliest memories. Although the outcome of much of his subsequent work, or at least much of that which he did in concert with Liebig, might be said to bring him in occasional conflict with Berzelius's cherished convictions on points of chemical theory, the master and pupil remained to the end bound together in the warmest friendship. Scarcely a month passed without an exchange of letters. Those from Berzelius were religiously preserved by Wöhler, who, after his master's death in 1848, presented them, to the extent of some hundreds, to the Swedish Academy of Sciences. We are told that in the later letters the "trauliche Du" appears in place of the more formal "Sie," and that "*Totus et tantus tuus*" is a not unfrequent signature.

Wöhler's gratitude and almost filial reverence are seen in the circumstance that even in the full tide of his vigour, and when time was doubly precious to him, he continued to charge himself with the yearly translation of Berzelius's *Jahresbericht* into German. It is easy to trace the influence of Wöhler's contact with Berzelius in his after work. To begin with, the men had much in common: their sympathies were as catholic as science itself, and they ranged at will over every department of chemical knowledge. Wöhler attacked the composition of a mineral with as much ardour as he did the preparation of an organic compound: to him the problems of physiological chemistry were not more important than the isolation of a rare earth or the perfection of some analytical method. The artificial barriers and fancied lines of demarcation in the science seemed to have no existence for Wöhler: indeed, it was the crowning triumph of his work to break down such barriers almost at a stroke, and to demonstrate the irrationality of these attempts to draw distinctions regardless of differences. The history of chemistry is indeed like that of the nation which has done so much to advance it: its unity to-day is as complete as that of Germany itself.

Wöhler was now to embark on his academic career, and under the advice of Gmelin and Tiedemann he prepared to settle in Heidelberg as *privat docent*. But to Heidelberg he was not destined to go. His work had already been gauged by such men as Leopold von Buch, Poggendorff, and Mitscherlich, and these, without his knowledge, had strongly recommended his election to the vacant teachership of chemistry in the newly-founded Trade School in Berlin. Berzelius advised him to accept the post, and to Berlin accordingly Wöhler went in 1825. He was now in possession of a laboratory which he could call his own, and he had to justify that possession by the use which he made of it. One of the problems which he now attacked was the isolation of *aluminium*, a metallic radicle more abundant and more widely diffused than any other of the fifty bodies we are accustomed to designate as metals. He succeeded in obtaining the body by the method which, nearly twenty years after, was worked out on a manufacturing scale by Sainte-Claire Deville. Deville caused the first bar of the metal thus procured to be struck as a medal, with the image of Napoleon III. on the one side, and the name Wöhler with the date 1827 on the other, and some time after the Emperor simultaneously designated the two chemists officers of the Legion of Honour.

But of the twenty-two memoirs and papers which Poggendorff's *Annalen* exhibits as the outcome of Wöhler's activity and power of work during his six years' stay in Berlin, that on the artificial formation of urea is by far the most important. No single chemical discovery of this century has exercised so great an influence on the development of scientific thought, and the words with which Wöhler closes his account of the molecular transformation of ammonium cyanate—a body of purely inorganic origin—into urea—a substance which of all that might be named is the most characteristic of the action of the so-called vital force—are full of meaning: "This unexpected result," he says, "is a remarkable fact, in so far as it presents an example of the artificial formation of an organic body, and indeed one of animal origin, out of inorganic materials." "The synthesis of urea," says Prof. Hofmann in his account of Wöhler's life-work, "was an epoch-making discovery in the real sense of that word. With it was opened out a new domain of investigation upon which the chemist instantly seized. The present generation, which is constantly gathering such rich harvests from the territory won for it by Wöhler, can only with difficulty transport itself back to that remote period in which the creation of an organic compound within the body of a plant or an animal appeared to be conditioned in some mysterious way by the vital force, and they can hardly realise the impresssion which the building up of urea from its elements then made upon men's minds. And yet it cannot be said that chemists were unprepared for this discovery. Men were long ago in the habit of perceiving that bodies of mineral origin were but the types of those met with in the animal and vegetable organism—in both classes there were the same differences in states of aggregation, the same mutual transformations, the same crystalline forms, the same constancy in combining relations, the same conjunction of the elements according to the weights of their atoms or in multiples of these, in both classes the appearance of the same species of compounds. But all attempts to build up organic compounds from their elements, as this for a large number of mineral substances had already been done, had hitherto been futile. The chemists of that period had nevertheless the presentiment that even this barrier must fall, and one can conceive the feeling of joy with which the gospel of a new unified chemistry was hailed by the intellect of that time. With the revolution thus effected in the ideas of men, science was directed into new paths and unto new goals. Who does not know with what zeal these paths have been trodden, and how many of these goals have been reached!"

But if at this time Wöhler made a great discovery for the world, he also, at about the same time, made a great discovery for himself: he discovered Liebig. The manner in which the two men were brought together is worth mentioning, for it would seem almost as if the hand of destiny was in it. At about the time that Wöhler was at Stockholm thinking and working on cyanic acid, Liebig was at Paris engaged with Gay Lussac on the study of the metallic compounds of an acid which, on account of their formidable explosive properties, has received the not inappropriate name of fulminic acid. Liebig, with rare skill and courage, had determined the composition of that acid, and had been rewarded by the honour of a waltz with Gay Lussac, it being the habit of that distinguished philosopher, as he explained to the astonished young German doctor, to express his ecstasy on the occasion of a new discovery in the poetry of motion. But the most extraordinary result of that investigation was to show that the terribly explosive fulminic acid and the innocuous cyanic acid were of identical composition. The idea that bodies could exist of identical ultimate composition—that is composed of the same elements united in the same proportion and yet possess essentially different properties, in other words be absolutely dissimilar things, was new to science; Berzelius, the great chemical lawgiver of his time, scouted the notion as absurd; to him it was impossible to conceive that identity in elementary composition should not result in identity of properties. And yet, later on, Berzelius was forced to realise the fact by the discovery by his pupil Wöhler of the molecular transformation of ammonium cyanate into urea, and to coin for us the word *isomerism*, by which that fact is denoted.

It was thus from the singular circumstance that Wöhler and Liebig were at the outset of their career engaged upon the elucidation of the nature of two bodies of identical composition, but of dissimilar origin, dissimilar relations, and very different properties, that they were brought into juxtaposition. They desired to know each other: they met in the house of a mutual friend at Frankfort, and the names of Liebig and Wöhler became henceforth linked together for all time.

The origin of that partnership, so fruitful in consequences for science, may be seen in the following characteristic letter:—

"Frederick Wöhler to Justus Liebig

"*Sacrow, near Potsdam, June* 8, 1829

"Dear Professor,—The content of your last letter to Poggendorff has been communicated to me by him, and I am glad that it affords me an opportunity of resuming the correspondence which we began last winter. It must surely be some wicked demon that again and again imperceptibly brings us into collision with our work, and tries to make the chemical public believe that we purposely seek as opponents these apples of discord. But I think he is not going to succeed. If you are so minded, we might, for the humour of it, undertake some chemical work together, in order that the result might be made known under our joint names. Of course, you would work in Giessen, and I in Berlin, after we were agreed upon the plan, and had communicated with each other from time to time as to its progress. I leave the choice of subject entirely to you.

"I am very glad that you have also determined the identity of pyrouric acid, and cyanic [cyanuric] acids. L. Gmelin would say: 'God be thanked, there is one acid the less!' . . .

"Yours, "Wöhler"

Liebig acceded to the proposition at once, and suggested some problem on the chemical nature of nitrogen; this Wöhler found himself unable to undertake, as it involved the use of chlorine, to the action of which he was at all times extremely susceptible. On the other hand, he proposed to Liebig that they should continue in common a research on mellitic acid, which he himself had begun. Their joint investigation on this body made its appearance within the following year.

It would be quite impossible within the limits of an hour to attempt to give you anything approaching to a complete analysis of Wöhler's work. In all, he was the author of 275 memoirs and papers, and of these fifteen were published in concert with Liebig. I must therefore confine my selection from this vast amount of material to those papers which are of paramount importance from the influence which they have exerted on chemical theory or on the development of the chemical arts.

Very shortly after the publication of the work on mellitic acid Wöhler proposed to Liebig a joint investigation on cyanuric acid, in the course of which he observed the extraordinary transformation of that acid into cyanic acid, and the reconversion of the cyanic acid into cyanuric acid—one of the most remarkable instances of molecular rearrangement known to the chemist. The work progressed little for some months, owing to the demands made by Berzelius's *Jahresbericht* on Wöhler's time. "Wirf die Schreiberei zum Teufel," wrote Liebig, "und gehe in das Laboratorium, wohin Du gehörst." It was that functionary, doubtless, who in due time carried off the writing to his master, the printer. Wöhler went back to his laboratory, and in a few weeks the two investigators had obtained the clue to the puzzle. Liebig wrote to Wöhler: "Now that I have received your experiments the whole thing is cleared up, and with what satisfaction for us! The matter is now decided: the cyanic aid of Serullas is identical with that from urea. . . . Ich bin ganz närrisch vor Freude, dass unser Kindlein nun fehlerlos in die Welt gesetzt wird, ohne Buckel oder Klumpfuss."

[It had been suggested to attack the fulminic acid again.] "The fulminic acid we will allow to remain undisturbed. Like you, I have vowed to have nothing more to do with this stuff. Some time back I wanted, in connection with our work, to decompose some fulminating silver by means of ammonium sulphide; at the moment the first drop fell into the dish the mass exploded under my nose. I was thrown backwards, and was deaf for a fortnight, and became almost blind."

The work on cyanic acid appeared in Poggendorff's *Annalen* during the last month of 1830, and Wöhler was able to send the "Kind'ein" "im neuen Kleide," as he says, with a New Year's greeting to his friend. Liebig had suggested fresh work, but at the moment Wöhler was in no humour to attack anything organic. The Swedish chemist, Sefström, had just announced the existence of a new element in the slag of certain iron ores, and this very substance had slipped through Wöhler's fingers unperceived. "I was an ass," he wrote to his friend, "not to have detected it two years ago in the lead ore from Zimapan in Mexico. I was busy with its analysis, and had found something strange in it, when I was laid up for some months in consequence of breathing hydrofluoric acid, and so the matter was allowed to rest. Meanwhile Berzelius sends me word of its discovery by Sefström in Swedish bar iron and in slag. It is very like chromium, and just as remarkable. Moreover, it is the same metal that Del Rio found in the Mexican lead ore, and called erythronium: Descotils, however, had declared this ore to be lead chromate."

Wöhler, no doubt, found a ready sympathiser in Liebig, to whom, not many years before, a similar experience had happened. We all know the story of the young chemist whose unscientific use of the imagination cost him the discovery of the element *bromine*. Wöhler had sent some of the substance to Stockholm, and Berzelius wrote as follows:—

"JACOB BERZELIUS TO FREDERICK WÖHLER

"*Stockholm, January* 22, 1831

"As to the small quantity of the body marked ? I will relate the following story:—'In the far north there lived in the olden time the goddess Vanadis, beautiful and gracious. One day there came a knock at her door. The goddess was in no hurry, and thought "They can knock again"; but there came no further knock, for he who knocked had passed on. The goddess, wondering who it could be that cared so little to be let in, ran to the window and recognised the departing one. "Ah!" said she to herself, "it is that lazy fellow, Wöhler! He richly deserves his name, since he cares so little to come in." Some days after, some one else knocked, repeatedly and loud. The goddess opened the door herself; it was Sefström who entered, and, as a consequence of their meeting, vanadium came to light.' Your specimen with the ? is, in fact, vanadium oxide.

"But he that has found the mode of artificially forming an organic body can well renounce the discovery of a new metal; indeed, one might have discovered ten unknown elements without as much skill as attaches to the masterly work which you and Liebig have carried out together and just communicated to the scientific world."

In 1831 Wöhler was called from Berlin to Cassel, and for some little time he was wholly engaged in the planning and erection of his new laboratory at the Gewerbe-Schule in that town. In the spring of the following year he was again ready for a new research; and this time it was to be the finest piece of work that the two investigators jointly engaged in. It was, in fact, to be the classical research on bitter almond oil. On May 16, 1832, Wöhler wrote to Liebig:—"Ich sehne mich nach einer ernsten Arbeit, sollten wir nicht die Confusion mit dem Bittermandelöl in's Reine bringen? Aber woher Material?" It must have been a *förscherblick* amounting to inspiration which led Wöhler to take up this subject; but neither he nor Liebig could have been wholly conscious of the consequences which were to follow from their work. To-day oil of bitter almonds is made artificially in Germany by the hundredweight: at that time the investigators could only obtain it in small quantities from Paris. They had indeed to thank Pelouze for the material with which they worked. Wöhler made this his greatest research under the cloud of a great sorrow: after barely two years of married life he lost his wife. Liebig, in the tenderest manner, brought him over to Giessen, and sought to win him from his grief and the sense of his loneliness by his company and the wholesome distraction of their joint work made side by side.

On August 30, 1832, Wöhler wrote to Liebig from Cassel:—

"I am here back again in my darkened solitude. I do not know how I shall thank you for the affection with which you received me and kept me by you for so long. How happy was I that we could work together face to face.

"I send you with this the memoir on bitter almond oil. The writing has taken me longer than I anticipated. I want you to read through the whole with the greatest care, and to notice particularly the numbers and formulæ. What does not please you, alter at once. I have often felt that there was something not quite right, without being able to find what was right."

I shall not attempt to dwell upon the outcome of this great work. The investigation on the radicle of benzoic acid will ever remain one of the greatest achievements in the history of organic chemistry: the work was indeed epoch-making in the far-reaching nature of its consequences. It was full of facts and rich in the promise of new material; a veritable mine from which subsequent workers like Cannizzaro, Fehling, Piria, Stas, and Hlasiwetz have dug rich treasure. The immediate effect of the paper was to establish the doctrine of organic radicles by demonstrating the existence of groups of bodies which had their analogues and prototypes in inorganic chemistry. The concluding words of the memoir strike, in fact, the keynote of the whole investigation. "In once more reviewing and connecting together the relations described in this memoir," so wrote Liebig and Wöhler, "we find that they may be grouped round a common nucleus which preserves intact its nature and composition in its associations with other bodies. This stability has induced us to regard this nucleus as a kind of compound element, and to propose for it the special name of 'benzoyl.'"

A significant feature in the memoir was that each of the substances described and correlated was the type of a distinct group of bodies, some of which were known, but of which the analogies and relations were unthought of; others of these bodies were yet to be discovered, a matter of little difficulty when the modes of their origin had been indicated. The effect of this memoir on the chemical world was instantaneous. Berzelius was delighted. "The facts put forward by you," he wrote to Wöhler and Liebig, "give rise to such considerations that they may well be regarded as the dawn of a new day in vegetal chemistry. On this account I would propose that this first-discovered radicle composed of more than two elements should be named *proin* (from πρωΐ, the beginning of day) or *orthrin* (ὄρθρος, daybreak), terms from which names like *proic acid*, *orthric acid*, *proic chloride*, *orthric chloride*, &c., could be readily derived."

Wöhler remained in Cassel for nearly five years. In the autumn of 1835 died Strömeyer, Professor of Chemistry in the University of Göttingen. Opinions were divided as to his successor; the choice lay between Liebig and Wöhler. Eventually Wöhler was selected, and entered on his work at Göttingen in the early part of 1836. He was succeeded at Cassel by Bunsen, who was at that time *privat docent* in Göttingen. In the October of that year Wöhler was again ready for fresh work. He writes to Liebig: "I am like a hen which has laid an egg and straightway sets up a great cackling. I have this morning found how oil of bitter almonds containing prussic acid may be obtained from amygdalin, and would propose that we jointly undertake the further investigation of the matter, as it is intimately related to the benzoyl research, and it would seem strange if either of us should work alone again in this field, denn es lässt sich gar nicht absehen wie weit es sich erstreckt, und ich glaube es ist gewiss fruchtbar, wenn es mit Deinem Mist gedüngt wird. . . ." In a couple of days afterwards Wöhler was ready with the fundamental facts for the research and had sketched out its plan. He writes:—

"I have just made a most remarkable discovery in relation to the amygdalin. Since it appeared that bitter almond oil might be obtained from amygdalin, it occurred to me that the one might be converted into the other by simply distilling almonds with water by an action similar to that of a ferment upon sugar, the change in this case being due in all probability to the albumen in the almonds. And this idea seems to be completely established. The facts are as follows:

"1. Amygdalin, dissolved in water and digested with a bruised sweet almond, begins almost immediately to smell of bitter almond oil, which after a time may be distilled off in such quantity that it would appear that the amygdalin was wholly transformed into it.

"2. A filtered emulsion of sweet almonds produces the same effect.

"3. A boiled emulsion of sweet almonds, in which, therefore, the albumen is coagulated, affords not the smallest trace of oil with amygdalin.

"4. Bruised sweet almonds, covered with alcohol, and freed therefrom by pressure, transform, as before, amygdalin into bitter almond oil.

"5. Bruised peas, or the albumen they contain, give no oil with amygdalin.

"There are three points, therefore, to be ascertained—

"*a.* What is the substance in bitter or sweet almonds which, in contact with amygdalin and water, forms bitter almond oil?

"*b.* Is the action by double decomposition or catalytic, like that of a ferment?

"*c.* What is the other product which in all probability is formed in addition to the oil and prussic acid?"

The merest tyro in organic chemistry to-day is familiar with the broad features of this investigation, and knows the answers which Liebig was able to give to his friend's interrogatories. The third substance Liebig discovered to be sugar. Under the influence of a nitrogenised ferment, termed by Liebig and Wöhler *emulsin*, amygdalin, in presence of water, is decomposed into benzaldehyde (bitter almond oil), prussic acid, and sugar (glucose), thus:—

$$\underset{\text{Amygdalin}}{C_{20}H_{27}NO_{11}} + \underset{\text{Water}}{2H_2O} = \underset{\text{Benzaldehyde}}{C_7H_6O} + \underset{\substack{\text{Prussic}\\\text{acid}}}{CNH} + \underset{\text{Glucose}}{2C_6H_{12}O_6}.$$

It simply remains to explain why this reaction only occurs when the almonds are bruised and digested with water. Both the emulsin and the amygdalin exist together in the almonds, but are contained in separate cells, and are only brought into contact by the rupture of the cell-walls and the solvent action of the water. Amygdalin was the prototype of a large and important group of substances classed together as the glucosides.

At the instigation of Wöhler, the friends again returned to the question of the chemical nature of uric acid, and the memoir which they eventually published on the subject is of the profoundest interest, not only to the chemist, but also to the physiologist. Uric acid, originally discovered by Scheele, was shown in 1815, by William Prout, then a boy of nineteen, to be the main constituent of the solid excreta of reptiles; other chemists had succeeded in obtaining various derivatives from it, indeed Prout himself had prepared from it the so-called purpuric acid, a substance which years after as murexide obtained a transitory importance in the arts as a colouring matter. But nothing was known concerning the constitution of the body or of its relations to its derivatives until Wöhler and Liebig attacked the problem. The extraordinary mutability of uric acid, which had baffled and deceived previous investigators, was to Wöhler and Liebig the very clue to the labyrinth leading to a veritable treasure-house, and the wonderful insight and rare analytical skill of these two great men were never more clearly indicated than in the way in which they trod this intricate maze. No fewer than fifteen new bodies were added to the list of chemical compounds, and these were correlated with the same masterly lucidity that was so strikingly exhibited in the memoir on the radicle of benzoic acid. Some of the greatest triumphs of modern chemistry are seen in the synthesis of organic bodies. That organic chemistry was about to advance along this line was clearly foreseen by Wöhler and Liebig. In opening their account of this the last great work they did in common, they say:—"From this research, the philosophy of chemistry will draw the conclusion that the ultimate synthetical formation in our laboratories of all organic bodies, in so far as they are not organised (in so weit sie nicht mehr dem Organismus angehören), may be regarded as not only probable but as certain. Sugar, salicin, morphin will be artificially obtained. As yet we know nothing of the way by which this result is to be attained, inasmuch as the proximate materials for forming these bodies are unknown; but we shall come to know them."

Henceforth the friends worked but little in common. Liebig's energies were spent in other directions, and Wöhler turned his attention to inorganic chemistry. Time allows only the very briefest mention to be made of his more important discoveries in this department of the science. We have first his isolation of crystalline boron, and the preparation of the compounds of boron with aluminium and nitrogen, work done in concert with Sainte-Claire Deville. The readiness with which boron unites with nitrogen, and the mode in which the compound may be decomposed, led Wöhler to a conception of the origin of boric acid and borax in the volcanic waters in which they are frequently found. In collaboration with Buff he discovered the spontaneously inflammable hydride of silicon, the analogue of marsh gas, the simplest of the hydrides of carbon, and thereby laid the foundation-stone of a superstructure, which in time to come may only be less imposing than that built up of the compounds of carbon. Many years ago Wollaston noted the presence of beautiful lustrous copper-coloured cubes in the slags from the iron blast-furnaces, which he assumed to be metallic titanium; Wöhler proved this substance to be a compound of carbon, nitrogen, and titanium, and showed how it might be obtained. Of all the elements known to the chemist up to the period of Wöhler's cessation from work, it may be safely averred that there was not one but had passed through his hands in some form or other. Now he was busy with chromium, then with cerium, next with uranium and the platinum metals; titanium, tantalum, thorium, thallium, tungsten—all came in for some share of his attention. Of the minerals and meteorites he analysed, the number is legion; indeed, as Prof. Hofmann says, whoever sent him a piece of meteoric iron gained his heart. His restless activity was a source of continual wonder to his friends. "How happy art thou in thy work!" wrote Liebig on one occasion; "thou art like the man in the Indian fable, who when he laughed dropped rose from his mouth."

The names of Liebig and Wöhler are now so closely intertwined in the history of chemistry that it is hardly possible to avoid comparing the men. Such a comparison has already been drawn by one who of all others is most fitted to draw it. "Liebig," says Dr. Hofmann, "fiery and impetuous, seizing a new thought with enthusiasm, and giving to it the reins of his fancy, tenacious of his convictions, but open to the recognition of error, sincerely grateful, indeed, when made conscious of it,—Wöhler, calm and deliberate, entering upon a fresh problem after full reflection, guarding himself against each rash conclusion, and only after the most rigorous testing, by which every chance of error seemed to be excluded, giving expression to his opinion—but both following the path of inquiry in their several ways, and both animated by the same intense love of truth! Liebig, irritable and quick to take offence, hot-tempered, hardly master of his emotions, which not unfrequently found vent in bitter words, involving him in long and painful quarrels,—Wöhler, unimpassioned, meeting even the most malignant provocation with an immovable equanimity, disarming the bitterest opponent by the sobriety of his speech, a firm enemy to strife and contention—and yet both men penetrated by the same unswerving sense of rectitude! Can we marvel that between two such natures, so differently ordered, and yet so complementary, there should ripen a friendship which both should reckon as the greatest gain of their lives?"

Who can fully gauge the influence of such a nature as Wöhler's? How it was exerted on Liebig is indicated in the following letter:—

"FREDERICK WÖHLER TO JUSTUS LIEBIG

"*Göttingen, March* 9, 1843

"To make war against Marchand, or, indeed, against anybody else, brings no contentment with it, and is of little use to science. . . . Imagine that it is the year 1900, when we are both dissolved into carbonic acid, water, and ammonia, and our ashes, it may be, are part of the bones of some dog which has despoiled our graves—who cares then whether we have lived in peace or anger; who thinks then of thy polemics, of the sacrifice of thy health and rest for science?—Nobody. But thy good ideas, the new facts which thou hast discovered, these, sifted from all that is immaterial, will be known and remembered to all time. But how comes it that I should advise the lion to eat sugar!"

It was thus in philosophic contentment, happy in his work, in his home life, and in his friendships, that Wöhler lived out his fourscore years and two. He made Göttingen famous as a school of chemistry; at the time of the one-and-twentieth year of his connection with the university it was found that upwards of 8000 students had listened to his lectures or worked in his laboratory. He was a man whom the world has delighted to honour; and there was hardly an academy of science or a learned society which has not in some way or other recognised his services to science. He was made a Foreign Member of the Royal Society in 1854, a Corresponding Member of the Berlin Academy in 1855, Foreign Associate of the Institute of France in 1864, and in 1872 he received the Copley Medal from the Royal Society. On September 23, 1882—

"He gave his honours to the world again,
His blessed part to heaven, and slept in peace."

METEORIC DUST

SIR WILLIAM THOMSON has sent us the following communication for publication:—

"*Portkil, Kilcreggan, March* 13, 1884

"DEAR SIR WILLIAM THOMSON,—Herewith I inclose some of the meteoric dust collected on a cotton filter, and both ignited at a red heat. The change of colour is interesting.

"On Saturday, March 1, the snow lay 5½ inches deep at 8 a.m., pure and white. At 9.15 a.m., when I next noticed it, it was sooty looking, the blackish appearance penetrating half an inch only. The sky was clear and calm, any tendency to movement of the air being from the south-east.

"I carefully measured a superficial foot on an outlying field sloping to the south-west at a spot bisected by the 200-foot line of the Ordnance Survey, and collected the snow into two bowls of white delft, half into each. After evaporating the snow water, thoroughly drying the residue, I collected and weighed it, that from one giving 1⅞ grains, and the other 2⅛ grains, or 4 grains to the square foot exactly.

"I can personally vouch for the dust being all over the Roseneath peninsula, as I trudged through the snow to Coulport on Loch Long, and found it the same all the way north, also on the top of the Gallow-hill (414 feet). I have since seen those who noticed it at Garelochhead, so that on this peninsula alone, taking 4 grains as an average, there has fallen over 100 tons.

"From hearsay it appears to have been noticed from Kippen on the north to Largs on the south, and from Hamilton on the east to Dunoon on the west, or over an area (in round numbers) of 810 square miles, and admitting the former estimate, we have the astonishing aggregate of say 5760 tons! A weighty gift to Mother Earth, surely of some value.

"I should mention that every crack, scratch, or depression in the glass of the bowls was filled with the finely divided matter; it was impossible, therefore, to collect it *all* for weighing, consequently 4 grains per square foot is under rather than over the probable average. The observer at Kippen, too, mentions that the snow was permeated there for one inch by the sooty appearance.

"On Monday (March 3), after snow had fallen to the depth of an additional 8 inches, I watched for a recurrence of the phenomenon, and on the sky clearing about midnight I fetched in a dish that I had left outside and found a little had fallen in small flakes; these had melted their way through the snow, leaving little tunnels about the size of crow-quills. The quantity, however, was exceedingly small. Tendency to movement of the air as before from the south-east. Barometer had risen from 29·4 at 2 p.m. to 29·6, steady at midnight, thermometer 42°. On Saturday previous barometer stood at 30·05 (90 feet above sea-level, aneroid), thermometer 44°, 12 noon. The dust I left with you previously contains a little organic matter (grassy fibre), though what I had under the microscope appeared entirely metallic.

"The snow had melted a good deal before I recognised the importance of obtaining a fair sample. My children, however, had rolled a huge snowball down the slope, at the top of which the cottage stands, and this had increased as it rolled until it was something like 6 feet in diameter, and so formed a mine from which to collect the dust. There is still some of the black water in process of evaporation; should you require it more of the dust is at your service.

"One of the older inhabitants remembers a similar occurrence here in 1828 on the 20th or 22nd of March, when the snow, he says, fell in black or sooty flakes.

"Perhaps it is well to mention that the goats suffered somewhat from influenza on Sunday and Monday, and that I myself had a sharp attack followed by severe headache for a day, caused probably by inhaling a minute quantity of the dust snuff fashion. It might have been from something else, only the coincidence is suggestive of caution.

"I am, yours faithfully,
"LEWIS P. MUIRHEAD
"Professor Sir William Thomson, Glasgow University"

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Boards for Medicine, Physics and Chemistry, and Biology and Geology, after joint deliberation, have recommended an important change in the appointments of Natural Science Examiners. It has been a regulation of the Natural Science Tripos that all answers shall be looked over by two examiners out of the eight, but it has become increasingly difficult to find examiners with the requisite extent of knowledge. Thus it practically happens that each examiner is sole examiner in a single subject, and the places of candidates are often practically dependent on the judgment of a single examiner to an extent unknown in the other Triposes. It is now recommended that two examiners shall be appointed in each subject of Natural Science, to undertake all the University Examinations in that subject, and thus the Natural Sciences Tripos, the Special Examinations for the ordinary B.A., and portions of the M.B. Examinations, will be brought into one system. The examiners should never both be changed at the same time. The payments recommended are—for each examiner in Physics and in Chemistry, 50*l.*; in Botany, Zoology, Human Anatomy, and Physiology, 40*l.*; in Geology, 20*l.*; and Mineralogy, 10*l.*

SCIENTIFIC SERIALS

Journal of the Franklin Institute, No. 697, January.—W. Dennis Marks, note on the losses per horse-power by condensation of steam in pipes and cylinders of engines.—De Volson Wood, the cheapest point of cut-off.—Prof. R. H. Thurston, the theory of turbines. This is the conclusion of a very valuable mathematical paper given in a very full abstract.—B. N. Clark, water-line defence and gun-shields for cruisers.—W. Dennis Marks, economy of compound engines.—Prof. E. J. Houston, the Delany synchronous-multiplex system of telegraphy. This invention is founded on La Cour's phonic wheel, and bids fair to supersede harmonic multiple telegraphs.

Annalen der Physik und Chemie, xxi. January.—O. Fröhlich, measurements of sun-heat. Describes amongst other matters a new pyrheliometer with a special thermopile arrangement.—A. W. Velten, the specific heat of water. The results confirm Regnault's values.—E. Pirani, on galvanic polarisation. The values are estimated by a compensation method.—W. Hittorf, on electric conductivity of gases (first part).—A. Oberbeck, on electric oscillations and on phenomena of polarisation caused thereby.—A. Toepler, on the estimation of horizontal magnetic intensity by use of the balance.—W. von Bezold, a simple experiment on the connection between the temperature of an incandescent wire and the composition of the light emitted by it. A platinum wire is stretched horizontally through the tip of a Bunsen burner and examined in a spectroscope with horizontal slit.—E. Ketteler, reply to Herr Voigt's criticisms.

No. 2, February.—S. Czapski, on the thermal variation of the electromotive force of galvanic batteries, and its relation to their free energy.—J. Kollert, on the properties of flame in their electrical relation. Confirms the previous measurements of Elster and Geitel.—F. Fuchs, on a compensation-method for estimation of the resistance of unpolarisable elements. A modification of Poggendorff's well-known method.—E. Budde, on the theory of thermo-electric forces.—H. Lorberg, on electrostriction. A discussion of Quincke's results.—B. Weinstein, on the calculation of the potential of coils. A mathematical paper.—A. von Waltenhofen, on an instructive experiment which may be made with asymmetrical thermopiles. On passing an independent current through the thermopile certain non-reversible phenomena of polarisation are observed arising from the asymmetry of the junctions that are heated.—C. Christiansen, on the emission of heat from uneven surfaces.—A. Tschirch, researches on chlorophyll and some of its derivatives.—W. Holtz, a lecture experiment in proof of the law that the velocity of rotation increases as the rotating masses approach the axis.

Journal de Physique, tome iii. No. 2, February.—G. Lippmann, physical definition and determination of absolute temperatures. This is the first part of a communication in which the author seeks to find stricter thermodynamic definitions of temperature. He attributes to Carnot the discovery of the scale of absolute temperature!—D. Gernez, researches on the duration of the solidification of sulphur, and on a new variety of sulphur. The crystallisation in octahedra takes from 25 to 100 times as long as the crystallisation in rhombic prisms. The new crystalline kind obtained by M. Gernez is in the form of very elongated prisms of a nacreous texture. They are produced by rubbing the side of the test-tube containing the surfused sulphur with the end of a platinum wire or glass rod. When these crystals are introduced into surfused sulphur, they determine a growth of similar crystals throughout the mass; and the formation is much more rapid than that of either of the previously known forms.—E. Mathieu, suspension of a liquid by a capillary vertical tube.—E. Mathieu, modification of the pressure of a liquid by capillary forces.

Rendiconti del R. Istituto Lombardo, Milan, January 24.—Biographical memoir of Emilio Cornalia (1824–1883), by Prof. Leopoldo Maggi.—Necrological notice of the late Camillo Hajech.—*Résumé* of the meteorological observations made at the Brera Observatory, Milan, during the year 1883, by E. Pini.—Some applications of Cournat's principle of least effort to the equilibrium of linked systems (theoretical mechanics), by Prof. G. Bardelli.—Meteorological observations made at the Brera Observatory during the month of January, 1884.

SOCIETIES AND ACADEMIES

LONDON

Mathematical Society, March 13.—Prof. Henrici, F.R.S., president, and subsequently Mr. S. Roberts, F.R.S., vice-president, in the chair.—The Rev. A. C. E. Blomfield, Messrs. J. Chevallier, E. H. Hayes, R. S. Heath, and Prof. J. Larmor were elected Members.—Mr. Tucker read a paper by Prof. M. J. M. Hill on the closed funicular polygons belonging to a system of coplanar forces having a single resultant; and communicated a paper by Prof. J. Larmor, on the direct application of the principle of least action to dynamical analogues.—Mr. J. W. L. Glaisher, F.R.S., read a paper on the square of Euler's series.—Mr. J. J. Walker, F.R.S., communicated a note by Mr. J. Griffiths, further results from a theory of transformation of elliptic functions.—Mr. S. Roberts, F.R.S., read a note concerning the Pellian equation.

Physical Society, March 8.—Prof. Guthrie, president, in the chair.—Lord Rayleigh read a paper on the electro-chemical equivalent of silver. The determination was made by a method described to the last meeting of the British Association at Southampton, which consists in using two fixed coils and a movable coil suspended between these from one end of a balanced beam. These coils are in circuit with the current and voltameter. The current is reversed in the fixed coils at intervals of five minutes, and the weight required to bring the balance even is noted. The calculation of the effect by this method is independent of the precise measurement of the coils. Two or more silver voltameters were in circuit, nitrate of silver being the solution used. Careful precautions of various kinds were taken, and the result was that unit C.G.S. current deposits $1·118 \times 10^{-2}$. It follows that 1 ampere will deposit 4·025 grm. of silver per hour.—Lord Rayleigh also read a paper on the absolute electromotive force of Clark's cell. Experiments made at the Cavendish Laboratory gave the electromotive force of this cell as 1·453 volts. The accepted value is 1·457 volts. If the B.A. unit (as Lord Rayleigh believes) is about ·9867 of a true ohm, the result, 1·453, becomes 1·434 volts.—Lord Rayleigh also mentioned that he had been making experiments on the rotation of the plane of polarised light in bisulphide of carbon, and obtained a result agreeing more nearly with Gordon's than with Becquerel's.—Profs. Guthrie and Ayrton spoke on the papers, the former eliciting the reply that electro-corrosion was less satisfactory than electro-deposition for determining the equivalent; and the latter that silver was better than copper for accurate results in the voltameter.—Mr. Shelford Bidwell, M.A., read a paper on some experiments illustrating an explanation of Hall's phenomenon. By these experiments Mr. Bidwell sought to explain Hall's effect through a combination of mechanical stress and the well-known Peltier effect on the thin metal plate which is placed between the poles of the magnet. He repeated many of the experiments, and showed how he had obtained the same results as Hall, except in the case of aluminium, which he found to be + like iron, whereas Hall made it −. Mr. Bidwell reversed the effect by cutting two slits in the strip of metal, thereby altering the stress on it. Righi's effect was also explained on the same grounds. Mr. Walter Browne said that difference in the quality of the aluminium might explain the anomaly with this metal. Prof. Perry criticised the explanation of the slitted plate, and Prof. G. C. Foster suggested that results in absolute measure should be obtained.

EDINBURGH

Royal Society, February 18.—Sheriff Forbes Irvine, vice-president, in the chair.—Prof. Tait read a paper on radiation, in which he called attention to Stewart's papers of 1858 as containing, so far as it has yet been developed, the theory of exchanges. Yet, in the most recent authoritative treatise on the subject, the name of Stewart is not even once mentioned. The basis of the whole theory is Carnot's principle, and therefore no demonstration can be considered absolutely rigorous. Thus it is probable that as there are very hot particles in a gas at ordinary temperatures, so there may be feeble radiation of high wave-lengths from a black body at ordinary temperatures.—Mr. Saug read a paper on the need for decimal subdivisions in astronomy, trigonometry, and navigation, in which he pointed out the inconvenience of the sexagesimal system, and estimated it as doubling the labour of calculation. The decimal division of the second, used throughout the *Nautical Almanac*, was appealed to as evidence of the need for a change. The paper was accompanied by a number of tables suited to the decimal division of the quadrant, or useful therefor.—Prof. Ewing communicated a paper by A. Tanakadaté on an electromagnetic declinometer.—Prof. Tait showed that when one polygon has its corners at the middle points of the sides of another, the condition that the first, second, or *n*th derived polygon shall be similar to the original, involves a singular equation in quaternion differences.—Prof. Tait also made some remarks on the basis of the theory of vortex atoms, pointing out that there is not necessarily any direct action between vortices in a perfect fluid; the present theory, which indicates such action, being based upon the assumed continuity of motion throughout the fluid.

PARIS

Academy of Sciences, March 10.—M. Rolland in the chair.—The election of M. G. Darboux was announced, as successor to the late M. Puiseux in the Section of Geometry.—On the forms presented by the nucleus of the Pons-Brooks comet on January 13 and 19 (one illustration), by M. Faye. The author rejects the explanation of these remarkable forms proposed by Bessel, who attributed to the nucleus a polarity like that of the magnetic forces. In virtue of this polarity the nucleus and anterior nuclear emission are supposed to oscillate in presence of the sun like the needle of a compass in presence of a magnet. But M. Faye sees in these changes nothing but the effect of a rotatory motion powerfully affected by solar attraction. Under these conditions the rotation may acquire irregular pendulant vibrations without having recourse to the intervention of polar forces.—Explosive gaseous mixtures; calculation of their temperatures and specific heat at the moment of explosion (continued), by MM. Berthelot and Vieille. Tables of the results of these experiments are appended for the oxyhydric and oxycarbonic mixtures, for cyanogen, and the carburets of hydrogen.—Note on a letter of the astronomer Méchain in connection with the completion of the triangulation of Spain and the extension of the meridian to the Balearic Isles, by M. J. Lefort.—On a differential equation of the third order, by M. E. Goursat.—On the decomposition of polynomes which admit only of primary divisors of a determined form, by M. Lefébure.—On the remarkable variation of the nucleus of the Pons-Brooks comet (one illustration, by M. Ch. Trépied.—On the barometric oscillations produced by the Krakatoa eruption, by M. P. Tacchini.—On the crepuscular and auroral lights observed at Morges, in Switzerland, during the winter of 1883–84, by M. Ch. Dufour.—On a method for measuring the coefficient of cubic expansion of solid substances in the form of minute particles, by M. J. Thoulet. To determine the coefficients of these bodies the author employs a solution of iodide of mercury in iodide of potassium. The extreme delicacy of the process is shown by its application to quartz, which yields a coefficient of 0·0000357 compared with M. Fizeau's 0·00003619.—On the action of two consecutive parts of the same electric current, by M. A. Buguet.—On the spectrum of absorption of water; preliminary studies connected with the spectral analysis of the rays transmitted through a more or less dense layer of water, by MM. J. L. Soret and Ed. Sarasin.—Action of electric effluvia on oxygen and nitrogen in the presence of chlorine, by MM. P. Hautefeuille and J. Chappuis.—Observations on the formula of some sal ammoniacs, by M. R. Engel.—Observation relative to a note of M. Calmels on the poison of Batrachians, by MM. A. Gautier and Étard.—On the Malpighian vessels of the Lepidoptera, by M. Cholodkovsky.—On an aberrant form of the phylum Sporozoa, by M. J. Kunstler.—On the presence of manganese in the white cipoline marbles of Carrara, Paros, and the Pyrenees; geological deductions, by M. Dieulafait.

BERLIN

Physical Society, February 22.—Prof. Landolt produced a cylinder of solid carbonic acid he had prepared about an hour before the sitting, and described the mode of its formation. From a Natterer compressing vessel a stream of liquid carbonic acid was made to penetrate into a conical cloth bag. The bag speedily got filled with a loose snow of carbonic acid, which was then, by means of a stamper, hammered together in a cylindrical vessel into a solid cylinder. Compact carbonic acid cylinders of this kind could be touched gently with the hand, and possessed the hardness of chalk, which, too, they resembled in appearance, and on account of their brittleness did not readily admit of being cut with a knife. The specific gravity of solid hammered carbonic acid was found to be 1·2.—Prof. Schwalbe showed on a beech twig the ice-swellings he had described at the last sitting. These were produced in a moderately freezing mixture, their formation failing in a strongly freezing mixture. A twig which by way of experiment had been completely dried entirely lost the capability it previously possessed in a high degree of forming ice protuberances.—Prof. Erdmann related an observation he had made some time ago, and had since very frequently repeated. In a perfectly dark room he was able only by indirect vision to perceive an object which reflected light very faintly, while, on endeavouring to look at it fixedly, the object completely disappeared. This phenomenon he observed only in the evening in going to bed, after he had been working for a considerable time in a brightly illuminated room. On the other hand, [illegible] faintly lucent ol[illegible] He was of opinion that this phenomenon [illegible] the lassitude of the middle parts of the retina, while Prof. von Helmholtz explained it by the inferior sensitiveness to light of the yellow spot in comparison with its surroundings.—Dr. Kœnig reported at length the experiments which in common with Dr. Dietrici he had instituted with a view to determining the colour-sensitiveness of normal eyes. Exhibiting the apparatus he had made use of, Dr. Kœnig explained its construction and the procedure he had followed in the experiment. Towards one angle of a prism was directed an observing telescope, which, instead of an eye-piece, had a diaphragm provided with a slit, on which the spectrum fell, so that it was possible to observe sections of any degree of minuteness whatsoever. Towards each of the two other angles of the prism was placed a collimator, which in the focus of its lens had a slit for the entrance of the light, which was polarised by means of a Nicol prism. Behind the slit was a double refracting prism, by varying the position of which in the collimator the slit-image could be doubled at pleasure. Through the slit of the objective were seen close beside each other the spectrum of the light which had passed through one collimator, and the spectrum of light which had passed through the other. While one collimator was now kept fixed, the other, by means of micrometers, was displaced till the point was reached at which the observer found the colours in both spectra alike. The wave-lengths in both spectral stripes were then measured, and their difference was the standard of colour-sensitiveness in the single regions. For each wave-length fifty readings were in this way made by each of the two observers, and the mean difference calculated of the wave-lengths in the two spectral ranges, which were perceived to be equal. These experiments extended from the wave-length of 640 millionths of a millimetre to the wave-length of 430, and were made from each 10 millionths of a millimetre, each particular spot being examined under two different intensities of light. From the results of these measurements it was established that the colour-sensitiveness of normal eyes ranged from more than 1 to about 0·2 millionths of a millimetre. The difference of the D-lines in the solar spectrum amounted to 0·6 millionths of a millimetre. Altogether three maxima of sensitiveness were found. The first maximum appeared with the wave-length of 570 near the D-line. A second greater maximum approached the F-line with a wave-length of about 490 to 470. Finally, a third smaller maximum was found with a wave-length of 450 to 440. The place of the maximum changed with the intensity in such a manner that, the greater the intensity was, the more the maximum shifted towards the more refrangible part of the spectrum. Beyond the wave-lengths of 640 and 430 these experiments could not be carried out, because, at the red end especially, no differences of colour, but only differences of brightness, were perceived. From the colour-sensibility thus found, it was calculated that within the range of the normal spectrum the healthy eye was able to perceive about 300 differences of colour. Dr. Kœnig hoped to be able to set forth on a future occasion further experiments in conjunction with the measurements here communicated, and the consequences resulting therefrom in respect of the theory of the perception of colour.

THURSDAY, MARCH 27, 1884

THE CHOLERA BACILLUS

N his capacity as chief of the German Cholera Commission Dr. Koch has issued a further—his sixth—port, and it is one which must become historic in conection with inquiries as to the etiology of that disease. itherto Dr. Koch has almost entirely confined himself reporting facts as they were elicited, and whenever he as referred to any inferences which might be drawn om them, it has only been to show how many sources error stood in the way of all attempts to arrive at ustworthy conclusions. This attitude of Dr. Koch has aturally tended to increase the confidence in which e is held as a scientific worker, and it has an important earing on the character of the present report, in which e reserve hitherto maintained is thrown off, and Dr. Koch announces that the bacilli he has discovered are ltogether peculiar to cholera, and further, that they are e actual cause of cholera.

The further investigations which have been made relate the cultivation of the bacilli in question, to their beviour in the bodies of patients during the various ges of the disease, and to the examination of addinal bodies of persons dying both of cholera and of her diseases. The result is that what are now termed e cholera bacilli can be found in no bodies except those cholera patients; that at certain stages of the cholera sease they are invariably found in the bodies of the ents, whether these have lived and died in Egypt or a country so far distant from it as India; that these anisms confine themselves to the organ which is the seat the disease, namely, the bowel; and that they behave actly as do other pathogenic bacteria, their first appearce coinciding with the commencement of the disease, ir increase being proportional to its advance, and their appearance corresponding with its decline. Certain idental studies have also tended to confirm the corrects of the hypothesis that these bacilli are the cause of era. It is well known that the linen of cholera ents, has conveyed the infection of that disease. Now Koch has repeatedly observed that such linen, when ed by the alvine discharges and kept moist for a od of twenty-four hours, has been the seat of an raordinary multiplication of the special organisms; in connection with these experiments it was found precisely the same result took place whenever cholera ctions, or the contents of the intestines of persons ng died of cholera, were spread upon such substances oist linen or blotting paper. And further, a thin of the same discharges, when placed on a moist was found within twenty-four hours to have been erted into a thick mass of cholera bacilli. This latter very is one of extreme importance in connection he observations so frequently made as to the spread olera in India by means of water-sources, the soil d which is so often befouled by the natives.

om one point of view the report gives special se. Some bacilli of disease will, in certain stages, and almost every form of maltreatment; they may be dried, frozen, and otherwise dealt with, and yet they remain as potent as ever for mischief. But Dr. Koch's cholera bacilli die off rapidly when dried, all vestige of life apparently disappearing after three hours' desiccation. And not only so, but these bacilli will only grow in alkaline solutions, a very small quantity of a free acid standing in the way of their development. To these two circumstances we may in all probability to a large extent attribute the frequency with which those who are directly associated with the sick and their discharges escape infection; and the fact that the healthy stomach contains a sufficient amount of acid to destroy the bacilli may possibly lead to the discovery of some therapeutic or other measure of prevention which may be generally adopted. Directly gastric disturbance steps in and the gastric juices give a different reaction, we are probably face to face with conditions specially favourable to the reception of the poison, and in this respect it is noteworthy that cholera so often attacks those persons who have suffered, or are suffering, from diarrhœa and other gastric disorders.

In one respect Dr. Koch's experiments have failed. He has not succeeded in producing cholera artificially in any of the lower animals. As we have already pointed out, cholera is not the only specific disease to which man alone appears to be susceptible; and it is possible that the fact of cholera discharges and portions of diseased intestines having been given as food to the lower animals with impunity may find much of its explanation in the absence, in the stomachs of those animals, of the needed alkaline cultivation fluid.

At one point of the report our confidence in the correctness of Dr. Koch's inferences is weakened. It is where he, in maintaining his view that the bacillus he has discovered is the actual cause of cholera, refers to its resemblance in one respect to the bacillus of enteric fever. Now, leading micro-pathologists in this country have hitherto declined to regard it as proved that any such specific bacillus has been discovered. Dr. Koch's views have therefore still to stand the test of scientific criticism by his fellow workers, who will doubtless, as occasion offers, repeat his experiments.

THE SCIENCE OF THE EXAMINATION-ROOM

THOSE persons whose unhappy lot it is to have much to do with examinations must often feel that there is some fundamental common factor dropped out in the relation between examiner and examinees. A straightforward paper is set in a subject, say A, in which we will suppose there is no attempt to "catch" or perplex the student, but simply to sample, as it were, the ordinary commonplace knowledge which average industry might acquire. There returns to the examiner in due time a mass of manuscript, evidently written with pains and labour, mostly quite seriously meant, but which does not deal with the subject A, but with something which, though apparently related, is evidently quite different, and which we may call A′. After a little while he begins to wonder whether the whole thing is not a nightmare. The form is apparently rational, and yet the details are hopelessly incongruous and absurd. Or, to put the thing in another shape, it is as if one set a paper in solid geometry and got answers from Prof. Sylvester's infinitely thin book-worm.

If the examination-system is to be maintained without being on the one hand hopelessly discredited, or on the other lapsing into a kind of ceremonial observance like academic dress or a Guy Fawkes celebration, something must seriously be done to ascertain the real relation between A and A′. It is generally presumed that the object of "plucking" a candidate is to indicate to him his imperfect knowledge. But though the student of the subject called A′ is usually plucked by the examiner in A it is not clear that what may be called the moral result is in any way satisfactory. The examiner is disgusted equally with the candidate who has likely enough done his very best, just as the infinitely thin book-worm might do his best. The candidate grinds away at his A′ with more assiduity than ever if he is modest enough to think his ignorance to be in fault; but this only makes his subsequent failures with the examiner in A more assured, because the radical incommensurability of A and A′ becomes more intensified.

There is really reason to think that underneath the rational fabric of science as understood by intelligent persons of common sense there is a vast substratum of something altogether different, but with which a large number of individuals are quite seriously occupied. A′ is only a term in fact of a very considerable series. Every now and then in the pages of this journal strong evidences crop up of the existence of this singular body of knowledge. This existence, however, is scarcely really grasped by the scientific world proper, and it might be compared to a sort of inverse of Prof. Tait's unseen universe.

The present state of things can hardly go on. It is quite certain that, whatever intrinsic interest science of the A′ type may possess, it is of no kind of practical use to ordinary human beings. If it cannot be displaced by the real thing of which it is a kind of phantom, it is a serious question whether the struggle of the examination-room had better not be for a time suspended.

In the meantime it is very important to investigate the true nature of this phantom science. A little work, of which the second edition has been lately sent to this journal for review, appears to belong to its literature, which there is reason to think is rather copious. This particular publication is part of the "Students' Aids Series," bears the motto, "*Mens sana corpore sano*," and deals with botany.[1] It is impossible to seriously criticise it; indeed, from the point of view of what has been said above it would not be easy to do so. We may content ourselves with reproducing textually from its pages the *entire account* given of a well-known and very characteristic group of Thallophytes:—

THE OLIVE SEAWEEDS.

These weeds vary in general appearance from small tufted filaments to immense stalks terminated by a branched thallus.

In the higher forms a shrubby aspect, a kind of r
and an epidermal layer are observed. Their colour is
bright green, but in general olive.

The zoospores originate in **Oosporangia**, situated
ends or joints of the frond, or in each of the cells o
filamentous body called a **Trichosporangium**; th
resemble those of the Green Algæ.

The zoospores from the Trichosporangium have be
mistaken for spermatozoids.

The spores reside in sacs termed **Perispores**, havin
lining membrane, the **Epispore**.

The perispores or sporangia are either scattered or
arranged in **Sori** or groups on the frond's surface, or
cavities, **Scaphidia** or conceptacula, communicating
a pore with its surface.

The scaphidia may appear as club-shaped masses
receptacula at the edges of the frond.

The antheridia are ovate sacs which contain **Antl**
rozoa or **Phytozoa** (two ciliated spermatozoids), a
appear on slender filaments in the same or other plan
and in the same or other conceptacles as the spores.
on the same plant, they are called **Monœcious**; if
different, **Diœcious.** When in the same conceptac
with the spores, they are Hermaphrodite. To the slen
filaments destitute of antheridia the name of Paraphy
is given.

We must leave to our botanical readers to notice
themselves where this instructive specimen of A′ scie
differs from the kind of lesson which an ordinarily c
stituted teacher of real botany would try to communic
to his pupils. At any rate we may ask, would any
having learnt all this by rote (for there is reason to th
that such is the method insisted upon) be secure in rec
nising a piece of bladder wrack when shown to him,
certain of any single fact in its life-history.

A curious point about the A′ science is the copiousn
and more or less unintelligibility of its terminolo
There is no doubt, however, that this is very genera
mastered, however repulsive such a task might seem
first sight. But the problem is still unsolved as to w
is the end gained. With the same effort it is proba
that the rudiments of an Oriental language might
acquired—say Arabic—and the question arises whet
in every way this would not be more profitable.

LEFROY'S MAGNETIC SURVEY IN CANA

Diary of a Magnetic Survey of a Portion of the Domin
of Canada, chiefly in the North-Western Territor
Executed in the Years 1842-44. By Lieut. Lefroy, R.
now General Sir J. H. Lefroy, C.B., F.R.S.,
(London: Longmans and Co., 1883.)

THIS record of magnetical work performed forty ye
ago by Lieut. Lefroy of the Royal Artillery—n
General Sir J. Henry Lefroy—is a contribution of inte
to the science of terrestrial magnetism.

The Magnetic Survey of the British Possessions
North America authorised by Her Majesty's Governm
in the year 1841 at the recommendation of the Ro
Society, and in great part executed in 1843 and 1
under the supervision of the late Sir Edward Sabine,
for its primary objects the determination of the reg
and irregular changes of the magnetic elements, especi
that of the horary variation of the declination; this va
tion being then known as subject to wide differences
the high magnetic latitudes of the northern hemisph

---

[1] "Aids to Botany." By Armand Semple, B.A., M.B., Cantab.; L.S.A., M.R.C.P., Lond., Physician North-Eastern Hospital for Children, Hackney, Physician to the Royal Society of Musicians, late Senior Examiner in Arts at Apothecaries' Hall, late Medical Clinical Assistant and Surgical Registrar at the London Hospital, author of the "Essential Features of Diseases of Children," "Aids to Chemistry" (Inorganic and Organic), "Aids to Materia Medica" (Inorganic and Organic), "Tablets of Materia Medica," "Aids to Medicine." (Double Part.) Third Thousand. (London: Baillière, Tindall, and Cox, King William Street, Strand. Dublin: Fannin and Co., Grafton Street. Edinburgh: MacLachlan and Stewart, South Bridge. Glasgow: A. and W. Stenhouse, College Gate. New York: Putnam and Sons, 1883.)

as compared with those observed in middle latitudes, both in respect of the turning hours and in the direction of the movement at the same local time. Furthermore, investigation of observations made by Polar voyagers and Arctic travellers had shown that the northern part of these British possessions was a region of peculiar interest as comprising in its area the most powerful of the two foci of magnetic intensity in the northern hemisphere, and also the locus of vertical dip commonly recognised as the North Magnetic Pole.

To Lieut. Lefroy—furnished with transportable magnetometers—was assigned the arduous and responsible duty of traversing this region of such striking magnetical interest, to determine the absolute values of the declination, inclination, and intensity at available stations; and at one or more fixed winter residences in high latitudes to make hourly and term day observations of those regular and irregular fluctuations in the movements of the needle presumed to exist in values of more than ordinary magnitude.

Sir Henry Lefroy's present volume contains the diary of his journeys—these latter extending to 5480 geographical miles—in which is given in more or less detail the magnetical elements determined at three hundred and fourteen stations, combined with such astronomical observations as were necessary, in the then imperfect state of the maps of the region traversed, to approximately assign the geographical positions of the places of observation.

The extended series of hourly and term day magnetical and meteorological observations made at the fixed winter and spring residences [1843-44] of Fort Chipewyan on Lake Athabasca (lat. 58° 43′ N., long. 111° 19′ W.), and at Fort Simpson on Mackenzie River (lat. 61° 51′ N., long. 121° 25′ W.), with their very complete and able discussion by Capt. Lefroy, were printed by order of Her Majesty's Government in 1855. This masterly work is well known to those interested in the science of terrestrial magnetism. The Diary now for the first time published is a fitting sequel to the earlier work; and is not the less valuable from what may appear to be its tardy production. The author's preface—which conveys a graceful tribute to his old chief—in a few words clears up the seeming anomaly. He says:—

"The renewed attention directed to the distribution and periodical changes of the earth's magnetism in the North Polar region, suggests an endeavour on my part to present the observations of my magnetical survey of 1843-44 with fuller explanation, and in a form more convenient for reference than that in which they were originally published" [Sabine's 'Contributions to Terrestrial Magnetism,' No. vii. *Philosophical Transactions*, 1846, and No. xiii. *Philosophical Transactions*, 1872]; "and being still the principal authority for the received position of the focus or pole of greatest magnetic intensity, as well as for the lines of equal magnetic force, equal inclination, and equal variation over a large part of the continent of North America, it is certain that whenever they come to be repeated, the observer of the future will inquire for particulars not contained in, and not suitable for, the *Philosophical Transactions*."

Apart from the value of a full record of the observations made over so great an extent of continental America, is the consideration of the graphical treatment of the isoclinal and isodynamic lines, as embodied on maps accompanying the Diary. The author dwells on the difference in rendering the mapped results on the system followed by Sabine—as given in the *Philosophical Transactions*—and on that adopted by himself. Sabine's aim was to present, over the vast area he was dealing with, the normal values of the magnetical elements, free—so far as his judgment permitted—from the local disturbances experienced at individual stations, depending on geological conditions; and stations at which the disturbances obviously affected the assumed normal values were designedly rejected. Lefroy's treatment includes every station at which he set up his instruments, rejecting no observation because of its anomaly where there was no internal appearance of error. By the one investigator we are thus presented with a harmonious mapped system of regular lines or curves indicating equal values of the magnetic elements; by the other the equivalent lines of equal values are more or less sinuous, in some places much distorted, and losing the semblance of regularity.

In the case of the isoclinal lines as so developed, the author partly infers that their greater inflections bear some relation to the courses of the rivers; and he further draws attention to his isodynamic lines or curves, differing both in form and position from those of Sabine.

In a discussion as to the appositeness of either of the systems pursued, it must be borne in mind that, at numerous well-known points on the earth's surface, a movement made by the observer of the magnetic needle a foot or two vertically, or a few feet horizontally, either way, considerably affects the observations. This is notably the case at many oceanic islands, and a marked example is to be found on our own coasts at Canna near the island of Skye. Sir H. Lefroy's experiences in this direction are well marked at Stations LII. and CXXI., where the total force observed was 15·26 and 15·38 respectively; the normal value undoubtedly was about 14·10 and 14·15; the disturbance from a local geological cause thus increased the total force by 1/14th. It is therefore certain that, unless we have some fairly approximate knowledge of the normal value of the magnetic elements at the disturbed station, we should remain in ignorance of the extent of the disturbance.

In the present state of our knowledge of the distribution of magnetism in the several determinate values of declination, inclination, and intensity over the earth's surface—limited in the best explored regions to a very small number of points of observation compared with the great areas of land and water which they represent—it appears premature to give interpretation to local disturbances as being connected with topographical features rather than geological. On general grounds we must consider the delineation of the normal lines in any region as a primary need, whether in a theoretical or a practical direction.

Local magnetic disturbances demand a special study; this has been given effect to in a theoretical direction by Lamont in Germany ("Researches on the Direction and Intensity of Terrestrial Magnetism in Northern Germany, Belgium, Holland, and Denmark in the Year 1858," Munich, 1859), and practically is being now worked out in the United States; it is understood a special magnetic survey of the State of Missouri is nearly complete.

As magnetical observations multiply over large areas of land, it is possible that the normal lines may be found to lose symmetry by disturbing causes which may extend over many square degrees of surface, as distinct from local irregularities. Lamont's observations in continental Europe point to this. A first essay on a large scale has been lately made by the able and diligent magnetician, C. A. Schott, to chart the distribution of the magnetic declination of the United States for the epoch January 1885. In this work distinct notice is taken of all local disturbances in the direction of the magnetic needle, the number of observing stations being 2359. This valuable essay is published as an Appendix to the Report for 1882 of the United States Coast and Geodetic Survey.

It should be observed that in Sir Henry Lefroy's maps the lines of magnetic declination are reproduced as given by Sabine ; in Mr. Schott's paper this is the only element discussed, doubtless from the more ample material at his command, and possibly from its practical value for topographical, geological, or mining purposes.

Whenever the time arrives for undertaking a magnetic survey of the British possessions in North America, Sir Henry Lefroy's Diary will be invaluable as a pioneer work. At the present time his early published magnetical and meteorological observations at Lake Athabasca and Fort Simpson are of great interest in connection with those recently made in a neighbouring region by Capt. Dawson, R.A., at the International Circumpolar Station, Fort Rae.

F. J. EVANS

EXCURSIONS OF AN EVOLUTIONIST

Excursions of an Evolutionist. By John Fiske. (London: Macmillan and Co., 1884.)

MR. FISKE is certainly one of the most successful of the writers who have undertaken the task of popularising the many new ideas which have been originated by the theory of evolution. He has not himself added anything of any importance to these ideas ; but, having accepted them with enthusiasm, he represents them to the public with so much force and clearness, as well as grace of literary style, that while reading his pages we feel how the function of a really good expositor is scarcely of less value in the world than that of an originator. The applicability of these remarks to his earlier works will, we think, be generally recognised by the readers of this journal; and, if so, they are certainly no less applicable to the series of essays which we have now to consider.

The first essay is on "Europe before the Arrival of Man," and it gives an exceedingly clear and well-condensed *résumé* of the present standing of the question as to the probable date of man's appearance in geological time. Next in logical order we have three essays on "The Arrival of Man in Europe," "Our Aryan Forefathers," and "What we learn from Old Aryan Words." Within the compass of the pages allotted to them we do not think that it would be possible to give a more instructive and entertaining history than is presented by these chapters. The fifth essay is on the question, "Was there a Primitive Mother-Tongue?" which is very conclusively answered in the negative. "Sociology and Hero-Worship" is devoted to arguing the relations that subsist between a genius and the age or society in which he lives; this is appropriately followed by the essay on "Heroes of Industry," which is a kind of historical sketch of the philosophical principles that govern the possibilities of invention. A new point of departure is taken in the next three essays on "The Causes of Persecution," "The Origins of Protestantism," and "The True Lesson of Protestantism." Here the main argument is that the rise of Protestantism and the decline of the persecuting spirit are due to an increasing recognition of the right of private judgment, coupled with an increasing refinement of moral feeling. The theory of corporate responsibility, which is more or less essential to the integrity of the social state in the earlier stages of its development, becomes gradually superseded by the theory that the individual is alone responsible for his beliefs and actions ; hence the growing recognition of the right of private judgment. "The Meaning of Infancy" is a brief restatement of the author's views already published in his "Cosmic Philosophy." These are the views which deserve to be regarded as perhaps the most original that Mr. Fiske has enunciated. The general fact that the protracted period of infancy among the anthropoid apes (and therefore presumably among the brutal ancestry of man) must have had a large share in determining the evolution of man is a fact which could scarcely escape the observation of any attentive evolutionist; but Mr. Fiske is the only writer, so far as we are aware, who has treated this fact with the consideration that it deserves. Of the remaining essays, "Evolution and Religion" is an after-dinner eulogium on Mr. Herbert Spencer, "A Universe of Mind-Stuff" is an exposition of Clifford's essay upon this subject, and "In Memoriam: Charles Darwin," is a well-written obituary review of Mr. Darwin's life and work.

As we have not detected any errors on matters of fact, the only criticisms we have to make pertain to matters of opinion. In particular, it appears to us that, in his anxiety to raise the cosmic theory of evolution into a religion of cosmism (or, as he terms it, in his earlier work, "Cosmic Theism"), Mr. Fiske entirely loses the clearness of view and precision of statement which elsewhere characterise his work. Although no friend or admirer of Comte, with a strange inconsistency he follows implicitly the method of the French philosopher in blindfolding judgment with metaphor, and then, without rein or bridle, running away upon a wild enthusiasm. We have here no space to justify this general statement, but we feel sure that no sober-minded man can read the after-dinner speech or eulogy on Mr. Spencer without feeling that its extravagance runs into absurdity. We have no wish to deprive Mr. Fiske of any happiness that he may derive either from his "religion" or from his "hero-worship" ; but we cannot review his essays without observing that in neither of these respects is he likely to meet with much sympathy among "men of science," to whose opinion he habitually professes so much deference.

GEORGE J. ROMANES

OUR BOOK SHELF

The Zoological Record for 1882. Being Vol. XIX. of the Record of Zoological Literature. Edited by Edward Caldwell Rye, F.Z.S., &c. (London: Van Voorst, 1883.)

ALMOST before the shadow of 1883 had passed away, the "Record of the Zoological Literature of the Year 1882" made its appearance, and the circumstances attending its publication are, as the editor informs us, without precedent in the nineteen years during which this important and most valuable annual has been issued. The sudden death on the Niger of Mr. W. A. Forbes, the late recorder of the literature relating to the mammals, was soon followed by the loss of the help of Mr. Howard Saunders in the arduous work concerning the recording of the literature of the birds. These severe losses have been supplied by Mr. Oldfield Thomas and Mr. R. B. Sharpe. In the records of the fishes Mr. Boulenger has had the assistance of Mr. R. Ogilvie-Grant. Mr. Ridley has handed the recording of the Protozoa over to Mr. W. Saville Kent, and the Myriapod literature has fallen to Mr. I. D. Gibson-Carmichael. It thus happens that of the recorders who, just twenty years ago, assisted Dr. Günther in the arduous undertaking of bringing out the first volume of this work, but one, Dr. E. von Martens, still responds to the editor's call, though happily all of the first recorders still survive to overlook and appreciate the labours of their successors.

The editor apologises for some slight delay in the appearance of the volume, owing to the mechanical difficulties brought about by all these changes, difficulties only to be thoroughly understood by those who have experienced them, and which we trust will not trouble the editor again. It is not without interest to note that nearly two-thirds of this volume is compiled by officers of the Natural History Department of the British Museum; indeed, if we include Dr. E. von Martens' work, and remember that he occupies the position of assistant in the Natural History Museum of Berlin, it would appear that over 600 out of 700 pages have been compiled by writers whose lives are devoted to the subjects about which they write.

The editor has again to thank the British Association for the Advancement of Science and the Government Grant Committee of the Royal Society for kindly aid in assistance of the publication. The number of new genera and sub-genera recorded in this volume is 1015 as against 1438 in the last volume, and it will be remembered that this latter number included 483 new genera made by Haeckel.

Each recorder seems to have executed his share of the work well and painstakingly. The special treatment of the literature of each group is on the lines of that followed in the later volumes of the series. We warmly congratulate the Zoological Record Association on the result of their editor's labours.

Sketches of North-Western Mongolia. Vol. IV.—*Ethnographical Materials.* By G. N. Potanin. 1025 pages, with 26 Plates (Russian). (St. Petersburg: Published by the Russian Geographical Society.)

THE first two volumes of this important work contained the results of the journeys by the author in 1876 and 1877. The third, which is in print, will contain the geographical materials collected during the journey of 1879, and the volume we have before us deals with the ethnographical part of the same journey. It begins with an enumeration of the Turkish and Mongolian peoples who inhabit the region: Tartars, Uryankhays, Kirghiz, Durbuts, Darkhats, and Buryats, with the legends current about their origin. There is no general sketch of the populations dealt with; the aim of the author seems to have been to give in this volume a collection of materials, rather than to enter the field of general conclusions. With regard to the former, the present volume is a most valuable one. We find in it interesting facts as to the family, social, and religious life of the inhabitants; a list of names of stars, plants, and animals, together with the beliefs about them, and finally, their legends and folk-lore. Of these, no less than 200 are given, containing a rich and new source of information. On almost every one of the 500 pages occupied by these legends and tales one is attracted either by their poetical beauty or by the light they throw on the mythology and popular conceptions of the inhabitants of this border region of Central Asia; while M. Potanin's name is the best warrant for the accuracy of the transcription of the legends reported. However rich this material, one hesitates to say which of the two is more valuable, the folk-lore published, or the annotations which follow them. These last cover 300 pages of small type, and we find there, philological explanations, comparisons with the legends of other Finnish tribes, most valuable materials for comparative mythology, and so on, all being the result of a thorough study of nearly the whole of the Russian literature of the subject, disseminated through periodicals of the most various descriptions. While perusing these invaluable materials one only regrets that the author has not yet been brought to summarise his wide studies and to draw therefrom some conclusions which may enter into the domain of science. In any case a careful index of all matter mentioned in the volume would much facilitate the researches. The plates represent mostly the pictured tambourines of the shamans and the *ongons* (holy pictures and idols) of the Tartars, Uryankhays, and Buryats.

P. K.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Quintino Sella

IT is proposed to place a bronze wreath on the tomb of the distinguished Italian geologist and statesman, Quintino Sella. English geologists are invited to express their sympathy with their Italian fellow-workers by sending in their names with a small subscription. I have been requested to bring the matter before their notice, and to collect the subscriptions in this country.

THOS. M'KENNY HUGHES

Woodwardian Museum, Cambridge, March 25

Electrostatic Measurement of E.M.F.

PERHAPS you will allow me to make known through your columns to those who have from time to time made inquiries concerning my Absolute Sine Electrometer, that, after many months' work, I have satisfactorily concluded a series of experiments with the instrument which was made for Prof. Anthony. When this instrument was finished last year, I made some observations with it which were so unsatisfactory that I did not feel justified in allowing it to be sent to America. I have now, however, removed all the difficulties connected with it, and I uniformly obtain results perfectly consistent one with another. Indeed my difficulties during the last six weeks were due to the fact of my employing cells which were not sufficiently constant, and not to any fault of the electrometer, a fact which I did not realise for some time.

I hope to publish in a few days a full report on the various points connected with the instrument and on the experimental results obtained.

GEORGE M. MINCHIN

Royal Indian Engineering College, Cooper's Hill, March 24

Pons' Comet

THIS comet has been visible here some time. I first saw it at 9 p.m. on January 15, but only for two or three minutes, through the clouds. On the following evening (January 16) I saw it well. To the naked eye it looked like a star of the first magnitude seen through a haze; the tail was visible, but not at all conspicuous. In the telescope (4-inch) the head was large, but appeared wholly nebulous, with a bright central condensation; the tail broad, but faint. I could only trace it some 2° or 3°. The brightness of the nucleus must have been considerable, as when close to the horizon I could see it through a pretty thick cloud. Subsequently the nucleus has seemed to me decidedly more disk-like, I suppose from being better seen. I may add that the sunset-glows and the unusually cloudy weather we are having have interfered greatly with satisfactory observation.

Nelson, N.Z., February 1 A. S. ATKINSON

The Access to Mountains and Moorlands Bill

I AM glad to observe that you have called the attention of scientific men to the importance of Mr. Bryce's Bill. Perhaps nothing can better show the need of such a measure than certain facts in regard to the Clova district in Forfarshire, which is classic ground to the botanist; indeed, I think I may venture to say that it is the richest ground in the British Islands. From time immemorial a right of way existed through Glen Dale, and, I can remember the time when botanists could ascend any of the hills in that district without being subjected to the tender, though somewhat embarrassing attention of gamekeepers. I have good reason to believe that the case is somewhat altered in recent years, and that, after a man has gone hundreds of miles in order to see *Oxytropis campestris* growing in its only British station, he may find himself turned back just within sight of the goal. The thing can still be done by taking advantage of a curious fact in natural history, viz. that two gamekeepers cannot remain long in loving converse with three men: by keeping this fact in mind, one out of three may still study the botany of Clova. After having gone pretty well over Scotland I am glad to say that there are many places in which there is no need for Mr. Bryce's Bill. In most cases in which it is needed it is where "new men" usurp a power which the old lords of the soil never dreamt they possessed. A. CRAIG-CHRISTIE

Edinburgh, March 24

A Sixth Sense

IN the valuable address given by Sir William Thomson at the Midland Institute, Birmingham, on October 3, and reported so fully in the columns of NATURE, it is implied that Dr. Thomas Reid of Glasgow brought out the distinction of a sixth or muscular sense. I cannot find any satisfactory evidence of this, although Reid came very near it indeed when he stated in his "Inquiry into the Human Mind," chap. v. section 1:—"By touch we perceive not one quality only, but many, and those of very different kinds;" and again:—"There is, no doubt, a sensation by which we perceive a body to be hard or soft;" and again, further on he even speaks of its being strange that this sense should "be so much unknown as never to have been made an object of thought or reflection nor to have been honoured with a name in any language."

And on the other hand, while I cannot detect any attempt whatever to refer this sensation to the muscles as its peripheral origin, while speaking of our conception of the hardness of bodies, Dr. Reid says (p. 121, ed. of 1846):—"We have no way of coming at this conception and belief, but by means of a certain sensation of touch;" and again, "I see nothing left but to conclude that, by an original principle of our constitution, a certain sensation of touch both suggests to the mind the conception of hardness and creates a belief of it." Reid, in short, like his eminent predecessor Hutcheson in the same chair, was dissatisfied with the ordinary division of the senses, and really felt disposed to split up the varied phenomena bundled up under the term "touch" into two or more divisions; but it was reserved for Dr. Thomas Brown, a good physiologist according to the light of the times, and Professor of Moral Philosophy in Edinburgh (1810-20), explicitly to complete the distinction hinted at by Reid, and to refer our conception of resistance or tension (as we find in estimating weights by the hand) to a distinct sixth or muscular sense. Thus in his twenty-second lecture he says:—"The feeling of resistance is, I conceive, to be ascribed, not to an organ of touch, but to our muscular frame, to which I have already more than once directed your attention, as forming a distinct organ of sense." In the lecture which follows that, Brown admits the frequent mingling of mere tactual sensation with that of muscular effort:—"But it is not of this mere tactual feeling we think when we term bodies hard or soft—it is of the greater or less resistance which they afford to our muscular contraction."

It is remarkable that the teaching of this eminent psychologist, the preceptor of James Mill, should so early have been forgotten in Scotland. HENRY FAULDS

Laurel Bank, Shawlands, Glasgow, March 18

MR. FAULDS, in the preceding letter, is no doubt quite correct in remarking that the distinction pointed out and insisted on (not merely hinted at) by Thomas Reid, a little more than a hundred years ago, in the Moral Philosophy Chair of the University of Glasgow, was more clearly and fully defined by his eminent successor in Edinburgh, Thomas Brown. But I cannot agree with his last sentence, implying that Thomas Brown is forgotten in Scotland. In fact, my mind was so full of Reid and Brown, from my recollections of the teachings of the Professors of Moral Philosophy and Logic in this University, that, in giving my address at Birmingham, I said Thomas Brown, meaning Thomas Reid, but feeling the names of Reid and Brown both thoroughly mixed up with all I had ever learned of this subject. WILLIAM THOMSON

The University, Glasgow, March 20

Earthworms

THE theory of the formation of vegetable mould through the action of earthworms, by Darwin, received little attention when published from people who had been accustomed to examine the soils of various countries. That the vegetable soil had been formed as he states seemed to have been accepted by his followers without hesitation. In your columns, however, of late, letters have appeared from Messrs. R. M. Christy and T. E. Wilcox, showing that earthworms do not exist in the prairies in the north-west of Canada or in the United States, in those of Kansas, the Indian Territory, or in Idaho and Washington Territory. This is simply what may be expected. Notwithstanding the keenness of observation of Darwin and his width of observation, there seem vast regions where earthworms have had little to do with the formation of the vegetable soil. In many parts of Australia, and also in the moister climate of New Zealand, the soil affords few indications that earthworms ever passed it through their bodies. In a section of soil I brought from the Mataura plain, South Island of New Zealand, nothing could be seen to indicate that worms had ever swallowed it. That vegetable soil forms a fit habitation for earthworms is undoubted. Darwin admits "that a layer, though a thin one, of fine earth, which probably long retains some moisture, is in all cases necessary for their existence." Before this thin layer existed, how could they—the worms—form vegetable soil? This thin layer must have been formed in some other way; Darwin does not say how. It is not necessary to call in the aid of earthworms to do so. The very name which has been universally applied to the thin upper covering, the exterior film enveloping the surface of the deposits underneath, viz. vegetable soil, speaks to its origin in the decay of vegetation. Take for instance the boulder-clays of this part of the Lothians in Scotland, with their tough, stony texture, their pebbles as finely striated as when the ice squeezed them into the pasty mass of crushed shales out of which they appear to have been partly formed. While these surfaces could have afforded none of the conditions required by Darwin, or indeed supply any other save inorganic food, the slow growth on their surfaces of the more simple forms of vegetable life, and their decay, would in the lapse of ages supply the thin film which Darwin requires. It surely, then, is attempting too much to ascribe to the earthworm the formation of the vegetable soil. The earthworm is not the only occupant of the material which the growth and decay of vegetation supplies as a surface covering. The earthworm is not the only drainer. The roots of many plants not only descend deeply into the subsoils, but also fetch up from depths where worms could not reach supplies of material to mix with the superficial covering; and so do the various insects which have their habitat in the soil, burrowing as they go, and casting, like the mole, the stuff behind them or upwards as they descend.

So far as I have examined soils, I am inclined to think that the earthworm is far more plentiful when animal matter in a decaying state is applied to soils near the dwellings of man, or when his deposits are laid over those of the larger animals. As against the views of Hutton and Playfair, and as stated by Darwin, that the vegetable soil or mould is always diminishing, I have to say it seems entirely the reverse; it seems to have had a beginning, is increasing, and shall increase so long as vegetable and animal life covers the surface of the earth. This is not the case where vegetation ceases to cover the surface, and the sun and wind get direct access to the surface; any soil that may have been formed there soon disappears. In such situations, until vegetation has again spread itself, all the earthworms that could congregate there would only add to the decaying animal matter, as live they could not, there being no food for them in the absence of vegetation and other animal matter.

Bonnington, Midlothian JAMES MELVIN

I INCLOSE an excerpt from NATURE of January 3 (p. 213), which I saw in one of our daily newspapers. The observation there made is correct as to the absence of earthworms in the region mentioned, but the reason assigned is, I think, incorrect. It is well known to settlers on virgin soils in this country that in the first tillage of the ground they will see no earthworms. This is equally the case whether they settle upon prairie land which has been swept annually by fires, or upon wood land which has been cleared for cultivation and which has never been burned over. Even in the natural meadows called "beaver meadows," which one will chance upon in an otherwise completely forest-covered region, one will at first find no sign of the earthworm. Some sluggish stream is dammed by a colony of beavers, and the land flooded is cleared of trees by them. Alluvial deposits accumulate, and when the beavers have been killed or driven away the dam is destroyed by freshets, and the little stream regains its former dimensions, while the flooded ground, drained naturally, becomes a meadow covered with wild grasses nourished by rich depths of soil. But, until settlement and tillage by man, there is no trace of earthworms even in these most favourable localities. At first they are found about the stableyard, then in portions of ground enriched by stable manure, garden or meadow, till at length they may be found in all soils, either those cultivated or those pastured by domesticated animals.

For years I have been accustomed to go to Mukoka, in the Canadian Dominion, for shooting and fishing. This section is a wooded wilderness with numerous lakes and streams. It is still Governmental wild land, and in part unsurveyed for settlement. The frontier settlers there tell me that until a place has been inhabited for five years it is useless to search for the earthworm. HY. F. WALKER

8, East Thirtieth Street, New York City, U.S.A., March 5

The Remarkable Sunsets

THE following extract from a letter written at Auspaki, province of Vitebsk, Russia, may be of interest:—

"*February* 26 (Old Style), *March* 9

"February has been the coldest and the pleasantest month this winter, particularly the latter part of it; frost from 5° to 12° Reaumur; bright sunshine. Now we have been able to see the roseate sunsets, which for at least three months have been hidden by clouds. We are, however, so accustomed to brilliant sunsets here, that we might not have remarked them if our attention had not been directed to them. Here, generally, when the sky is clear and the frost severe, the eastern horizon is a misty blue, above which is a rosy streak melting away into the clear blue above. But these latter sunsets have differed from that in a great measure. The west has often been blood-red, and the eastern horizon has been rosy, not so much in a streak but in patches, which have sometimes been visible over head. At the beginning of the month I was in Riga, and found the river open below bridge; indeed, the navigation has not been closed the whole winter. Snow there was none in Riga, and I saw them carting the most miserable ice for the ice-cellars; I think it was little more than six inches thick. We have been favoured here; we have retained our snow, and have had, and still have, good sledge roads. We filled the ice-cellar the day before yesterday, and the ice was more than a foot in thickness. . . ." J. M. HAYWARD

Sidmouth, March 24

THOUGH we are no longer favoured with the gorgeous sunsets which marked the autumn and early winter, yet two phenomena are still frequently visible which seem referable to the same cause as those splendid displays.

The first is the unusual *white glow* in the western sky before sunset which was an almost constant precursor of the brilliant and long-continued colouring of the past months. It was very marked on November 8, the occasion of the first remarkable sunset, and it is still to be seen on almost any fine evening before the sun sets, though it is no longer followed by the more striking phenomena.

The second is a decidedly unusual *pink tinge* occasionally visible for some ten to twenty degrees round the sun when shining in a somewhat hazy sky, the colour being brought out with great distinctness if light cumulus cloud happens to be passing across it. I first observed it about 1 p.m. on Sunday, March 2, and it was very marked last Thursday (20th) between 10 and 11 a.m., and again on Friday (21st) between 1 and 2 p.m., as well as on one or two other days which I have not specially noted.

May not both be due to the gradual subsidence to a lower level in our atmosphere of the particles which at a higher elevation caused the wonderful colouring of the past months?

Hampstead, March 24 B. W. S.

P.S.—Since first writing the above, I see in NATURE that it was from March 1 to 3 that the fall of dust was noticed at Kilcreggan. Writing from the neighbourhood of London, it may be as well to say that the appearance is wholly different from any effect of London smoke (with which I have been familiar for nearly fifty years) both in colour and in being produced at a higher level than that of ordinary clouds.

"Curious Habit of a Brazilian Moth"

IN NATURE for May 17, 1883 (p. 55), appeared a letter entitled as above, by Mr. E. Dukinfield Jones, in which the author stated that he had observed a kind of moth in Brazil engaged in sucking up water in large quantity through its proboscis. I may say that this strange habit is not confined to *Panthera apardalaria*, as I have observed the same thing in two species of butterfly (*Papilio orizabus*, B., and *Appias saba*, F.), and imagine that the phenomenon is by no means rare. These two butterflies are very common by the sides of streams and damp places on the Ankay plain in Madagascar.

One morning while sitting by the side of one of these streams I noticed the Papilio, which is an insect measuring about four inches from tip to tip of its wings, resting on the wet bank; and wishing to procure it as a specimen, I approached it as gently as possible, the creature being apparently so absorbed in what it was about as to be totally unconscious of my proximity to it. Noticing strange and unaccountable movements—sundry jerks and probings with its proboscis—I quietly sat down near it to watch it more closely. I observed that every second or two a drop of pure liquid was squirted (not exuded merely) from the tip of its abdomen. I picked up a leaf that was lying near, and inserted the edge of it between the insect's body and the ground so as to catch the liquid. Unfortunately I had no watch with me at the time, nor means of measuring liquids; but I reckoned that about thirty drops were emitted per minute. I held the leaf for about five minutes—as nearly so as I could reckon—and at the end of that time there was caught in it about a saltspoon full of what seemed to be pure water, without either taste or colour. After watching the butterfly for a time, I seized it by the wings between my thumb and fingers with the greatest ease, so utterly lost did it appear to be to what was going on near it.

In another spot I saw as many as sixteen of these large butterflies within the space of a square foot, all engaged in the same strange action. Some of them emitted the liquid more frequently and in greater quantity than others; and one of them squirted the liquid so as to drop fully a quarter or a third of an inch beyond the point on the ground perpendicular with the end of its body. It was at this spot that I saw the second of the butterflies alluded to also engaged in the same curious proceeding.

Antananarivo, Madagascar, January 3 R. BARON

Representation of Students

THE students in residence at Girton College are indirectly represented by the members elected by the "certificated students," but cannot themselves, whilst they are in the condition of undergraduates, elect a representative on the governing body.

The College Hall of Residence has advanced one step further in the same direction by offering direct representation to students *in residence*, and it is this new departure which was mentioned in NATURE (vol. xxix. p. 388).

Ever since the establishment of Girton College, students in residence have valued their prospective right to have a voice in the management more dearly than would generally be credited, and have held that Girton stood first among colleges for women partly because it conferred this dignity upon its students.

But the dignity conferred by the actual enjoyment of a privilege exceeds that conferred by a prospective right to the same privilege. ANOTHER CERTIFICATED STUDENT OF GIRTON COLLEGE

"Suicide" of Black Snakes

IN NATURE, March 13, p. 452, Mr. Edward Hardman, Government Geologist of Perth, West Australia, mentions an instance of the suicide, by its own venom, of a black snake. The snake had been wounded, and, the wounded part having been attacked by black ants, "it instantly turned short round and hit itself twice on the neck with seeming determination; in less than one minute it was dead." Mr. Hardman believed the death to be due to its own venom.

He records further instances, *which, though he had not witnessed himself*, had been *related* to him by those who had witnessed the facts.

I believe it to be a generally accepted opinion among thanatophidiologists that, from what is known of the virulent properties of snake-poison, though fatal to man and other living beings, it is innoxious in its effects to serpents of like nature. Sir Joseph Fayrer, a great authority upon this question, has said: "Strange to say—and this to me is one of its greatest mysteries—a snake cannot poison itself or one of its own species, scarcely its own congeners, and only slightly any other genus of venomous snake, but it kills innocent snakes quickly" (address on "The Nature of Snake-Poison," delivered at a meeting of the Medical Society of London, January 28).

The glands which secrete such venom draw their secretion from the blood; that blood, therefore, must have within itself, as part of itself, the elements which constitute its virulence, and cannot therefore be injuriously affected by a further introduction of these elements. Their presence in the blood gives to this vital fluid a power whereby an immunity is obtained, somewhat similar to that which vaccination and syphilisation give to human beings, and which the vaccination of the cultivated virus of anthrax, of rinderpest, of foot-and-mouth disease, gives to animals.

It may, however, happen that the climate of Australia has a special action producing effects different from those observed in India, and, if so, requiring close investigation and study.

The question becomes an interesting one, and, if philosophically prosecuted, may elicit facts which would give to this instance of venom envenoming itself a significance and an established position in the history of natural science.

JAMES DONNET

Unconscious Bias in Walking

THIRTY or more tests in walking, with closed eyes, on a nearly level lawn lightly covered with newly-fallen snow, gave the following results:—My natural gait, in which I step a half to three-quarters of an inch further with my right foot than with my left, always produced a sharp curve to the right. Whenever the step made by either foot was about three inches greater than that made by the other my course was substantially straight. A curve to the left always resulted when either foot stepped more than three inches further than the other. Unnatural toeing out of either foot did not change the result. My right arm is three-quarters of an inch longer than my left, but my legs are of equal length. Both limbs on my right side are stronger and more skilful than those on the left. When but a single action is required, it is my right arm or my right leg that prefers to perform it. When two actions are necessary, the right side chooses that requiring the greater skill, leaving to the left the plainer work, regardless of the power demanded by it. Thus, in mounting a horse, or leaping across a ditch in the ordinary manner, I spring from the left foot; yet if I am to land on the foot from which I start, I can hop higher and farther with my right leg. I can also lift a greater weight with it; and can lower myself to, and raise myself from, a kneeling position with the right leg alone—a feat impossible for me to perform with the left. In my case, at least, the division of labour is decided by skill, and not by strength. These facts, considered in connection with the further observation that in walking the foot which for the time being supports the person does not rock into a pushing position until the other foot has completed its forward motion and is ready to drop to the ground, incline me to the opinion that walking is a reaching rather than a pushing process. Perhaps photography may help to decide this point. J. E. SMITH

New York, March 10

Recent Weather in North America

THE ice-storm, as we call it, which we have lately experienced, seems to call for a permanent record. It began at about 4 p.m. on the 7th inst., and until 12 noon of the following day there was a constant drizzle or rain, the thermometer being a few degrees below the freezing-point. The amount of the rainfall at the surface of the ground was 1·10 inches. As the rain fell upon the trees it soon formed a coating of ice upon every exposed branch and twig, and this grew thicker and heavier until saplings were bent to the ground and large branches were broken from many trees over a wide area of country. The wind blowing gently from the north, the coating of ice was much thicker on that side of each twig or branch. Fences were decorated with long icicles hanging at a decided angle towards the south. Telegraph wires were so heavily loaded that many fell, and some of them, besides the coating of ice, had a most curious decoration in the shape of little icicles hanging about two inches apart, some of them appearing horizontal, and some (it is said) actually pointing upwards. The storm is reported as having extended over an area of some 20,000 square miles. It was not immediately followed by a thaw, which might have relieved the trees of their load; a gentle precipitation, partly of snow and partly of sleet, took place at intervals from 5 p.m. on the 8th till early in the morning of the 10th, the temperature remaining below freezing. The view on the 10th, when the clouds broke away and the sun shone on the trees, was beautiful beyond description, but the most remarkable effect was that produced by the moonlight on the evening of that day.

In order to gain something like an accurate idea of the amount of ice which had frozen on the trees, I made measurements of a number of twigs taken from the extremities of branches, in order to compare their diameter in their natural state with that they had when covered with ice. Some of the figures may be of interest. One twig ·11 of an inch in diameter was enlarged to ·73; another of the same size to ·84; one of ·12 inch diameter measured ·84 with its ice-covering, and another of ·12 inch measured 1·03; one of ·18 diameter had become 1·21, and one of ·21 had become 1·07. The largest ratio of increase which I found on a tree was in the case of a twig ·09 of an inch in diameter, which had attained to ·97, having gained nearly nine times its original diameter. But some upright stalks of weeds standing about eighteen inches above the ground gave still larger proportional measurements. One 5/100 of an inch in diameter now measured ·87, and another of 4/100 of an inch measured ·85, having increased its diameter by more than twenty times.

I made another estimate of the quantity of ice on the trees by breaking the ends of some branches from an apple-tree and weighing them with and without the ice that coated them. It appeared that wood which weighed ten ounces was carrying ice which weighed sixty-nine ounces.

Perhaps it should be noted that the ice did not freeze on the twigs or stalks so that the cross-sections would be exactly circular, and that the measurements made were those of the largest diameters in the several instances.

Prof. Brocklesby writes to the papers of a similar storm many years ago, when a piece of branch weighing four ounces carried four pounds of ice. SAMUEL HART

EDUCATION IN THE UNITED STATES[1]

A SUCCESSFUL effort made to meet a strong desire that this Report should be brought out sooner enables us to call attention to it in less than twelve months after the last, but, as in material food so in the case of the many reports embodied here, thorough digestion has been essential.

---

[1] "United States Report of the Commissioner of Education for the Year 1881." (Washington: Government Printing Office, 1883.)

An additional interest, moreover, is lent to this Report by the working up of the information supplied by a Compendium of the Census of 1880. Here are given very full particulars of the changes in distribution of population during the last ten years, and of the amount of education still required by its various classes.

As to the former we may mention in passing that the Report calculates that more than half the English-speaking people of the earth live now in the United States, which in size and population has become the fourth nation of the world. Rather more than one-eighth, six and a half out of fifty millions, of its inhabitants are immigrants; and a singularly similar proportion exists between the coloured and the white population. Emigration is a stream westwards, not only across the Atlantic but across the continent of America. While 1,211,000 of the population of the State of New York were immigrants to it, 882,000 had emigrated from it. Nearly 10,000,000 out of 43,000,000 of natives had moved from the States of their birth to other States. It would seem to an Englishman in his own land that this "unsettled" state of the country must loosen all the feeling of attachment to the soil suggested by the word "home"; but it must, as the Report describes, tend immensely to consolidate the widespread territories; and it certainly suggests the fairness of the great work of education being made a national and not a State function.

Of the emigrants from Europe there were twice as many from Ireland as from Great Britain, but the Irish were equalled in number by the Germans alone, and the total Teutonic immigration in proportion to that of Irish was as 40 to 18. "The preponderance, therefore, of Celtic methods and ideas among our immigrant population is at an end, at least for the present. The German, Scandinavian, and British elements will exert an ever-increasing Teutonic influence, and will form a strong, steady, and sensible influence to counterbalance the volatile and brilliant qualities of the Irish blood. Not the least among the attractions which have drawn to America the Swedes, Danes, and Norwegians whose steady industry and stalwart vigour is felt with immense effect along the northern border States and Territories, are the schools, to which they give their hearty support. In these schools they find less of class education in America even than in Germany, where the children are separated, the high from the low, the rich from the poor, at the entrance into the school-room; instead of the social intercourse, the common interest, the mutual enjoyment which may be the result of the American public school." Nor is all the advantage to the immigrant only. "The influence of the Germans has been exercised in behalf of better methods of primary instruction, thorough training, and high standards in the intermediate and higher grades, the introduction of the German language into the schools, and science training, especially as related to the development of our internal resources." Much do we want more of a similar element in England! Much information is condensed in sixteen diagrams or outline maps showing at a glance various results of the census.

A list is given of 251 "cities," towns, that is, containing over 7500 inhabitants. Belonging to these are—

17 per cent. of the population;
26 ,, ,, daily attendance;
33 ,, ,, annual school income;
49 ,, ,, school property.

Nothing can speak more strongly than the above figures of the advantage to education afforded by the concentration of population such as is the case in England. Even in a country where the rural population forms five-sixths of the whole, and is felt to be of vastly greater importance than it is in England, only one-half of the school property and two-thirds of the income is devoted to them; whereas, to secure equal advantage to the scholars, these proportions ought to be more than reversed. As it is, a rural school and an ungraded school are almost synonymous, and more exact reports from each State of their efficiency and means are strongly urged, and their want of trained teachers regretted. But even in the cities the population keeps ahead of the provision of "sittings," till New York already requires over 50,000, and Brooklyn and Chicago over 30,000, more than their present supply. The latter has been driven to the certainly unhealthy practice of "double divisions," teaching, that is, one set of children after another within twenty-four hours. Very far, therefore, are these large cities from carrying out the suggestion here quoted from the London School Board, of providing schools beforehand for increasing population.

The excess of female over male teachers has become a national characteristic, and our Report accounts for it not only by the superior attractions of pioneer life for the men, for it is the case even in States where men largely preponderate; but also by the industry and intelligence which have become the inherited tendencies of the women of the Northern States. In the colleges, accordingly, we note that just over ten thousand women are being co-educated with men, and "the experience of these institutions shows that co-education is entirely practicable, and is recommended by their officers upon considerations of economy, its agreement with the conditions of family life, and its practical results." The equal capacity of women with men for higher education, our Report asserts, has been conceded both in Europe and the United States; and it quotes elsewhere the large increase of female pupil-teachers in England compared with the corresponding increase in males. Extra care has been given to the reports on this subject, both on account of the attention directed from other countries upon the United States and also because it may well form a standard of social progress. But the "meagre wages" of which the Report speaks are illustrated by the fact that even in Pennsylvania, where excellent provision is made for the examination and appointment of teachers, the average salaries for men were about 40*l.* for the six months' teaching required in the year, and 33*l.* for women, while in Alabama the average was only 20*l.* A large increase in the number of female students at the normal colleges shows, however, that these wages are not to be spurned, if they do not attract the highest talent desirable. All Bills introduced into Congress agree in providing that a large part of the national aid proposed shall be applied to the increase of teachers' salaries. It would seem, however, that the difficulty of the thinness and dispersion of the population causing schools to be small, and therefore education per head costly as well as inefficient, is rather increased by an unwise feeling of independence which objects to be joined with neighbouring districts, even where distance allows it. To gratify this same feeling, also, the State Government, after laying down wise and complete rules, has left in some cases to the school authorities and to the people themselves in each city or town, the whole practical control of the work. It is like passing an Act of Parliament without making it the duty of any body of men to see that it is enforced. A State supervision is a step towards centralisation, which is, no doubt wisely, recommended strongly by our Report.

The desirability that curriculums should be laid down by the central authority is quoted as the experience of the world, and of Belgium particularly, where, whenever the schools have followed definite programmes, progress has been marked, while in schools in which the whole matter has been left to the teachers routine has prevented it.

The long recesses, caused in a new country by the scarcity of labour during harvest times, so shorten the educational year that while on the one hand it is felt that not enough is provided for in the curriculum of most schools, on the other hand, time is too short to allow the effective teaching of what is already there. The Report remarks that it is impossible to examine the various courses without being struck with the general neglect of elementary science; adding that "the rural schools would seem to be favourably situated for the study of nature in some of her varied aspects. The well-known effect of such study upon the mind, its value as a resource to the individual, and its relation to the tendency of modern thought, are so many reasons for its introduction into these courses."

The higher classes, we are told, are working harder at the schools, but the key to the reports from so many States in which population as well as cost and efficiency are said to have increased while attendance has not, evidently is that a class is rapidly increasing in America now who make no demand for education and do not appreciate it. The chief of the four recommendations with which the Report ends is the appropriation of more national land for the purposes of education in impoverished portions of the country. Yet the special reports of New York and Connecticut show that ignorance is not caused by want only: for the reduced attendance is accounted for by commercial prosperity and demand for labour, during which a hard-struggling population is tempted to forsake school in order to earn money.

Maryland reports great illiteracy among both blacks and whites, and shows a decrease in everything except expenditure. North Carolina is much more satisfactory, partly through the help of religious bodies, who are making great efforts for the benefit of the negro, whose education remains the difficult question of the United States. More than half as many more black children are uneducated in the whole Union than white children. From the Report it is evident that many of the Northern States feel that they are already heavily taxed for the support of their own schools. Yet their wealth is immense compared with that of the Southern States; the Report quotes personal property and real estate as two and a half times greater per head in the three States of New York, New Jersey, and Pennsylvania than it is in the south. Again, it is a small class in the north that does not appreciate education, but in the south not only is the negro himself careless about it, but there is often to be found among the whites a bitter hatred of the educated black. It is absurd to leave a difficult and costly matter like his education in the hands of his late masters, and expect them to both do it and pay for it; and the only practical method is, as our Report recommends, for the nation to establish and maintain good schools in the face even of hostility. In some places where the Peabody Fund is pushing the work on, the negro is better cared for than the white child, but its administrators cannot undertake the education of a whole people.

The endeavour to make elementary science a feature of the higher grade schools has revealed the same difficulty as has been pointed out at home, viz. the lack of teachers prepared to give the instruction. "The lifeless routine of memorised recitations is worse than useless in science. It paralyses the faculties by which the facts of science are apprehended, and renders true progress impossible. This is a matter demanding attention in normal schools." In a few cities special means have been provided for meeting the emergency. In Boston, courses of lectures were given successfully by the professors of the Institute of Technology upon different branches of natural science, designed to meet the want of teachers; and a similar course before the Teachers' School of Science, on physics, zoology, botany, and geology, were well illustrated by experiments and specimens, and attended by 400 teachers, the entire expense being borne by two ladies. The Lawrence Scientific School, Harvard University, teaches all the principal sciences experimentally, students being assisted also by scholarships. Many women in the normal colleges are now giving special attention to them. A branch specially recommended to be taught there is the laws of health. Of all agencies these normal schools can do most to promote the systematic training of the body. A gymnasium, the study of physiology, hygiene, and sanitation are urged as invaluable to teachers, and it is to them that we must look in some measure for the diffusion of knowledge with reference to the laws of health. A quotation from Dr. Schrodt is made, almost equal to saying that every boy when he leaves school "ought to be either a fool or a physician"! The laws of health should be made as familiar to the minds of children as the rudiments of language and numbers. We are glad to note in Prof. Hitchcock's report on college hygiene that he recommends simultaneous care of the digestive organs with relaxation of mental effort, rather than violent exercise, for students. A larger number of the training schools report laboratories, museums, &c., and the Bureau urges the usefulness of an educational museum from which it would circulate illustrations of the most improved appliances.

Passing to more specialised education, hardly any schools have increased in every way more than commercial and business colleges; there were one-fourth more establishments and scholars than in the previous year.

Kindergarten schools had more than 60 per cent. more scholars. They may well be supported if they carry out all that their programme lays down, which includes, and indeed places foremost all that ought to be the work of home, and uses the word education in its very widest sense. The training described in the normal kindergarten schools surely must wonderfully assist all the students in their future duties as mothers; and an orphan in the care of one of these schools, many of which are carried on as charities, is hardly to be pitied!

Two fewer colleges, but more property and greater teaching power, with 3000 more students, shows that the multitude of these institutions in the United States is being checked by natural selection, while greater efficiency is found among the surviving fittest. Much interchange of the inhabitants of the various States to the Universities of others takes place. There is happily hardly any local feeling in favour of attending a college in the student's native State, and there could hardly be a more unifying action upon a population like that of the United States than this of students meeting from all points to disperse again and take influential positions in all quarters.

At Harvard College the President remarks that the scientific turn of mind is comparatively rare among the young men who enter the college, a large majority of the students preferring languages, metaphysics, history, and political economy to mathematics, physics, zoology, and botany—perhaps the result of the training in the secondary schools. But studies made to a great extent elective have not led to the choice of those requiring least effort. Many more selected scientific subjects in their senior than in their junior years. At Columbia College geology was elected by every member of the class, and astronomy by all but one. About three-fifths selected chemistry, two-fifths philosophy, and one-fifth political economy. Studies are thus selected in harmony with tastes and proclivities, and pursued with interest and satisfaction. "The mental discipline incident to the study of chemistry especially entitles the science to take a place among advanced courses of study, a truth recognised by many collegiate institutions, both by giving the science increased attention in fixed courses, and also by placing it on an equality with classical and mathematical studies when the elective system has been adopted."

Well worthy of the attention of all friends of technical education in England are the numerous efforts to carry out the same desirable ends in the United States. A school of applied science has been organised at Cleveland, Ohio, for this purpose. "The course of study will be four years in length. One half the time will be spent in a careful study of mathematics, chemistry, physics, modern languages, and the methods of scientific research, the other half in professional studies in some department of applied science, as mechanics, in which are unfolded the laws of natural forces underlying processes and existing in materials. Mathematics has given the rules of calculation; drawing, a skill of eye and hand; and shop-practice, familiarity with actual labour accurately performed." Fourteen similar institutions during the last ten or twelve years have been started, but in all of them, as may be expected in a new country like America, the great demand is for knowledge in the arts of working wood and iron; the former is taught from felling the tree to cabinet-making, and since little of such work can be done without the aid of the companion art of working metals up into tools and machinery, they are, in varying proportions, taught together in nearly all. Several schools report that the time—in some cases two afternoons a week—assigned for shop-work did not diminish the intellectual tasks required. Rather less ambitious in its aims, but excellently practical, is the Worcester County Free Institute, founded by some gentlemen of wealth for the training of boys for the duties of an active life, "broader and brighter than the popular method of learning a trade, and more simple and direct than the so-called liberal education." The education there is based on mathematics, living languages, physical sciences, and drawing, but the distinguishing feature is the method and amount of practice in a machine-shop. A manual training school also at Boston and a school for miners and mechanics of a little lower grade still at Drifton, Pa., are schools in each of which an increasing proportion of time is devoted to technical subjects, in the latter entirely free.

On the whole, nevertheless, with seven and a half million dollars bequeathed for educational purposes during 1881, our Report regretfully remarks this year that the "claims of science do not seem to be sufficiently regarded by the benefactors of learning." While these various schools of science have increased in number slightly, and teachers and pupils by about one-tenth, schools of theology, though similarly increased in number, have lost one-tenth of their pupils.

Like the higher colleges, the schools of law have fallen off in number, but they contain more pupils. The influence of their work as affecting all future legislation in the States, and therefore the importance of their pupils being grounded in the science of legislation and not learning it in offices only by the rule of thumb, is wisely urged. Here it is history which is chiefly required to underlie "technical" training. Still more must every one feel the necessity for a high moral as well as mental standard in a profession that has in these days gathered such despotic powers to itself.

Many weighty remarks, similar to those we referred to last year, on the insufficiency of the medical course of study, are to be found in this Report. The necessity of elevating the standard of medical education is universally admitted, and a general improvement to some extent is noted. It is evidently entirely in the hands of the Universities, for themselves report that, where the standard has been raised, students have by no means fallen off, but the reverse; and medical men know well that where diplomas differ in standard, the highest are well worth working for. The importance of the degree to this profession is also shown by more being taken in medicine than in anything else, and more in medicine and science together than in letters, law, and all other subjects.

On no point does England show to such disadvantage by the side of the United States as in the matter of free libraries. It is the more inexplicable because the marvellously, not to say unfairly, cheap literature there, together with the scattered habitations, would each tend to every man's house being his library; while in England the exactly reverse conditions of costly books and closely packed population must make free libraries a most convenient arrangement. Yet in the United States seventy-one additional libraries with 178,000 volumes were started in 1881, making up nearly 4000 libraries with 13,000,000 volumes. "The true aim in the administration of these libraries should be to make the books in them accessible and useful to the greatest number of readers. The time has passed when the preservation of a library was the chief end of its economy. Methods of arranging, classifying, numbering, and charging books affect materially the usefulness of any collection." It well deserves consideration what an influence for good or for evil 4000 librarians guiding the tastes of their readers to one or other class of literature may have. A further step also is being taken in many places. Librarians and the trustees of libraries generally are trying to cooperate with teachers and parents both in selecting and supplying literature for the young; the librarian and the schoolmaster together choosing a number of volumes from the main library to be circulated at the discretion of the latter among his scholars.

An interesting matter for discussion is the principle again laid down by this Report in its remarks upon the defective classes, that those deficient in natural powers, as the deaf, the blind, have as good a right to their education as those with a sound mind in a sound body; that it is a duty and not a charity to educate them effectually. The necessity of a "technical" education also, in their case, *i.e.* teaching them a trade as well as "letters" is clearly urged. This is carried also with success in some cases as far as a college education, and the late President Garfield complimented the authorities of the Deaf-mute College at Washington upon their presenting so many more capable men to the State. This is, in bare fact, true of the college's work; but, like the view taken of much benevolent work, it seems to forget that the same amount of power bestowed upon better material would have done much more for the State, and that this better material is never scarce. It is taking much safer ground to base it upon benevolence which, like the "quality of mercy," will bring a blessing also to the giver.

There are fourteen institutions for the benefit of feeble-minded youth. Our Report pleads for them that money spent on their education will be more productive than that spent on lunatics. The census of 1880 reports 76,895 idiots and 91,997 insane. Inquiry into the cause of such large numbers in a country where overcrowding ought not to be necessary, and the fact that 14 per cent of them had a weak-minded parent and 20 per cent. a weak-minded relative, raises a doubt as to the good in the long run of relaxing the natural check to the survival of the unfit. That 33 per cent. of the parents are addicted to drink is, alas, a too natural explanation to us in England. There can be no doubt that it would be not only wise State economy, but it would bring very valuable scientific evidence upon the most home-reaching of subjects "to attach to all appropriations for charitable purposes an enabling clause that institutions disbursing this charity should contribute to the commonwealth, in as precise a form as possible, statistics of the origin of the evils they affect to relieve."

Reform schools on the excellent plan of the celebrated Michigan one at Coldwater are increasing in number, and one for females also has been opened in this State at Adrian; and while the argument from benevolence is even stronger for their inmates than for the weakminded, the economical objection is far weaker, as the morality of colonies like Botany Bay shows that moral infirmities, when not carefully cultivated in gaols and prisons, are not so deeply set. Again, while natural checks have a tendency to eradicate *weak* mental powers, they act much more slowly, if at all, in crowded cities against diseased morality. It is therefore the more necessary to expend money and labour upon the victims of the latter, as is the special aim of the New Jersey State Reform School. The high aim of the Female Industrial School in this State is "to make it such a home that any parent having a wayward daughter may with confidence have her committed for reformation with the assurance that her surroundings will be of an elevating character." The risk of putting a premium upon vice is easily guarded against where private feeling is not allowed to rule.

The system of public instruction in Ontario (Canada) is so highly approved and has been so successful that a detailed account of its principles and organisation is given here; and the lucid, concise *résumé* of the work of other countries supplied in this United States Report would be valuable to many a reader in Europe who has not the time or the taste to go through the more lengthy documents published in his own country. W. O.

PATHOLOGICAL ANTHROPOLOGY

A NEW and important departure in anthropological studies is taken by Prof. Klebs of Zurich in a paper "On the transformations of the human race as a result mainly of pathological influences," read at the recent meeting of the Swiss Scientific Association at Freiburg, and of which we give the leading points. Hitherto pathology can scarcely be said to have been seriously considered at all in the speculations of anthropologists on the evolution of the fundamental human types. Monogenists especially, deriving all from one primeval stock, have sought an explanation of present varieties mainly in *outward* causes, such as diet, social habits, climate—in a word, the environment. Now the learned Zurich professor attempts to refer existing varieties rather to *inward* causes, without of course pretending to deny that these may themselves ultimately to a large extent depend on external conditions.

Prof. Klebs starts with the assumption that the form of the human body cannot be endowed with greater elements of persistence than other varieties of animal species, which may be modified either naturally or artificially, as, for instance, by stock-breeders. Thus, by the laws of heredity, individual characteristics may be blended together, and give rise to new forms within the several specific groups. The intermingling of races amongst civilised peoples tends in this way, not to universal uniformity, but rather to an endless multiplication of forms. But, besides heredity, these results may be brought about by other influences which make themselves felt, especially during the period of growth, and in a less degree in later years. Such are the deformities associated with certain pursuits, the typical and special characters of certain social circles, the aristocratic, agricultural, and other types, familiar examples of which are offered by the lettered, labouring, and criminal classes.

It may be concluded from this decided tendency to variation that the bodily forms, like all other phenomena of the organised world, are subject to continual modification, that they are essentially plastic, sensitive to, and perpetuating the traces of all external influences. Thus the Danish anatomist, Schmidt, finds that the numerous crania recovered from the prehistoric graves in Jutland and the neighbouring islands present the most varied anthropological types, ranging from that of the Neanderthal skull to those of foreign races, which can scarcely be supposed to have had any direct contact with the Danish aborigines.

But amongst the causes producing structural change, none, according to Prof. Klebs, are more effective than pathological affections. It is now well ascertained that the most prevalent ailments, and especially those of an infectious character, are of a parasitic nature, so that their diffusion takes the character of a struggle for existence between two organisms. Henceforth it becomes possible to study the action of these phenomena on racial and specific transformation.

But modern anthropology has approached this question only from one point. It recognises that within a given population, limited to a definite territory, typical features may be produced, such as those observed by Virchow amongst the Frisians and by Ranke amongst the Bavarians. Yet the former refuses to attribute to rachitis the flat shape of the East Frisian skull, although analogous deviations from the normal German skull are elsewhere also produced by rachitis. A whole series, however, of pathological phenomena have been determined which place in the clearest light the connection between structural change and internal affections.

Cretinism at once suggests itself, the domain and nature of which are best defined by describing it as a malady spread over the Central European highlands, and probably connected with the action of certain upland waters on the production of goître. It has been found that in Bavaria, Switzerland, and Austria these waters contain certain minute infusoria, which, when introduced into the waters of disaffected localities, produce like effects on the inhabitants.

The bodily structure of cretins, resulting from a premature arrest of the growth of bone, recalls in the most vivid manner the descriptions of dwarfs handed down by popular traditions. Hence it seems not improbable that this degeneracy may at a given point have resulted in the formation of a definite, although possibly not permanently fixed, type. A slight general influence of cretinism may still be detected in many places, as in Salzburg, and especially in Pinzgau and Pongau, where the natives present a striking contrast to those of their kindred, who have been driven by priestly intolerance to quit their homes and settle in the North German lowlands.

The opposite deformity, that is, excessive growth of structure, is also met in upland regions, where its presence recalls the legends of giants who usually dwelt in the same districts as the dwarfs. In fact the greatest irregularity in the length of the body occurs in the highlands, although mountaineers are, on the whole, of shorter stature than lowlanders. Thus the natives of Hasle, in the Bernese Oberland, and those of Elm, in the Canton of Glaris, are above the average height. This has suggested the theory of foreign immigration, a theory, however, supported only by a few local geographical terms of somewhat doubtful origin. In reality this deformity may also depend on pathological causes. At Elm a case has occurred of gigantic growth setting in at the late age of thirty-six and continuing till the death of the subject in his forty-second year. Although we may be still ignorant of the first and true cause of this disorder, the existence of analogous cases in the same locality, the unusual size of the inhabitants, and the established fact of gigantic growth in highland regions, all seem to point at some subtle relation between such pathological phenomena and the nature of the soil. They should perhaps be regarded as due to the action of organisms in the system, as has been shown to be the case with cretinism.

Another series of pathological symptoms is associated with the development of the pigments, which have hitherto been considered as a salient characteristic of races. A distinct relation has already been established between pigmentation under certain pathological conditions, such as the so-called "bronze-skin," and a morbid state of the supra-renal capsules. Since then special attention has been directed to these organs, which would appear to be the chief centre of pigmentary development. It is now found that in the dark races, as among swarthy individuals of the fair races, the medullar portion of the supra-renal capsules is always pigmented. From this remarkable coincidence it may be concluded that to the functional activity or sluggishness of these vascular glands are due the changes so frequently occurring in the colour of the hair and of the other cutaneous organs. Here also the pathologic action passes step by step from its most aggravated forms to its lightest phases, merging at last in simple physiological functions. The dark races, notably the Negroes, have had their origin in malarious regions, whose influence generates in serious cases a deposit of pigment or melanosis, occasionally manifested under the form of black tumours. The observations made by Prof. Klebs and others in the Pontine Marshes and Roman Campagna, show that the malaria is caused by a certain bacillus developed in the soil of those districts. Hence it may in this case be admitted that pathological actions of a comparatively mild form may exercise a modifying influence on the structural development of man. They should perhaps even be regarded as the true causes of the evolution of human types.

However crude and even unsatisfactory these views, they will doubtless serve a useful purpose by directing attention to a hitherto neglected field of research. They at all events reopen the whole question of the origin of human varieties, a question which cannot be considered as closed until monogenists and polygenists have reconciled their differences. The author's theory seems so far to support the monogenist school, inasmuch as it tends to account for present diversity by natural causes, without the necessity of having recourse to several independent centres of human evolution. The weak point of the theory seems to be that these natural causes are themselves confessedly of an exceptional character. It requires us to believe that the human varieties were evolved under morbid, that is, abnormal, conditions. Before that conclusion can be accepted, it will be necessary to show that the normal conditions of climate, diet, and so forth, were inadequate for the purpose. Unless this is done, the normal will probably continue to be regarded as, *cæteris paribus*, more efficacious than the abnormal causes. A. H. KEANE

THE GERMAN EXPEDITION TO SOUTH GEORGIA

THE following is an abstract of the report of the German Meteorological Expedition which was despatched under the international scheme to South Georgia Island, in lat. 54° S. and long. 37° W.

The Expedition, which was chosen by a Commission appointed by the German Government, consisted of the following members:—Dr. C. Schrader, chief, observer of the Hamburg Observatory; Dr. P. Vogel, sub-chief, mathematical instructor in Munich; Dr. C. von der Steinen, physician and zoologist, physician at the Charité Hospital in Berlin; Dr. H. Will, botanist, of the Forest Academy; Dr. O. Claus, mathematician; Herren E. Mosthoff, engineer, and A. Zschau, assistant; and a few sailors.

The object of the Expedition was to effect meteorological and magnetic observations, and to study the physical condition and the flora and fauna of the island, as well, as far as permissible, to observe the transit of Venus on December 6, 1882.

The Expedition arrived at Monte Video on July 4, 1882, by one of the Hamburg liners, and left that place on the 23rd on board the German man-of-war *Moltke*, after having adjusted their instruments and obtained a few domestic animals.

After twenty days' sailing the island was sighted; on August 20 the ship reached Royal Bay on the east coast. On the shore preparations were at once begun for removing the metre-deep snow, and erecting the dwelling house, 11 × 8 metres, two smaller houses for the magnetic observations, an astronomical observatory, and a small tower. A house was also built for the cattle.

All the scientific members, with the exception of those on the watch for reading the meteorological and magnetic instruments, met daily in the work-room from 9 a.m. to 12 noon, and from 2 to 6 p.m., to execute the scientific labours.

The instruments were read every hour, while the watches of the twenty-four hours were divided so that two members were on duty, the one from 3 to 9 a.m., and from 3 to 9 p.m., and the other from 9 a.m. to 3 p.m., and again from 9 p.m. to 3 a.m., and in this manner each member had two days' watch in the week. On the 1st and 15th of every month magnetic observations were effected every fifth minute, and for one hour on these days every twentieth second. But the labour was not found to be at all too heavy.

The lowest temperature registered was $-14°$ C., and the highest on one single occasion 18° C., but the thermometer varied generally in all seasons between $-5°$ and $+7°$ C., so that the difference between winter and summer consisted chiefly in the length of the days. Once during the winter—in August—the phenomenon occurred of the thermometer during, with a heavy westerly gale, to 14° C. The westerly and partly south-westerly winds were, during the winter, the warmest, which was ascribed to the circumstance that these passed over mountains some 2000 metres in height protecting the station on one side, which made them "Föhn-like."

The barometer readings varied between 715 and 770 mm. The lowest readings were never attended by violent storms; these occurred always quite unexpectedly when the glass stood at "fair." The force of the storms, which generally lasted twelve to twenty-four hours, and reaching the island seven to eight times a month, was calculated by a splendid Racknagel anemometer. The tide was carefully measured by ebb and flood gauges.

Falls of rain or snow were very rare during the year, and the plateau surrounding Royal Bay was already, in August, free from snow, and became first in April, when the ground was frozen, covered with snow. It snowed, however, several times in the middle of the summer, as, for instance, at Christmas.

The most frequent winds were those from west and south-west; the northerly ones always brought fog. In the summer the weather was nearly always thick and hazy, which greatly impeded excursions. Such were, nevertheless, undertaken several times, and the highest peaks of the arms—about 700 m.—of the chain of mountains running through the island were ascended. The central mountains range from 2000 m. to 3000 m. The climbing of the slate rocks was very difficult and fatiguing, and in spite of every effort the greatest distance covered was only about a German geographical mile, and the task of exploring the island was impossible of accomplishment, as the glaciers could not be passed by the small force at disposal. The mountains fell often abruptly into the sea, and the highest tops were about 15 km. from the station. The peaks of the above-mentioned arms were free from snow in the summer, and then covered with various kinds of moss.

The only rock found was clay-slate, in some places interspersed with varieties of quartz. Even the blocks carried down by the glaciers from the central part of the island—which was not reached—were of the same nature. No metals were found, but the slate rock contained a little iron; the quantity was, however, so small that it hardly affected the needle.

No land mammalia were found on the island, and of maritime mammals only the sea-elephant (*Phoca proboscidea*) and the sea-leopard, the latter in very small numbers. They did not breed in the bay. Of birds there were several. Two kinds of penguins (König and Esel) visited the island in great numbers, making their nests there, which always faced the sun. The eggs were very delicious. During the pairing-season large quantities of *Procellaria gigantea* came to the island, whose eggs were also very good. *Procellaria capensis*—the Cape Pigeon—was a summer visitor only, but was found in great numbers, hatching in little holes under the turf. This bird was so persecuted by a kind of gull that it only left its nest after dark. Another specimen of Procellaria also visited the island in the summer. It was named "Equinoxalis." There was only one kind of duck, and this became very scarce through shooting. The number of cormorants was very small, while the albatross (Diomedea) remained during the summer only, when it made its nest hanging from the rocks. They had magnificent brown feathers. Of the white albatross only two specimens were seen, but the white Dominican gull was common. Some few of the *Chionis alba*—the Antarctic Pigeon—which were eaten, remained during the whole year, as well as a singing-bird of the size of a lark.

The insects found were few, viz. only a species of land-beetle without wings, about one centimetre long, resembling the common German *Lauf-käfer*, and a water-beetle of the same size. A kind of red spider was caught under big stones. Of lower maritime invertebrates a good collection was made, which has, however, not yet been classified. The greatest part of this was, however, obtained when the tide was out and no boat was necessary, and the dredging was unsatisfactory.

In the summer two species of fish were caught in calm weather, varying from 5 to 20 cm. in length. But none were caught during the winter. The Expedition collected only about forty species of land and water plants, among the former of which were several varieties of the Tussack grass, two kinds of moss, two kinds of fern, and a little shrub with leaves and red blossoms. The grass was ravenously consumed by the cattle and the goats, but the sheep preferred this little shrub. Dr. Will is under the impression that he has discovered some new varieties.

The transit of Venus was seen in perfect weather, although a severe storm raged at the time. The ingress and egress were clearly observed, as well as the progress over the sun's disk, but no photographs were taken, as the Expedition was not furnished with suitable apparatus.

The island possessed, in spite of its desolateness, a beautiful Alpine nature, the tranquillity of which was only broken by the constant thunder of avalanches. The dwelling-house was comfortable, although it would have been more so if each member had had a separate room instead of its being shared with another. The provisions furnished to the Expedition left, however, much to be desired. The tinned Australian meat was tasteless, and the vegetables bad. The milk (in tins) only lasted six months, while the salt meat and fish, although good, were not sufficient. No fresh potatoes were furnished, the claret was bad, and the beer was soon consumed. The cook did wonders, however, in the way of culinary achievements. There was no case of scurvy, neither any serious case of illness. Some experiments were made during the summer to cultivate beans, peas, and potatoes, but they failed, as the shoots were destroyed by cold as soon as above the ground.

The Expedition left the island on September 5, 1883, in the German corvette *Marie*, but all the houses were left intact.

Four of the members of the Expedition returned home, but Dr. Vogel spent a couple of months in travelling in the Argentine Republic, while Messrs. Will and Claus are negotiating with the Argentine Government about taking the command of an expedition for exploring the course of the River Pilcomayo, in which the celebrated explorer Creveaux lost his life. Should their negotiations fail, these gentlemen intend to undertake a journey to the Brazilian province of Matto Grosso, and thence make an exploration of Central Bolivia (Santa Cruz de la Sierra), and eventually follow the watercourses of Mamore and Madeira into the Amazon River, and then the latter to its mouth.

ALLEN THOMSON

BORN in Edinburgh, April 2, 1809, Allen Thomson had nearly completed his seventy-fifth year when he died on the evening of Friday last, March 21. He was the son of John Thomson, a distinguished physician, who was the first occupant of the Chairs of Military Surgery and of Pathology in the University of Edinburgh, and it is remarkable that both chairs were founded on his own recommendation. Allen Thomson graduated as M.D. at the University of Edinburgh in 1830, and in 1831 he became a Fellow of the Royal College of Surgeons of Edinburgh. Soon after graduation he became an extra-mural Lecturer on Anatomy along with William Sharpey. The atmosphere of the Edinburgh school at this time was highly charged. A number of men, afterwards famous, were either students or extra-mural teachers. It is sufficient to mention the names of John Reid, John Goodsir, Martin Barry, Edward Forbes, William B. Carpenter, and John Hughes Bennett. All of these became distinguished in biological science, and amongst them in these days there was the clash of intellect and the rivalry of a noble ambition. None of these remain except Dr. Carpenter, who must feel that the death of his friend Allen Thomson is the severance of another link connecting him with what was undoubtedly a brilliant epoch in the history of the Edinburgh medical school.

Dr. Thomson filled the Chair of Anatomy in Marischal College, Aberdeen, from 1839 to 1841, when he was appointed to the Chair of Physiology in Edinburgh. He held this office for six years, when he was transplanted to the Anatomical Chair in the University of Glasgow, which he occupied till 1877. Since then he has resided in London. Of his scientific honours it is unnecessary to say more than that they came without stint; but probably the crowning honour of this kind was when he filled the Presidential Chair of the British Association at the Plymouth meeting in 1877.

Allen Thomson had a double career to a greater extent than most scientific men. He was not merely, by his own researches and by his well-known exhaustless stores of knowledge, one of the leading living authorities in the department of embryology, but he was an eminent public man, interested and influential in many matters of social and scientific politics. In Glasgow for many years he rendered the city and the University invaluable service. By his energy and tact he contributed more than probably any other man to the great work of building the new University on Gilmore Hill.

But with all his public work he was a busy man in his own department. His early work brought him reputation as an embryologist, and he kept it up by many important papers in the same department of science. In addition he wrote on physiological optics, especially on the mechanism of accommodation, and on the sensibility of the skin. His writings were not characterised so much by brilliant originality as by facility of interpretation of the writings of others, and by a running commentary of his own, showing that he had repeated the observations he was narrating with the effect of adding a few facts here and cutting out what he believed to be erroneous there. His method of thought and literary style were both severe. He was always sceptical until convinced, and he strove to get from himself and from others accuracy in detail. Hence he was inclined to be severe on new discoveries or theories, and whilst ready to listen was rather apt to quench the enthusiasm of a tyro by a douche of cold praise. But still his mind was open and receptive, and in not a few instances he changed his opinions under pressure of argument, which cannot be always asserted even of scientific men. Dr. Thomson always had a greater interest in embryological science than in any other department of biology, and none hailed with more delight the rise of the modern British school, nor deplored more deeply the loss of its leader, F. M. Balfour. As an embryologist his fame will depend chiefly on the clear interpretation he gave to some of the descriptions of the German school, and to the application he made of these to human embryology. An adept with his pencil as with his pen, he gave expression to his views in diagrams that probably for many a day will help the bewildered reader. Thus, though his name will not be associated with any one great discovery, Dr. Thomson will be recognised as a potent force in biological science during this century. His own work, his judicious criticisms, his personal influence, his encouragement to workers, all had an important part in moulding the present state of scientific thought on biological questions.

As to the man himself, those who knew him can testify to the kindly courtesy, to the simplicity of address, to the indescribable charm of his manner, to the warmth of his friendship. He was wise in counsel and adroit in reconciling differences amongst men. To this he owed much of his social power. His finely-moulded and venerable face will be much missed, but not more so than his wise advice at the council board or to the young man who has chosen a scientific career. JOHN G. MCKENDRICK

QUINTINO SELLA

BY the death of Signor Quintino Sella, to which we briefly referred last week, Italian science loses one of her strongest supporters and most earnest students. Although some of the best years of his life were devoted to statesmanship, his early writings on mineralogy were of sufficient solidity to establish for their author a very high reputation. These mineralogical memoirs, contributed chiefly to the Royal Academy of Sciences of Turin, were distinguished by a profound knowledge of crystallography. When the Geological Survey of Italy was about to be established, Signor Sella was commissioned to visit most of the European countries where Surveys were in operation, and in 1861 he presented to Signor Cordova, then Minister of Agriculture, Industry, and Commerce, a valuable report, "Sul Modo di fare la Carta Geologica del Regno d'Italia." In collecting materials for that report he spent some time in this country, and took the warmest interest in the work of the Geological Survey. Ten years later he prepared an elaborate report on the mineral wealth of Sardinia. When the International Geological Congress was held at Bologna in 1881, Signor Sella, as one of the most representative scientific men in Italy, was selected to act as the president; and those who had the advantage of attending that meeting carried away with them the most pleasant recollections of his courtesy. Signor Sella died at Biella in Piedmont on the 14th inst.

We direct attention to the letter from Prof. Hughes in connection with a memorial to the Italian *savant*.

NOTES

AT the final meeting, on Saturday last, of the General Committee of the International Fisheries Exhibition, the balance of the funds was disposed of. The surplus amounts to over 15,000*l*., and of this 10,000*l*. were allotted to alleviate the distress of widows and orphans of sea fishermen, while 3000*l*. were voted as an endowment to a society which is to be called "The Royal Fisheries Society," whose functions will be somewhat similar to those of the Royal Agricultural Society; the remaining 2000*l*. are kept in reserve.

PROFESSORS MARTENS, Mendeléeff, and Minaieff are to attend the jubilee of Edinburgh University, as delegates from the University of St. Petersburg, and Prof. Rokhmaninoff as delegate from the University of Kieff.

THE great gold medal of the Paris Geographical Society has been awarded to the Deep-Sea Expeditions of the *Talisman* and *Travailleur*; a gold medal to M. Arthur Thouar, for his journey across the desert of the Northern Chaco in search of the remains of the Crevaux Expedition; a gold medal to M. Désiré Charnay, for his Central American explorations, and especially his researches in Yucatan.

A MEETING of the Governors of the City and Guilds of London Institute for the Advancement of Technical Education was held last week for the purpose of receiving the Annual Report of the Council. The chair was occupied by the Lord Chancellor. The Chairman, in moving the adoption of the Report, said that the Institution had arrived at a critical point of time, at a point of time at which he might remind them of the progress which things had made, but one, nevertheless, at which it became necessary that they should recognise the importance of proceeding energetically. With respect to the Central Institution, the buildings were nearly completed, and it was expected that the public opening of those buildings might take place in June of this year. It was proposed that four professors should be appointed to the Central Institution—viz. Professors of Chemistry, of Engineering, of Mechanics and Mathematics, and of Physics, the whole being superintended by a Board of Studies. There would be laboratories properly fitted up, and workshops and drawing offices, all with a view to supplying instruction which would combine the elements of those fundamental studies which underlay practical art. It was hoped that, as time went on, the number of exhibitions and scholarships, which would enable poor and meritorious students to obtain the benefits of the Institution, might increase. It was estimated that 9000*l*. a year would be available for the maintenance of the Institution, and that the fees of the students would amount to 2000*l*. That would give 11,000*l*. as an expected present income. When the grant amounted to 10,000*l*., and the students numbered from 150 to 200, paying in fees 5000*l*., the income would be 15,000*l*., and it was estimated that that amount would be required for maintaining the Institute in full working order. Passing from the Central Institution to Finsbury College, the Chairman said that the progress of that branch had been very satisfactory. During the past year it had instructed 799 persons, of whom 100 had been day students and the rest students attending the evening classes. The day students had to pass a preliminary examination in elementary mechanics, and there were six free scholars. The South London School had an attendance of 300 students. The candidates presented for examination this year were 2397, being an increase over the former year of 425, and the passes were 1498, showing an increase over the former year of 276. They came from 104 centres, showing an increase of seven centres; and they were examined, as in the former year, in thirty-seven subjects. What was still more remarkable was the rapid extension of the desire to have the benefit of these examinations, for there were now preparing for them 5862 students, being an increase over those who were under similar preparation in the former year of no less than 1814. He recognised with gratitude the liberality with which they had been supported by the City Guilds and other bodies, and he could not but think that those who had helped them so far would help them still further. Since the report had been written, the Skinners' Company had increased their subscription for the year 1884 from 500*l*. to 1000*l*., and their donation to the building fund from 2000*l*. to 3000*l*.

A CORRESPONDENT sends us the following:—"The new scheme for examinations for admission to Sandhurst which has been agreed upon (it appears) by the War Office and the Civil Service Commissioners must, if unmodified, work serious mischief to scientific education in public schools in which any proportion of the pupils are looking forward to the army as a profession. This will be seen from the following scale of marks, which has been communicated to the Committee of the Head Masters' Conference :—

		Marks
Obligatory Subjects (*Three* out of the four to be taken up by every candidate)	Mathematics	3000
	Latin	3000
	French	3000
	German	3000
Optional Subjects (*One* only to be taken up)	Higher Mathematics	2000
	Greek	2000
	Chemistry	1500
	Electricity and Magnetism ...	1500
	Geology and Physical Geography	1500
	English History	1500

A glance at this table is sufficient to show that the authorities are holding out a *distinct bribe* to candidates to eschew the experimental sciences altogether ; and whatever their intention may be, the result will be the reduction of scientific knowledge among future officers of Her Majesty's army to the lowest possible minimum. This is surely a retrograde step in these late decades of the nineteenth century. Nor must it be forgotten that the application of the same scheme to examinations for admission to Woolwich is contemplated. Not only will every candidate be induced, if he can do so, to take up simply the four subjects in the first category, but, more than this, the scientific subjects (exclusive of mere mathematics) will only hereafter be taken up by those candidates whose performances in the more highly rewarded subjects are hopeless—the scientific subjects, in other words, will become simply a *refuge for mediocrity and incompetency*. Men who are spending the best years of their lives in combating the traditional prejudices which exist in this country in favour of the older studies will not only feel that they have to complain of the tardy and grudging recognition which is given to the 'new learning'—they will feel now, and justly so, that they have been betrayed by those from whom, on every ground, they ought to be able to look for more encouragement."

THE Worshipful Company of Clothworkers, who have already given 3500*l.* to the Bradford Technical School, have also promised an annual subscription of 500*l.* towards the working expenses of the school.

DR. DOBERCK writes from Hong Kong Observatory, February 17 :—" The building of the Hong Kong Observatory was begun in June 1883, but only the foundations had been laid at the end of July, when I arrived. The main building, the architectural details of which do credit to the Surveyor-General's department, was so far finished by January 1 that I could take up my residence there, and tridiurnal eye-observations were commenced. Before the middle of the month the magnetic hut was ready, and I lost no time in making a complete set of magnetic observations. I expect that it will be possible to start the self-recording apparatus by March 1. I get telegraphic weather information from the Treaty Ports, Nagasaki, Vladivostock, and Manilla, and publish weather reports, which, as you will see from one of the three newspapers which publish them (sent herewith) also indicate winds to be expected from the gradients."

THE Belgian Royal Academy proposes for public competition the subjoined subjects in the mathematical and physical sciences: —1. To resume and coordinate the researches hitherto made on the integration of linear equations of the second order with two variables, and to complete this theory, or at least advance it by further original research. 2. To establish by fresh experiments the theory of the reaction of bodies in the so-called nascent state. 3. Fresh spectroscopic researches with a view to ascertain especially whether the sun contains or not the essential constituent principles of organic compounds. 4. A complete exposition of the theory of deviations from the vertical, and verifying whether it applies to existing observations. 5. Fresh researches on the nutritive deposits in cereals, and especially on the transformations experienced by them during germination. 6. Fresh researches on the development of the Trematodes, from the histogenetic and organogenetic standpoint. 7. A study of the influence of compressed oxygen on the vital phenomena. Medals of the intrinsic value of 32*l.* and 24*l.* are offered respectively for the best papers on the first three and last four subjects. The papers must be legibly written in French, Flemish, or Latin, and forwarded prepaid to M. Liagre, Permanent Secretary, Palais des Académies, Brussels. They are to be signed by a motto, which is to be repeated in a sealed note containing the authors' names and addresses.

IN the *American Journal of Science and Arts*, vol. xxiii. 2nd series, p. 276, a letter from Rev. George Jones, U.S.N., to Prof. Silliman, written at Quito, Ecuador, December 13, 1856, describes a fall of ashes from Cotopaxi, which was thirty miles distant, in which a purple sky was noted. The paragraph in which the mention is made runs as follows :—" Yesterday morning we noticed that at the south the sky had an unusual appearance, being of a purple colour for about 90° along the horizon, and so up to about 45° in height, the edge of this being mixed up with patches of white. About 12 o'clock ashes began to fall, first in small quantities ; but by 8 o'clock the fall had got to be so considerable as to powder the clothes quickly, on our going out ; and people coming into a house would look as we do at home when coming in from a snowstorm."

THE exploring expedition, under the direction of M. Regel, the naturalist, has again left for Bokhara on its way to Chardshui, Kelif Kabadian, and Baldshuat, whence it will proceed *viâ* the Pamir plateau as far as the Kashgar frontier. M. Schwartz, the astronomer, accompanies the expedition.

PROF. OSBORNE REYNOLDS will give a discourse at the Royal Institution to-morrow (Friday, March 28) on the Two Manners of Motion of Water shown by Experiments ; and Prof. T. G. Bonney, the President of the Geological Society, will give a discourse on Friday (April 4) on the Building of the Alps.

ON Monday, at 9 p.m., a violent shock of earthquake, accompanied by a loud subterranean rumbling, was felt at Fünfkirchen, in Southern Hungary. It was also felt in Essegg and all over Slavonia. It is reported from Vierno that a shock of earthquake was felt there as well as at Karakul and in the Issyk-Kul district on the 13th inst.

AT one of the last meetings of the Russian Chemical Society, Prof. Mendeléeff made the following interesting communication with regard to solutions :—It would be easy to prove, with the data of Gerlach, Marignac, Cremers, and Schiff, that the volume of a given amount of a salt in its solutions (for instance, of a molecule) varies with the variations of temperature and the degree of concentration of the solutions. It increases as both increase ; and it might be concluded therefrom that the force on which solution depends varies with the degree of concentration. Still, another conclusion can be arrived at, if Grassy's measurements of the decrease of volumes of NaCl and $CaCl_2$ be taken into account. Interpolation shows that these solutions are reduced in volume, by pressure, as the amount of the dissolved salt varies ; and the reduction of volume which accompanies the solution enables us to calculate the corresponding pressure. It appears that to each molecule of NaCl dissolved in 100 parts of water corresponds a nearly permanent pressure of about 120 atmospheres, whatever be the degree of concentration. For $CaCl_2$ the pressure also remains constant, but is nearly three times the above. Thus, if the tendency towards solution be measured by pressure, it results, for the two salts above mentioned, that the first amounts of salt dissolved exercise the same pressure as the last which bring the solution near to saturation. Prof. Mendeléeff points out that researches pursued in the direction just mentioned could throw some light on the internal forces which are active in solutions and other chemical compounds.

It appears from the annual report of the Russian Chemical and Physical Society that the chemical section has now 162 members; its income, including several grants, reached 5734 roubles (about 570*l.*), and its capital 13,932 roubles, of which 7894 roubles were devoted to premiums. The physical section has 103 members; its income reached 1851 roubles, and its capital 16,000 roubles.

At the annual general meeting of the Hackney Microscopical and Natural History Society held on March 19 at the Morley Hall, Hackney, a valuable microscope was presented to the honorary secretary by the members. The president, Dr. M. C. Cooke, in presenting the testimonial, made some highly eulogistic remarks upon the energy and unremitting attention given by the honorary secretary during the seven years of the existence of the Society, to which he ascribed its present flourishing condition. A silver plate bearing the following inscription was attached to the instrument:—"Presented to Collis Willmott, Esq., by members of the Hackney Microscopical and Natural History Society in appreciation of his services as Hon. Secretary, 19th March, 1884."

We have received from the Direction of Schools at Tiflis its annual report, and we are glad to recognise that education in the Caucasus—which is perhaps more independent of the Ministry of Public Instruction than other parts of Russia—is spreading more rapidly than might have been supposed. On January 1, 1883, there were no less than 1168 schools under the supervision of the Ministry, with an aggregate of 80,838 scholars, of whom 15,036 are girls. If the 60 Jewish and 1920 Mussulman schools at synagogues and mosques be added—however low the degree of education given to their 18,647 scholars—as also 31 schools of various descriptions, military, theological, and lower medical, the aggregate number of scholars would reach 102,728. There is thus (excepting the Jewish and Mussulman schools) one school for each 4880 inhabitants, surely still a very low figure; but it is a little higher in the more densely peopled Northern Caucasus (1 to 3060 in Kubau). Of the 1168 schools above mentioned there were 1055 primary schools, with 52,251 scholars, one-fifth of whom are girls; 33 higher primary schools, with 5213 scholars; 5 schools for teachers, with 500 scholars; 8 technical schools, or *Realschulen*, with 2312, and 10 lyceums, or half-lyceums, with 3555 scholars. We see with pleasure that there were also 6 lyceums and 6 half-lyceums for girls, with the high figure of 3127 scholars. The distribution of education among different nationalities is very interesting. Of the above-mentioned 80,838 scholars, 46 per cent. per cent. were Russians, 25 per cent. Armenians, 17 Georgians, and 5·2 Tartars and Circassians. With regard to the population, the proportion of Armenians receiving instruction is 1 to 41, while it is only 1 to 44 with the Russians, 1 to 75 with the Georgians, 1 to 350 with the Circassians, 1 to 851 with the Tartars, 1 to 33 with Jews, and 1 to 7 with the Western Europeans settled in the Caucasus. Even in lyceums the Armenians (1 to 858) come first after the Jews (1 to 210) and before the Russians (1 to 866), while only 1 to 11,237 Circassians, 1 to 9352 Tartars, and 1 to 1246 Georgians, enter the lyceums. The Russians like the technical schools better, and the daughters of the functionaries take the lead in the lyceums for girls. Altogether the tendency towards education is well felt in Northern Caucasus, and it is agreeable to see that in secondary schools—male and female—11 to 12 per cent of the scholars are children of peasants and Cossacks. The number of these schools is even too small, and in 1882 no less than 441 boys were refused admission to lyceums on account of want of room. One may be sure that this tendency would be still greater were it not for the want of sympathy displayed throughout Russia with the so-called classical lyceums, where a mechanical study of Latin takes the place of sound instruction in natural sciences. We must notice also a beautiful educational map of the Caucasus which accompanies the Report for 1880. Owing to a system of coloured signs of different shapes, one sees at a glance the number of schools of different descriptions, male and female, spread throughout the Caucasus, as well as who pays for them—the State, the municipalities, the village communes, or private persons; while a number of coloured plates on the borders of the map show the tendency towards instruction in different provinces, the nationalities of the scholars, and so on.

We are informed that Mr. Robert Hunt's (the Keeper of Mining Records) large and comprehensive work on the history, discovery, practical development, and future prospects of metalliferous mines in the United Kingdom, under the title of "British Mining," will be published early next month by Messrs. Crosby Lockwood and Co.

AN IMPROVED THERMO-ELECTRIC PILE FOR MEASURING SMALL ELECTROMOTIVE FORCES[1]

This paper contains a description, illustrated by sketches, of a new and convenient form of thermo-electric apparatus for measuring small electromotive forces by the method of opposition, and of the method of constructing and using the apparatus.

The apparatus consists essentially of a series of about 300 pairs of horizontal, slender, parallel wires of iron and German silver, the former alone being covered with cotton. The wires are about 8 inches long, fixed side by side in close mutual contact, though insulated from each other, as a continuous flat layer about 16 inches long, in a wooden frame, and soldered end to end in single continuous series. About 1½ inch in length of the opposite ends of the wires are bent downwards to a vertical position, so as to enable them to dip into two liquids of different temperatures contained in two long, narrow troughs. The liquids employed are non-conductors; this was found to be necessary. The one for the hot junctions is melted paraffin kept at a temperature of 120° C., and the one for the cold ones is non-volatile petroleum, known by the name of "thin machinery oil." The ends of the wires are immersed about one-fourth of an inch in the liquids.

The maximum power of the instrument is of course limited by the amount of difference of temperature of the two liquids, and of the two series of ends of wires immersed in them. Any lower degree of electromotive force is obtained by attaching a copper wire to one end of the series, and sliding the free end of the other terminal wire across the middle part of the upper surface of the wires, from that end of the series towards the other; the German silver wires being bare permit metallic contact.

An apparatus as above described, consisting of 295 pairs of wires, had a resistance of 95·6 ohms at 16° C., and by a difference of 100° C. of temperature of the two baths, gave a current having an electromotive force of ·7729 volt, or with a difference of 130° C., 1·005 volt. Each element therefore equalled ·0000262 volt for each C. degree difference of temperature.

After having been verified with a standard voltaic cell, such an apparatus (or any fraction of it) may itself be employed as a standard. It is capable of producing and measuring as small a degree of electromotive force as a 34861st part of a volt. When the potential of the currents to be measured exceeded one volt, either an additional pile or a standard voltaic cell was employed with it.

Several apparatus of this kind have been constructed, and a large number of determinations of electromotive force have been made with them. Fifteen determinations per hour have frequently been made; the rate of working, however, depends upon the steadiness of the current to be measured.

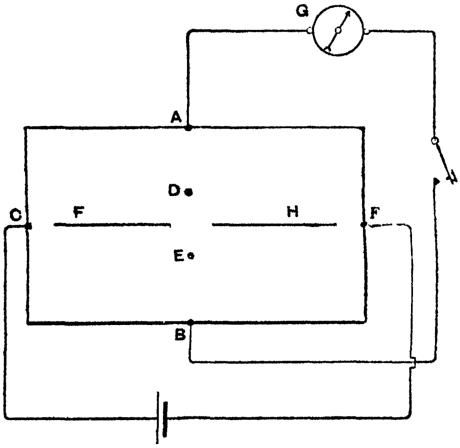
---

[1] Abstract of a paper read before the Birmingham Philosophical Society February 14, by Dr. G. Gore, F.R.S.

THE REVERSAL OF HALL'S PHENOMENON

IN a recent communication to the Physical Society I mentioned among other things that I had succeeded in reversing the direction of the Hall effect in iron. It was, however, found to be so exceedingly difficult to keep the two points where the galvanometer connections were made at the same potential, even for a few seconds, that the extent of the deflections due to the Hall effect could only be roughly guessed at, and the experiment was hardly a satisfactory one. I believe this inconvenience arose from the fact that the iron, being a strongly magnetic metal, was slightly displaced whenever the polarity of the electromagnet was reversed, thus shifting the points of contact with the galvanometer wires. I have since repeated the experiment with gold, which turns out to be perfectly easy to work with, and altogether more suitable for the purpose. The following is an account of four experiments:—

Experiment 1.—A piece of nearly pure gold foil 5 cm. long and 3·5 cm. broad was cemented to a plate of glass and the whole placed between the flat pole pieces of an electromagnet. The middle points, A, B (see figure) of the longer sides of the foil were connected to a galvanometer, G, and the middle points, C, F, of the shorter sides to a battery. A current was passed through the metal from left to right, and the electromagnet excited so that a south pole was beneath the glass and a north pole above it. The galvanometer was immediately deflected, indicating a current flowing in the direction B G A. If either the polarity of the magnet or the direction of the current through the foil was reversed, the transverse current was also reversed and flowed in the direction A G B. This is the ordinary "Hall effect," and the direction of the transverse currents agrees with that mentioned by Mr. Hall for gold. The extent of the deflections varied from about 50 to 70 scale divisions on each side of zero. Similar but smaller deflections occurred when the galvanometer was connected with points nearer to the middle of the plate.



Experiment 2.—Two longitudinal slits, F, H, about ¼ mm. wide, were then cut along the middle of the foil, leaving a connection 4 mm. wide between the two halves of the sheet, and the former experiment was repeated. The following are the details; and to understand them it must be remembered that the galvanometer is affected by two causes besides the transverse current: (1) by the direct action of the electromagnet upon the galvanometer needle, though 13 feet away from it; (2) by a small permanent current due to the fact that, however carefully adjusted, A and B are never (or hardly ever) at exactly the same potential.

The image of the galvanometer wire was brought as nearly as possible to zero of the scale before beginning the experiment, and the connections were made so that a current in the direction A G B caused a deflection to the left (−), and a current in the direction B G A caused a deflection to the right (+).

Upper pole of magnet north:—

Galvanometer key, K, raised, deflection + 25 divs.[1]
" " depressed, " + 102 divs.[2]

Upper pole of magnet south:—

Galvanometer key raised, deflection − 24 divs.
" " depressed, " − 42 divs.

Net deflections due to current (subtracting effect of the magnet on the galvanometer needle):—

Upper pole north (102 − 25 =) + 77 divs.
" south (− 42 + 24 =) − 18 divs.

Sum of opposite deflections due to transverse current, (77 + 18 =) 95, or deflection on each side of zero = 47·5 divs.

The slits therefore had the effect of reducing the amount of the Hall deflections; the direction was unaffected.

Experiment 3.—The galvanometer contacts were now moved from the edges to the points D, E, about 5 mm. from the middle line, and the experiment was repeated with the following result:—

Upper pole of magnet north:—

Key raised, deflection + 18 divs.
" depressed, " + 165 divs.

Upper pole south:—

Key raised, deflection − 35 divs.
" depressed, " + 180 divs.

Net deflections due to current:—

Upper pole north (165 − 18 =) + 147 divs.
" south (180 + 35 =) + 215 divs.

Sum of deflections due to transverse current (215 − 147 =) 68.
Deflection on each side of zero = 34 divs.

Thus when the galvanometer contacts were near the middle of the plate the deflections were almost as great as when the galvanometer was connected to the edges. *But they were in the opposite direction*, showing that the Hall effect was reversed.

Experiment 4.—A repetition of the last.

Upper pole north:—

Key raised, deflection + 28 divs.
" depressed, " + 170 divs.

Upper pole south:—

Key raised, deflection − 24 divs.
" depressed, " + 170 divs.

Net deflections due to current:—

Upper pole north (170 − 28 =) 132 divs.
" south (170 + 24 =) 194 divs.

Sum of deflections due to transverse current, (194 − 132 =) 62.
Deflection on each side of zero = 31 divs.

These results, curious as they are, were of course not unexpected, the experiment having been in fact devised for the purpose of testing in an absolutely conclusive manner the sufficiency of the explanation of Hall's phenomenon by strains and Peltier effects which I have recently proposed (see NATURE, p. 467).

Supposing the magnet and the battery to be so arranged that before the slits were made the points A and D were in stretched districts, and B and E in compressed districts of the metallic sheet, then the effect of cutting the slits will be practically to divide the plate into two independent plates, each of which undergoes strains similar to those originally existing in the whole. A and B therefore will still be in regions which are respectively stretched and compressed, while on the other hand the region in which D is will now be compressed, and that in which E is will be stretched. Thus as regards the points D and E the result of making the slits is to reverse the strain, and in consequence the Peltier effects and the galvanometer deflections. If Mr. Hall's own theory were correct, the existence of the slits should make no appreciable difference of any kind. That they should have the effect of *reversing* the action of the magnet upon the current is altogether inconceivable.

SHELFORD BIDWELL

---

[1] Due solely to the action of the magnet upon the galvanometer needle.

[2] Due partly to the action of the magnet on the galvanometer needle, partly to the permanent current above referred to, and partly to the transverse current resulting from magnetisation.

DR. FEUSSNER'S NEW POLARISING PRISM

IN a recent number of the *Zeitschrift für Instrumentenkunde* (iv. 42–50, February 1884), Dr. K. Feussner of Karlsruhe has given a detailed description of a polarising prism lately devised by him, which presents several points of novelty, and for which certain advantages are claimed. The paper also contains an account, although not an exhaustive one, of the various polarising prisms which have from time to time been constructed by means of different combinations of Iceland spar. The literature of this subject is scattered and somewhat difficult of access, and moreover only a small part of it has hitherto been translated into English; and it would appear therefore that a brief abstract of the paper may not be without service to those amongst the readers of NATURE who may be unacquainted with the original memoirs, or who may not have the necessary references at hand.

Following the order adopted by Dr. Feussner, the subject may be divided into two parts:—

I.—OLDER FORMS OF POLARISING PRISMS

In comparing the various forms of polarising prisms, the main points which need attention are:—the angular extent of the field of view, the direction of the emergent polarised ray, whether it is shifted to one side of or remains symmetrical to the long axis of the prism; the proportion which the length of the prism bears to its breadth; and lastly, the position of the terminal faces, whether perpendicular or inclined to the long axis. These requirements are fulfilled in different degrees by the following methods of construction.

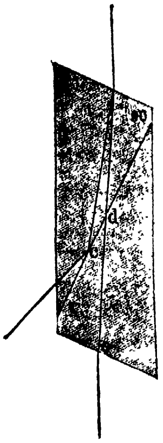


Fig. 1.

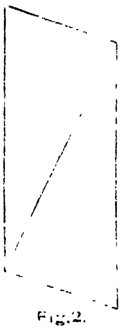

Fig. 2.

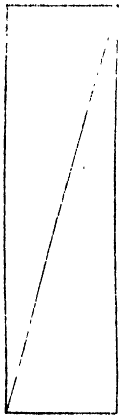

Fig. 3.

1. *The Nicol Prism* (*Edin. New Phil. Journal*, 1828, vi. 83).—This (Fig. 1), as is well known, is constructed from a rhombohedron of Iceland spar, the length of which must be fully three times as great as the width. The end faces are cut off in such a manner that the angle of 72° which they originally form with the lateral edge of the rhombohedron, is reduced to 68°. The prism is then cut in two in a plane perpendicular to the new end surfaces, the section being carried obliquely from one obtuse corner of the prism to the other, in the direction of its length. The surfaces of this section, after having been carefully polished, are cemented together again by means of Canada balsam. A ray of light, on entering the prism, is separated by the double refraction of the calc-spar into an ordinary and an extraordinary ray: the former undergoes total reflection at the layer of balsam at an incidence which allows the extraordinary ray to be transmitted; the latter, therefore, passes through unchanged. This principle of obtaining a single polarised ray by means of total reflection of the other is common to all the forms of prism now to be described.

Dr. Feussner gives a mathematical analysis of the paths taken by the two polarised rays within the Nicol prism, and finds that the emergent extraordinary ray can include an angular field of 29°, but that this extreme value holds good only for rays incident upon that portion of the end surface which is near to the obtuse corner, and that from thence it gradually decreases until the field includes an angle of only about half the previous amount. He finds, moreover, that, although of course the ray emerges parallel to its direction of incidence, yet that the zone of polarised light is shifted to one side of the central line. Also that the great length of the Nicol—3·28 times its breadth—is not only an inconvenience, but, owing to the large pieces of spar thus required for its construction, prisms of any but small size become very expensive. To this it may be added that there is a considerable loss of light by reflection from the first surface, owing to its inclined position in regard to the long axis of the prism.

It is with the view of obviating these defects that the modifications represented in Figs. 2 to 6 have been devised.

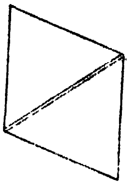

Fig. 4.

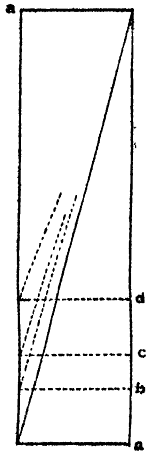

Fig. 5.

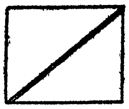

Fig. 6.

2. *The Shortened Nicol Prism.*—This arrangement of the Nicol prism is constructed by Dr. Steeg and Reuter of Homburg v. d. H. For the sake of facility of manufacture, the end surfaces are cleavage planes, and the oblique cut, instead of being perpendicular, makes with these an angle of about 84°. By this alteration the prism becomes shorter, and is now only 2·83 times its breadth; but if Canada balsam is still used as the cement, the field will occupy a very unsymmetrical position in regard to the long axis. If balsam of copaiba is made use of, the index of refraction of which is 1·50, a symmetrical field of about 24° will be obtained. A prism of this kind has also been designed by Prof. B. Hasert of Eisenach (*Pogg. Ann.* cxiii. 189), but its performance appears to be inferior to the above.

3. *The Nicol Prism with Perpendicular Ends.*—The terminal surfaces in this prism are perpendicular to the long axis, and the sectional cut makes with them an angle of about 75°. The length of the prism is 3·75 times its breadth, and if the cement has an index of refraction of 1·525, the field is symmetrically disposed, and includes an angle of 27°. Prisms of this kind have been manufactured by Dr. Steeg, by Mr. C. D. Ahrens, and others.

4. *The Foucault Prism* (*Comptes Rendus*, 1857, xlv. 238).—This construction differs from all those hitherto mentioned, in that a film of air is employed between the two cut surfaces as the totally reflecting medium instead of a layer of cement. The two halves of the prism are kept in position, without touching each other, by means of the mounting The length of the prism is in this way much reduced, and amounts to only 1·528 times its breadth. The end surfaces are cleavage planes, and the sectional cut makes with them an angle of 59°. The field, however, includes not more than about 8°, so that this prism can be used only in the case of nearly parallel rays; and in addition to this the pictures which may be seen through it are to some extent veiled and indistinct, owing to repeated internal reflection.

5. *The Hartnack Prism* (*Ann. de Ch. et de Physique*, ser. iv. vii. 181).—This form of prism was devised in 1866 by MM. Hartnack and Prazmowski; the original memoir is a valuable one; a translation of it, with some additions, has lately been published (*Journ. of the R. Microscopical Soc.*, June, 1883, 428). It is considered by Dr. Feussner to be the most perfect prism capable of being prepared from calc-spar. The ends of the prism are perpendicular to its length; the section carried through it is in a plane perpendicular to the principal axis of the crystal. The cementing medium is linseed oil, the index of refraction of which is 1·485. This form of prism is certainly not so well known in this country as it deserves to be: a very excellent one supplied to the present writer by Dr. Steeg is of rectangular form throughout, the terminal surfaces are 19 × 15 mm., and the length 41 mm. The lateral shifting of the field is scarcely perceptible, the prism is perfectly colourless and transparent, and its performance is far superior to that of the ordinary Nicol. The field of view afforded by this construction depends upon

the cementing substance used, and also upon the inclination of the sectional cut in regard to the ends of the prism; it may vary from 20° to 41°. If the utmost extent of field is not required, the prism may be shortened by lessening the angle of the section, at the expense however of interfering with the symmetrical disposition of the field.

6. *The Glan Prism* (Carl's "Repertorium," xvi. 570, and xvii. 195).—This is a modification of the Foucault, and in a similar manner includes a film of air between the sectional surfaces. The end surfaces and also the cut carried through the prism are parallel to the principal axis of the calc-spar. The ends are normal to the length, and the field includes about 8°. This prism is very short, and may indeed be even shorter than it is broad. It is subject to the same defect as that mentioned in the case of the Foucault, although perhaps not quite to the same extent.

II.—THE NEW POLARISING PRISM

This prism differs very considerably from the preceding forms, and consists of a thin plate of a doubly refracting crystal cemented between two wedge-shaped pieces of glass, the terminal faces of which are normal to the length. The external form of the prism may thus be similar to the Hartnack, the calc-spar being replaced by glass. The indices of refraction of the glass and of the cementing medium should correspond with the greater index of refraction of the crystal, and the directions of greatest and least elasticity in the latter must stand in a plane perpendicular to the direction of the section. One of the advantages claimed for the new prism is that it dispenses with the large and valuable pieces of spar hitherto found necessary; a further advantage being that other crystalline substances may be used in this prism instead of calc-spar. The latter advantage, however, occurs only when the difference between the indices of refraction for the ordinary and extraordinary rays in the particular crystal made use of is greater than in calc-spar. When this is the case, the field becomes enlarged, and the length of the prism is reduced.

The substance which Dr. Feussner has employed as being most suitable for the separating crystal plate is nitrate of soda (*natronsalpeter*), in which the above-mentioned values are $\omega =$ 1·587 and $\epsilon =$ 1·336. It crystallises in similar form to calcite, and in both cases thin plates obtained by cleavage may be used.

As the cementing substance for the nitrate of soda, a mixture of gum dammar with monobromonaphthalene was used, which afforded an index of refraction of 1·58. In the case of thin plates of calcite, a solid cementing substance of sufficiently high refractive power was not available, and a fluid medium was therefore employed. For this purpose the whole prism was inclosed in a short glass tube with air-tight ends, which was filled with monobromonaphthalene. In an experimental prism a mixture of balsam of tolu was made use of, giving a cement with an index of refraction of 1·62, but the low refractive power resulted in a very considerable reduction of the field. The extent and disposition of the field may be varied by altering the inclination at which the crystal lamina is inserted (Fig. 7), and thereby reducing the length of the prism, as in the case of the Hartnack.

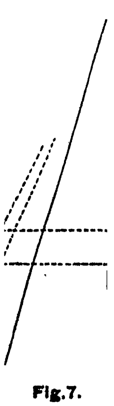

Fig. 7.

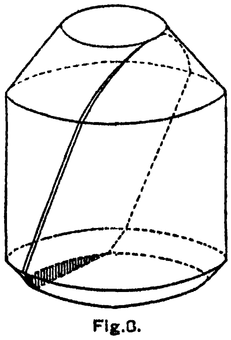

Fig. 8.

In order to obviate the effects of reflection from the internal side surfaces of the prism, the wedge-shaped blocks of glass of which it is built up may be made much broader than would otherwise be necessary; the edges of this extra width are cut obliquely, and suitably blackened.

The accompanying diagram (Fig. 8) represents a prism of cylindrical external form constructed in this manner, the lower surface being that of the incident light. In this the field amounts to 30°, and the breadth is about double the length.

Dr. Feussner remarks that a prism similar in some respects to his new arrangement was devised in 1869 by M. Jamin (*Comptes Rendus*, lxviii. 221), who used a thin plate of calc-spar inclosed in a cell filled with bisulphide of carbon; and also by Dr. Zenker, who replaced the liquid in M. Jamin's construction by wedges of flint glass.

Amongst others, the carefully considered modifications of the Nicol prism which have recently been devised by Prof. S. P. Thompson (*Phil. Mag.*, November, 1881, 349; and *Journ. R. Micros. Soc.*, August, 1883, 575), and by Mr. R. T. Glazebrook (*Phil. Mag.*, May, 1883, 352), do not appear to have been known to Dr. Feussner.

The following tabular view of different forms of polarising prisms is taken from the conclusion of Dr. Feussner's paper:—

	Field	Inclination of section in regard to long axis	Ratio of length to clear width	Fig.
I. THE OLD POLARISING PRISMS	°	°		
1. Nicol's prism	29	22	3·28	1
2. Shortened Nicol prism—				
a. Cemented with Canada balsam	13	25	2·83	2
b. ,, ,, copaiba ,,	24	25	2·83	2
3. Nicol with perpendicular ends—				
a. With Canada balsam	20	15	3·73	3
b. With cement of index of refraction of 1·525	27	15	3·73	3
4. Foucault's prism	8	40	1·528	4
5. Hartnack's prism—				
a. Original form...	35	15·9	3·51	5 *ab*
b. With largest field	41·9	13·9	4·04	5 *aa*
c. With field of 30°	30	17·4	3·19	5 *ac*
d. With field of 20°	20	20·3	2·70	5 *ad*
6. Glan's prism	7·9	50·3	0·831	6
II. THE NEW POLARISING PRISM				
1. With calc-spar: largest field ...	44	13·2	4·26	5 *aa*
2. ,, field of 30° ...	30	17·4	3·19	5 *ac*
3. ,, field of 20° ...	20	20·3	2·70	5 *ad*
4. With nitrate of soda: largest field	54	16·7	3·53	7 *aa*
5. ,, ,, field of 30°.	30	24	2·25	7 *ab* and 8
6. ,, ,, field of 20°.	20	27	1·96	7 *ac*

As an analysing prism of about 6 mm. clear width, and 13·5 mm. long, the new prism is stated by its inventor to be of the most essential service, and it would certainly appear that the arrangement is rather better adapted for small prisms than for those of considerable size. Any means by which a beam of polarised light of large diameter—say 3 to 3½ inches—could be obtained with all the convenience of a Nicol would be a real advance, for spar of sufficient size and purity for such a purpose has become so scarce and therefore so valuable that large prisms are difficult to procure at all. So far as an analyser is concerned, the experience of the writer of this notice would lead to the opinion that improvements are to be looked for rather in the way of the discovery of an artificial crystal which absorbs one of the polarised rays than by further modifications depending upon total reflection. The researches of Dr. Herapath on iodo-sulphate of quinine (*Phil. Mag.*, March, 1852, 161, and November, 1853, 346) are in this direction; but crystals of the co-called herapathite require great manipulative skill for their production. If these could be readily obtained of sufficient size, they would be invaluable as analysers.

This opinion is supported by the existence of an inconvenience which attends every form of analysing prism. It is frequently, and especially in projecting apparatus, required to be placed at the focus of a system of lenses, so that the rays may cross in the interior of the prism. This is an unfavourable position for a prismatic analyser, and in the case of a powerful beam of light, such as that from the electric arc, the crossing of the rays within the prism is not unattended with danger to the cementing substance, and to the surfaces in contact with it.

PHILIP R. SLEEMAN

ON VARIOUS SUGGESTIONS AS TO THE SOURCE OF ATMOSPHERIC ELECTRICITY[1]

WE have seen that, taking for granted the electrification of clouds, all the ordinary phenomena of a thunderstorm (except *globe* lightning) admit of easy and direct explanation by the known laws of statical electricity. Thus far we are on comparatively sure ground.

But the case is very different when we attempt to look a little farther into the matter, and to seek the source of atmospheric electricity. One cause of the difficulty is easily seen. It is the scale on which meteorological phenomena usually occur; so enormously greater than that of any possible laboratory arrangement that effects, which may pass wholly unnoticed by the most acute experimenter, may in nature rise to paramount importance. I shall content myself with one simple but striking instance.

Few people think of the immense transformations of energy which accompany an ordinary shower. But a very easy calculation leads us to startling results. To raise a single pound of water, in the form of vapour, from the sea or from moist ground, requires an amount of work equal to that of a horse for about half an hour! This is given out again, in the form of heat, by the vapour when it condenses; and the pound of water, falling as rain, would cover a square foot of ground to the depth of rather less than one-fifth of an inch. Thus a fifth of an inch of rain represents a horse-power for half an hour on every square foot; or, on a square mile, about a million horse-power for fourteen hours! A million horses would barely have standing room on a square mile. Considerations like this show that we can account for the most violent hurricanes by the energy set free by the mere condensation of vapour required for the concomitant rain.

Now the modern kinetic theory of gases shows that the particles of water-vapour are so small that there are somewhere about three hundred millions of millions of millions of them in a single cubic inch of saturated steam at ordinary atmospheric pressure. This corresponds to 1/1600 or so of a cubic inch of water, *i.e.* to about an average raindrop. But if each of the vapour particles had been by any cause electrified to one and the same potential, and all could be made to unite, the potential of the raindrop formed from them would be fifty million million times greater.

Thus it appears that if there be any cause which would give each particle of vapour an electric potential, even if that potential were far smaller than any that can be indicated by our most delicate electrometers, the aggregation of these particles into raindrops would easily explain the charge of the most formidable thundercloud. Many years ago it occurred to me that the mere *contact* of the particles of vapour with those of air, as they interdiffuse according to the kinetic theory of gases, would suffice to produce the excessively small potential requisite. Thus the source of atmospheric electricity would be the same as that of Volta's electrification of dry metals by contact. My experiments were all made on a small scale, with ordinary laboratory apparatus. Their general object was, by various processes, to precipitate vapour from damp air, and to study either (1) the electrification produced in the body on which the vapour was precipitated; or (2) to find on which of two parallel, polished plates, oppositely electrified and artificially cooled, the more rapid deposition of moisture would take place. After many trials, some resultless, others of a more promising character, I saw that experiments on a comparatively large scale would be absolutely necessary in order that a definite answer might be obtained. I communicated my views to the Royal Society of Edinburgh in 1875, in order that some one with the requisite facilities might be induced to take up the inquiry, but I am not aware that this has been done.

I may briefly mention some of the more prominent attempts which have been made to solve this curious and important problem. Some of them are ludicrous enough, but their diversity well illustrates the nature and amount of the difficulty.

The oldest notion seems to have been that the source of atmospheric electricity is aërial friction. Unfortunately for this theory, it is *not* usually in windy weather that the greatest development of electricity takes place.

In the earlier years of this century Pouillet claimed to have established by experiment that in all cases of combustion or oxidation, in the growth of plants, and in evaporation of *salt* water, electricity was invariably developed. But more recent experiments have thrown doubt on the first two conclusions, and have shown that the third is true only when the salt water is boiling, and that the electricity then produced is due to friction, not to evaporation. Thus Faraday traced the action of Armstrong's hydro-electric machine to friction of the steam against the orifice by which it escaped.

Saussure and others attributed the production of atmospheric electricity to the condensation of vapour, the reverse of one of Pouillet's hypotheses. This, however, is a much less plausible guess than that of Pouillet; for we could understand a particle of vapour carrying positive electricity with it, and leaving an equal charge of negative electricity in the water from which it escaped. But to account for the separation of the two electricities when two particles of vapour unite is a much less promising task.

Peltier (followed by Lamont) assumed that the earth itself has a permanent charge of negative electricity whose distribution varies from time to time, and from place to place. Air, according to this hypothesis, can neither hold nor conduct electricity, but a cloud can do both; and the cloud is electrified by conduction if it touch the earth, by induction if it do not. But here the difficulty is only thrown back one step. How are we to account for the earth's permanent charge?

Sir W. Thomson starts from the experimental fact that the layer of air near the ground is often found to be strongly electrified, and accounts for atmospheric electricity by the carrying up of this layer by convection currents. But this process also only shifts the difficulty.

A wild theory has in recent times been proposed by Becquerel. Corpuscles of some kind, electrified by the outbursts of glowing hydrogen, travel from the sun to the upper strata of the earth's atmosphere.

Mühry traces the source of electricity to a direct effect of solar radiation falling on the earth's surface.

Lüddens has recently attributed it to the friction of aqueous vapour against dry air. Some still more recent assumptions attribute it to capillary surface-tension of water, to the production of hail, &c.

Blake, Kalischer, &c., have lately endeavoured to show by experiment that it is not due to evaporation, or to condensation of water. Their experiments, however, have all been made on too small a scale to insure certain results. What I have just said about the extraordinary number of vapour particles in a single raindrop, shows that the whole charge in a few cubic feet of moist air may altogether escape detection.

And so the matter will probably stand, until means are found of making these delicate experiments in the only way in which success is likely to be obtained, viz. on a scale far larger than is at the command of any ordinary private purse. It is a question of real importance, not only for pure science but for the people, and ought to be thoroughly sifted by means which only a wealthy nation can provide.

---

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The General Board of Studies propose to appoint, early in Easter Term, a number of Readers and University Lecturers, including the following: a Reader in Comparative Philology, stipend 300*l.* per annum; a Reader in Botany, stipend 100*l.*; University Lecturers in Sanskrit, in Comparative Philology, in Mathematics (one in each group of the Tripos, Part 3), in Applied Mechanics, in Botany, in Animal Morphology, in Advanced Physiology (three), in Geology, in History (five), and in Moral Science; all at 50*l.*, except in Animal Morphology and in Geology, to which 100*l.* is assigned. The University Lecturers will for the most part be chosen from such College Lecturers as open their lectures to the University generally; but the Board is not necessarily restricted to such; nor to persons who may apply. Candidates are to send in their names and testimonials (if any) to the Vice-Chancellor not later than April 25. It is understood that two lectures a week during term time shall be the minimum during two terms for each lecturer receiving 50*l.* per annum. As far as possible the University Lecturers are to give special personal attention to their pupils, so as to obviate as much as possible the necessity of private tuition in the subject of the lectures; and the students' fees are to be understood as payment for this personal supervision.

The Special Board for Biology and Geology have published a report showing urgent need for a Senior Demonstrator in Elementary Biology and Animal Morphology at 200*l.* a year; the classes have grown enormously, consequent on recent changes in the M.B. examinations. They recommend that the Lecturers, by whose aid Mr. Sedgwick carries on the work of the late Prof. Balfour, shall be appointed University Lecturers, Dr. Hans Gadow in the Advanced Morphology of Vertebrates, and Mr. W. F. R. Weldon in that of Invertebrates. Moreover, they consider an Assistant Demonstrator as well as other occasional demonstrators are required.

Prof. Hughes has written a letter on the subject of the proposed Sedgwick Museum, suggesting that educational utility rather than architectural display should be the principal aim in the building, and pleading strongly against possible curtailment of the site available for the new museum to satisfy demands of other departments. The area now proposed, 240 feet by 50 feet, with room behind for future extension by annexes, &c., is not too large. If sufficient space can be secured for future extension, it is best to place the museum entirely on one floor; but if this is not certain, it would be desirable to have two long rooms one above another, each 20 feet high.

SCIENTIFIC SERIALS

THE *Quarterly Journal of Microscopical Science* for January, 1884, contains:—Notes on Echinoderm morphology, No. vii.: on the apical system of the Ophiurids, by P. Herbert Carpenter, M.A. (plate 1).—On the homologies of the primary larval plates in the test of Brachiate Echinoderms, by W. Percy Sladen (plate 1).—On the origin of metameric segmentation and some other morphological questions, by Adam Sedgwick, M.A. (plates 2 and 3).—On certain abnormalities in the common frog (*Rana temporaria*): (1) the occurrence of an ovotestis; (2) abnormalities of the vertebral column, by A. Gibbs Bourne, B.Sc. (plate 4).—Researches on the intracellular digestion of Invertebrates, by Dr. E. Metschnikoff (translated from *Arbeiten Zool. Instit. Wien*, 1883.—On the ancestral history of the inflammatory process, by Dr. E. Metschnikoff.—The structures connected with the ovarian ovum of Marsupialia and Monotremata, by Edward B. Poulton, M.A. (plate 5).—On the skeletotrophic tissues and coxal glands of Limulus, Scorpio, and Mygale, by Prof. E. Ray Lankester, M.A. (plates 6 to 11).

THE *Journal of Physiology*, vol. iv., No. 6, February, 1884, contains:—On the electrical phenomena of the excitatory process in the heart of the frog and of the tortoise as investigated photographically, by Dr. J. Burdon-Sanderson and F. J. M. Page (plates 13 to 20).—Experiments on the ears of fishes with reference to the function of equilibrium, by Dr. Henry Sewall.—On the influence of certain drugs on the period of diminished excitability, by Dr. S. Ringer and Dr. H. Sainsbury (plate 21).—On the action of digitalis, by Dr. J. Blake.—On the coagulation of the blood, by L. C. Wooldridge, D.Sc.—An investigation regarding the action of rubidium and cæsium salts compared with the action of potassium salts on the ventricle of the frog's heart, by Dr. S. Ringer (plate 22).—Some notes on the fibrin ferment, by S. Lea, M.A., and J. R. Green, B.Sc.

THE *Journal of the Royal Microscopical Society*, February, 1884, contains:—On the constituents of sewage in the mud of the Thames, by Lionel S. Beale, F.R.S. (plates 1 to 4).—On the modes of vision with objectives of wide aperture, by Prof. E. Abbe (figures); and the usual summary of current researches relating to zoology and botany.

Morphologisches Jahrbuch, Bd. ix., Heft 11, contains:—On the comparative anatomy of the excretory sexual organs of insects, by J. A. Palmen.—Contributions to the comparative anatomy of fishes, No. i.; on the cranium of *Amia calva*, L., by Dr. M. Sagemehl (plate 10).—A contribution to a knowledge of the pseudobranchiæ in osseous fishes, by Dr. F. Maurer (plates 11 and 12).—On the morphology of the mammalian teat, by Hermann Klaatsch (plates 13 to 17).

Archives Italiennes de Biologie, tome iv., fasc. 11, December 15, 1883, contains:—New researches on the alterations in organs in diabetes, by Dr. P. Ferraro.—New researches on the normal and pathological anatomy of the human placenta and of that of mammals, being the substance of three letters to Prof. Albert Kölliker, by Dr. G. B. Ercolani.—On the ciliary muscle in reptiles, by Dr. Ferruccio Mercanti.—On the reproduction of epithelium of the anterior crystalline capsule in adult animals under normal and pathological conditions, by Dr. F. SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 13.—"Notes on the Microscopic Structure of some Rocks from the Andes of Ecuador, collected by Edward Whymper. No. II. Antisana." By Prof. T. G. Bonney, D.Sc., F.R.S.

The specimens examined consisted of one series gathered by Mr. Whymper and another obtained by him from a collector. The latter came from the south-west or west side of the mountain, at elevations probably not exceeding 13,000 feet. Among them are pitchstones and augite-andesites, in which a little hypersthene possibly occurs. Mr. Whymper's own collection contains specimens of the great lava stream on the west side of Antisana, taken at about 12,340 feet above the sea. It is an augite andesite. The remainder represents the rocks forming the upper part of the mountain, collected from a moraine about 16,000 feet above the sea, supplied by occasional crags, which crop out through the snow and are mostly inaccessible. These are a series of augite-andesites, in some of which hypersthene is certainly present.

Linnean Society, March 20.—H. T. Stainton, F.R.S., vice-president, in the chair.—The Rev. Canon Jas. Baker, Mr. W. Brockbank, Mr. Robert Mason, and Mr. Ed. A. Heath were elected Fellows of the Society.—Mr. J. G. Baker showed and made remarks on a supposed hybrid between the Oxlip (*Primula elatior*) and the Cowslip (*P. veris*).—In illustration of his paper, a contribution to the knowledge of the genus *Anaphe*, Walker, Lord Walsingham exhibited a large and remarkable nest containing a packed mass of cocoons, also specimens of the insects and of the larvæ of a species of Congregating Moth of this genus from Natal; and he likewise showed a live example of a dipterous parasite which had emerged from the moth's eggs when hatched. He further stated that the nest and contents had been forwarded to him by Col. Bowker of Durban, and the larvæ were found alive on its receipt in England in August last. Many of the larvæ remained in the nest, but others in companies of twenty to forty occasionally marched out, moving in closely serried rank, much after the manner of the larvæ of the Procession Moth (*Cnethocampa*). From December to February about 250 moths emerged, but, from the difficulty of obtaining their natural food, all died, though a pair bred and the eggs hatched.

The mature insect closely resembles the *Anaphe panda*, Boisd., though under the latter name, it would seem, there are several well-marked local races. The genus is found in West Africa as well as Natal; and it appears that in the several species the colour, size, shape, and material of the common nest, as well as the individual silky cocoons, markedly differ. The habits of these moths when still more fully known in their native haunts will yet form a most interesting chapter to the traveller. Of *Anaphe* four species have hitherto been described, viz. *A. venata* from Old Calabar, *A. ambigua* from Angola, and *A. reticulata* and *A. panda* from Natal. To these Lord Walsingham adds *A. carteri* from the Gold Coast, and *A. infracta* from the Cameroons.—A paper, on the hairs occurring on the stamens of plants, by Mr. Greenwood Pim, was read. As to the morphology of these he sums up the groups thus: (1) simple unicellular, subulate, smooth, *Malva*, *Campanula*; (2) unicellular, subulate, rugose or papillar, *Cuphea*, *Nerium*, *Eutoca*; (3) unicellular, flattened, spathulate, rugose or striate, *Verbascum*, *Celsia*, *Antirrhinum*; (4) pluricellular, simple, smooth, *Salvia*, *Adhatoda*; (5) pluricellular, simple, rugose or striate, *Anagallis*, *Thunbergia*; (6) pluricellular and branched, *Browallia* and some forms of *Salvia*; (7) pluricellular with glandular tip, *Oxalis*, *Gesnera*; (8) multicellular, *Convolvulus*, *Ipomæa*.—A communication was read, "Closure of the Cyclostomatous Bryozoa," by Arthur W. Waters. While admitting that the group possesses few characters available for purposes of scientific determication, he nevertheless points out that the ovicells have a greater importance than that hitherto accorded them; also that the connecting pores are comparable with the rosette plates of the Chilostomata, and that stress must be laid on the size of the zooecial tube, and more particularly to the position and variation of its closure. The author states that in the Cyclostomata (simplest Bryozoa) he has found a calcareous partition closing the tubular zooecium, thus protecting the colony; whereas in the Chilostomata there is a horny operculum, which, unlike the other, is not a sign of death, but, being movable, protects the living polypide, and through it the colony.—A paper was read on the life-history of *Æcidium bellidis*, by Mr. C. B. Plowright, in which he gives the results of a series of experiments, noting the infection and appearance of the Uredo. He differs in opinion from most authorities, who regard the *Æcidium* of the daisy as a variety of *Æ. compositarum*, while he demonstrates it to be a true heterœcismal Uredine.—The last communication read was by Mr. F. Kitton, on some Diatomaceæ from the Island of Socotra, in which a number of new species are described and figured.

Geological Society, March 5.—Prof. T. G. Bonney, F.R.S., president, in the chair.—F. N. Maude, John Potts, and Corbet Woodall were elected Fellows, and Dr. Charles Barrois, of Lille, a Foreign Correspondent of the Society.—The following communications were read:—On the structure and formation of coal, by E. Wethered, F.G.S., F.C.S. The conclusions on the evidence elicited from the author's investigations were (1) that some coals were practically made up of spores, others were not, these variations often occurring in the beds of the same seam; (2) the so-called bituminous coals were largely made up of the substance which the author termed hydrocarbon, to which wood-tissue undoubtedly contributed. An appendix to the paper, written by Prof. Harker, Professor of Botany and Geology at the Royal Agricultural College, Cirencester, dealt with the determination of the spores seen in Mr. Wethered's microscopic sections. The writer concluded that the forms in the coal were from a group of plants having affinities with the modern genus *Isoëtes*, and from this Isoëtoid character he suggests the generic title of *Isoëtoides* pending further investigation.—On strain in connection with crystallisation and the development of perlitic structure, by Frank Rutley, F.G.S.—Sketches of South-African geology; No. 1, a sketch of the high-level coal-field of South Africa, by W. H. Penning, F.G.S. In this paper the author gave a sketch of the high-level coal-field of the Transvaal and the neighbouring region. This coal-field was described as extending 400 miles from north to south, with an average breadth of 140 miles, so that its area is about 56,000 square miles. The tract consists of an elevated plateau forming the "High Veldts" of the Transvaal and the plains of the Orange Free State. It slopes away to the north-west, and is scarped to the south and east by the heights known as the Stormberg and Drakensberg Mountains; nearly all the principal rivers of South Africa take their rise in this tract of land. The coal-bearing beds forming the plateau rest unconformably in the north upon deposits probably of Upper Palæozoic age, described as the Megaliesberg beds. In the south-west the Lower Karoo beds underlie the coal-beds, also unconformably. The beds of the high grounds consist above of sandstones, called the "High Veldt beds" by the author, and below of shales, for which the name of "Kimberley beds" is proposed, after the chief town of Griqualand West, in which district they form nearly the whole surface. These two series are conformable, and generally lie horizontally. In the shales coal occurs only in minute patches; the seams of coal are interstratified with the sandstones, into which the shales pass up gradually, and which sometimes include thick-bedded grits and conglomerates. Both shales and sandstones contain interstratifications and numerous dykes of trap, which have rarely produced much alteration in the sedimentary beds, from which the author concludes that the eruptions were sub-aqueous and contemporaneous, or nearly so. Owing to the persistent horizontality of the rocks, the mountains and valleys are merely carved out of the plateau, so that the thickness of the deposits is easily measured. The author gave 2300 feet as the minimum thickness of each series. By a comparative section it was shown that the coal-bearing sandstones ("High Veldt beds") are the "Upper Karoo" of Stow, and the "Stormberg beds" of Dunn. The "Kimberley beds" are the Upper Karoo beds of Dunn. In the latter part of his paper the author noticed briefly the different localities where coal has been found, namely, Newcastle, Lange's Nek, the Lebelelasberg Mountains, near New Scotland, several places on the High Veldt, Wemburg, Brandfoote, Cornet Spruit, Burgersdorf, and Indwe, twenty miles east of Dordrecht. The most northerly point of the Transvaal where coal has been found is on the Letsebo River. West of the Drakensberg coal occurs at a lower level.

Entomological Society, March 5.—Special General Meeting.—Mr. J. W. Dunning, president, in the chair.—Prof. J. O. Westwood, hon. life president, proposed, and Mr. H. T. Stainton seconded, a proposition "That it is desirable to obtain for the Society a Royal Charter of Incorporation." After a short discussion, the resolution was carried *nem. con.*

Ordinary Meeting.—Prof. Westwood, hon. life president, in the chair.—Two new members were elected.—Mr. E. A. Fitch exhibited a large geodephagous larva said to have been coughed up at Maldon by a young man who was suffering from bronchitis.—Mr. J. W. Dunning protested against the irregular manner in which the names of persons had lately been used in entomological nomenclature; and Mr. H. J. Elwes expressed his disapproval of the use of Hindoo mythological, and other names not of Latin or Greek derivation, in the same manner.—Mr. E. Saunders read the concluding part of his synopsis of the British *Hymenoptera Aculeata*, part iii. *Apidæ*; and also, further notes on the terminal segments of aculeate *Hymenoptera*.

EDINBURGH

Mathematical Society, March 14.—A. J. G. Barclay, vice-president, in the chair.—Mr. W. J. Macdonald gave an account of Pascal's "Essais pour les Coniques."—Mr. R. E. Allardice read a paper on the geometry of the spherical surface; and Prof. Chrystal gave an additional proof of one of his theorems.—Mr. Thomas Muir, F.R.S.E., contributed a note on the condensation of a special continuant.

Royal Physical Society, March 19.—Mr. B. W. Peach, F.R.S.E., F.G.S., president, in the chair.—The following communications were read:—Notes on a second collection of birds and eggs from Central Uruguay (with exhibition of specimens), by Mr. J. J. Dalgleish.—On a revised list of British *Ophiuroidea*, by W. E. Hoyle, M.A., F.R.S.E., of the *Challenger* Expedition Office.—On the Breadalbane Mines, by Messrs. J. S. Grant Wilson and H. M. Cadell, B.Sc., of H.M. Geological Survey of Scotland (communicated by permission of the Director-General of the Geological Survey). These mines are situated in the basin of the Tay, and the highest—those of Tyndrum—were first noticed. The galena veins were partly in a fissure traversing the quartzites in close proximity to a large fault which the authors had observed for the first time at Tyndrum. Another vein existed in the fault fissure itself or in the mica schists which were brought down by it against the quartzites. A difference in inclination brought the two fissures together, and at a certain depth they found a conjoint vein. Below the line of junction the ore almost disappeared, as had been proved by the old workings, and very little ore was visible in the portion of the conjoint vein exposed on the surface. The veins were of quartz with spathic iron and barytes, and were never more than four feet in thickness. The ore was distributed in broad rudely parallel diagonal bands, and the veins resembled in this as in other particulars those of the Upper Harz belonging to von Groddeck's "Type Clausthal." Lead ore was discovered at Tyndrum in 1741, and was mined with varying activity till 1862, when the mines were abandoned, as they had quite ceased to pay expenses. Chrome iron ore was known to occur in considerable quantity in a mass of serpentine at Coirie Charnaig in Glen Lochaig, but had never been extensively worked. An interesting occurrence of grey and yellow copper ore was found at Tomnadashan on the southern shore of Loch Tay. The ore was disseminated through a mass of crystalline rock resembling diorite, which had been injected into the schists, hardening and contorting them at its edges. The basic rock was in turn traversed by multitudes of veins of pink granitite, which at some places united and formed a stock-like mass with large pink orthoclase crystals. The ore was found most abundantly at the junction of the two rocks. Molybden glance occurred in the acid rock, but no traces of blende or galena had been discovered at Tomnadashan. At Corrai Bui near Ardeonaig rich argentiferous galena veins traversed the schists on the top of a hill which was capped by a series of calcareous beds. The galena contained from 85 to 600 ounces of silver per ton of ore, but the veins thinned out on passing down into the non-calcareous beds below, and became quite barren at a depth of 100 feet. There were many other very thin veins of pyrites, blende, galena, &c., in the Breadalbane district, but none were thick enough to be worked with profit.—Prof. Cossar Ewart, F.R.S.E., exhibited, with remarks, the following specimens:—(1) the Tadpole fish (*Raniceps trifurens*); (2) the Great Fork-beard (*Phycis blenniodes*); (3) the Power Cod (*Gadus minutus*); (4) an Albino specimen of the Haddock (*Gadus æglefinus*).—Prof. Ewart also exhibited and described a new hatching-box he had devised for adhesive eggs to take the place of the American "Clark" hatching-box. The advantage of Prof. Ewart's box is that the glasses are arranged in a horizontal position, so that the embryos, when hatched, pass at once into comparatively still water, instead of having to run over and under a varying number of vertical glass plates.—Prof. Ewart also described an easy method of stocking spawning beds capable of being readily used by the fishermen themselves. All that was required was an ordinary wooden tub and a shallow galvanised iron tray about twenty inches in diameter, with the bottom consisting of two portions each hinged to a central bar so as to open downwards. The object in view is to deposit stones on the spawning bed coated with fertilised ova. To do this the tray is placed in the tub, which is then filled with sea-water. Into the tray a number of flat stones are arranged; the water is then fertilised and the stones coated with eggs. This done, the tray is lowered to the bottom by means of four cords—two attached to the rim of the tray, and one to each half of the bottom. When the tray has reached the sea-floor, the cords attached to the false bottom are set free, and the tray raised by the cords attached to its edge, the result being that the egg-coated stones are left at the bottom. By this method the fishermen, without any trouble or expense, could add 200 or 300 eggs for every herring they removed from the sea, and thus do their best to restore the balance of nature which their operations had disturbed.

PARIS

Academy of Sciences, March 17.—M. Rolland in the chair.—On the new map of Tunis to the scale of 1 : 200,000, now being prepared in the French War Office, and the first six sheets of which have just appeared, by M. F. Perrier. The map, which will be completed early next year, will comprise twenty sheets altogether, uniform with that of Algeria, of which it forms a natural continuation.—Relative rapidity of combustion of explosive gaseous mixtures, by MM. Berthelot and Vieille.—On the solution of a very extended class of equations in quaternions, by M. Sylvester.—Notice of the labours of the late M. Sella, Corresponding Member of the Section of Mineralogy, by M. Daubrée.—Notice of the second volume of the Emperor of Brazil's "Records of the Rio de Janeiro Observatory," by M. Faye.—Remarks on a note by Sir Richard Owen on the discovery of a mammal (Tritylodon) in the South African Trias, by M. Albert Gaudry.—Application of the incandescent lamp for the lighting of astronomical instruments, by M. G. Towne.—Remarks on the shadows cast by the faculæ on the penumbra of the solar spots (one illustration), by M. E. L. Trouvelot.—On some arithmetical applications of the theory of elliptical functions, by M. Stieltjes.—On a new generalisation of the Abelian functions, by M. E. Picard.—On the thrust of a mass of sand with horizontal upper surface against a vertical or inclined wall, by M. J. Boussinesq.—Theory and practical formulas of magneto-electric machines with alternate currents, by M. Félix Lucas.—Note on Hall's electro-magnetic phenomenon, by M. A. Leduc.—On the laws regulating the decomposition of salts in water, by M. H. Le Chatelier.—Note on the action of chloruretted aldehydes on benzine in the presence of chloride of aluminium, by M. Alph. Combes.—On the addition of chloride of iodine to monobromuretted ethylene, by M. Louis Henry.—Note on the dialysis of the acid of the gastric juice, by M. Ch. Richet.—Distribution of the motor roots in the animal muscular system, by MM. Forgue and Lannegrâce.—Memoir on the relations between plants and the nitrogen consumed by them, by M. W. O. Atwater.—Note on the cultivation of the sedimentary matter brought up from great depths by the dredgings of the *Travailleur* and *Talisman* during the expeditions of 1882-83, by M. A. Certes. The object of these experiments is to show that the absence of plants or animals in decomposition at the bottom of the sea is probably due to the presence of microbes analogous to those which, under our eyes, are daily working at the transformation of organic into inorganic matter.—On the renal organs of the embryos of Helix, by M. P. de Meuron.—On spermatogenesis and the phenomena of fecundation in *Ascaris megalocephala*, by M. P. THE "CHALLENGER" REPORTS

Report of the Scientific Results of the Voyage of H.M.S. "Challenger" during the Years 1873–76, *under the Command of Capt. George S. Nares, R.N., F.R.S., and Capt. Frank T. Thompson, R.N.* Prepared under the Superintendence of the late Sir C. Wyville Thomson, Knt., F.R.S., and now of John Murray, F.R.S.E., one of the Naturalists of the Expedition. Zoology, vol. viii. (London: Published by Order of Her Majesty's Government, 1883.)

THE eighth volume of the Zoological Series of Reports on the Scientific Results of the Expedition of H.M.S. *Challenger* contains three Reports. That on the Copepoda is the second Report on the Entomostraca, and is by Dr. G. S. Brady. That on the Calcareous Sponges is by Mr. N. Poléjaeff of the University of Odessa; and that on the Cirripedia is by Dr. P. P. C. Hoëk. We learn incidentally from a note by the editor, Mr. John Murray, that the Report on the Foraminifera, by H. B. Brady, F.R.S., is now (December 1883) nearly printed, and that it will be issued at once as vol. ix.

Dr. G. S. Brady's Report on the Copepods contains descriptions of 106 species, for 12 of which it has been necessary to establish 11 new genera. These species were taken almost entirely from surface-net gatherings made during the cruise. While in some few of these gatherings no Copepods were found, Mr. Murray feels certain that these forms were rarely if ever absent from the tow-net gatherings when these were examined on board ship. It seems now certain that the sea from the Equator to the Poles supports everywhere a profusion of Entomostracan life, chiefly of the order Copepoda. The appearance of these little crustaceans on the surface would seem to depend on conditions not yet well understood. Night seems to call them up in larger numbers than the day, but sometimes even in the day they will appear in multitudes so vast as to colour the surface of the ocean for distances of many miles. The cold waters of the Arctic and Antarctic seas are even more favourable to the increase of the Copepods than the warmer waters of the tropics, and Dr. Brady notes that while individuals of some one or two species seem in the polar seas to predominate, in the equatorial and sub-tropical area no one species seems to occur in a very preponderating abundance, but there is a far greater variety of genera and species. While the range of the distribution of the Copepods is extremely wide, still some forms, as *Calanus finmarchicus*, seem to be characteristic of the Arctic seas, while others, as *Undina darwinii* and *Euchæta prestandreæ*, occupy a like position in the tropical and warmer temperate seas.

Dr. Brady follows the sevenfold division into areas adopted in his Report on the Ostracoda. The only undoubted deep-sea species found is *Pontostratiotes abyssicola*, a single specimen of which was dredged in a depth of 2200 fathoms. The fish parasites described are remarkably few, and with one exception seem to have occurred on surface-living fish. It would perhaps not be safe to conclude from this that the deep-sea fish are free from such parasites, but is it not possible that if such forms existed they may have been torn off or destroyed in the transit of the host fishes from the abyssal depths? The single species found was described in manuscript by the late Dr. von Willemoës Suhm, whose description and figures are given. It is called *Lernœa abysssicola*, and was found on a specimen of *Ceratias uranoscopus*, Murray, which was taken at Station 89, from a depth of 2400 fathoms. It is a strangely attenuated and wonderfully transparent form. The thread-like cephalic region and body portion together only a little exceed 13 mm. in length. This most important Report is accompanied by fifty-five plates, all drawn by the skilled hand of the author.

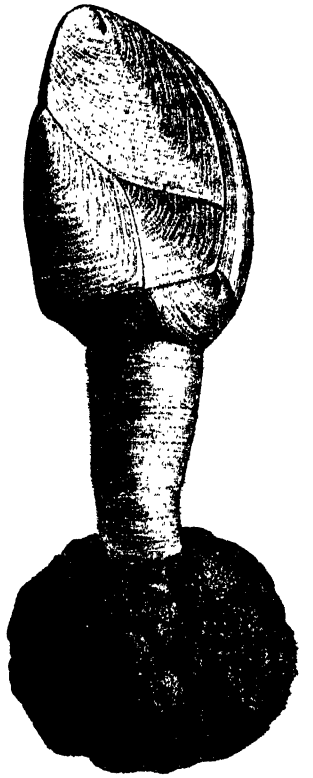
The Report on the Calcareous Sponges, by Mr. A. Poléjaeff of Gratz, a graduate of the University of Odessa, and a trusted pupil of Prof. F. E. Schulze, is a most excellent contribution to our knowledge of this highly interesting group, and entitles its author by its comprehensive criticism and by its attention to practical details, to a high place among modern systematic zoologists. The author had much invaluable assistance in his work, and though living in the somewhat out-of-the-way, though beautifully situated capital of Styria, he had the immense advantage of being able to consult the collection of Oscar Schmidt. It is with pleasure we fully recognise the good use he has made of all these opportunities, and we heartily congratulate him on the result. The Calcareous Sponges of the *Challenger* Expedition were found to belong to thirty species, twenty-three of which are described as new. To describe these was a comparatively easy task, and to arrange them in an orderly sequence was there not the splendid essay of Ernst Haeckel, "Die Kalkschwämme"? True; but there was just the difficulty: for the twelve years that had elapsed since the appearance of this most remarkable work had added so much to our knowledge of the morphology and embryology of this group as to expose the extremely artificial nature of Haeckel's system. Possibly, if the chapter of the history of the Calcareous Sponges had for ever closed on the publication of Haeckel's monograph, the systematic arrangement there adopted, however open to logical attack, might for convenience' sake have stood its ground. But as a *natural* arrangement it would have ever been open to a destructive criticism. Not the least important part of this Report is the free but generous criticism on Haeckel's classification which will command the attention of every one interested in the group of the Sponges. It should also be read by all working on the details of structure of the lower forms of animal life.

It would be impossible in a general notice of this Report to venture into minute details, but while referring those interested in the facts to the first two dozen pages of the introductory remarks, we may observe that the author concludes that "the peculiarities of the canal system of the sponges, the early development of their mesoderm, the circumstance that it is just the mesoderm which in them gives origin to the generative products, and finally the absence of cnidoblasts and nervous elements, taken altogether, though they do not justify the establishment of a new class for the Sponges, are yet important enough to entitle them to occupy an independent position among the Cœlenterata as a sub-class. Within this class the Calcareous Sponges occupy an essentially isolated position, and as a group these may be divided into two orders: (1) Homocœla, and (2) Heterocœla; the former with the single family Asconidæ (Leucosolenia, Bwbk.), the latter with the three families Syconidæ, Leuconidæ, and Teichonidæ. The concluding portion of the introductory chapter we quote as showing that, however destructive may be the author's criticism, he is not unmindful of the merits of the author of "Die Kalkschwämme;" while many of Prof. Haeckel's statements have thus proved to be founded on error, it must never be forgotten that it was his Monograph that called forth and facilitated later investigations, and if we are forced to agree to a certain extent with the judgment of M. Barrois upon this great work, that "l'imagination y a trop souvent pris la place de l'observation scientifique et froide," every one will also agree with another judgment of the very same naturalist, that with the appearance of Prof. Haeckel's Monograph "l'histoire des Éponges entra dans une phase nouvelle." M. Poléjaeff's Report is accompanied by nine plates, in which all the new forms are figured.

The Report on the Cirripedia is by Dr. P. P. C. Hoek. Taking Darwin's Monograph as a basis of departure, the author gives us (1) a sketch of the development of our knowledge with regard to the number of the genera and species known, their geographical and bathymetrical distribution; (2) a summary of what has been added to our knowledge of the anatomy, embryology, &c., of the group; and (3) a discussion of the different opinions published with regard to the classification of the group, especially since the discovery of the so-called Cirripedia Suctoria or Rhizocephala. The first of these sketches is, from a faunistic point of view, very interesting and instructive, showing both how much and how little is known as to the forms to be met with on our coasts or in our oceans; and, if properly studied, this section may give a very great impetus to the local study of these forms. We read that all "the Cirripedia of the Baltic belong to the genus Balanus;" but, if we are not mistaken, the extremely curious species *Anelasma squalicola* has been found on sharks in this sea, and specimens, we believe, from this locality are to be found in the Berlin and Dublin Museums. To the record given of species of fossil forms described since the date of Darwin's Monograph we may add one that has a peculiar interest being from the pen of the late head of the civilian staff of the *Challenger* Expedition, describing *Loricula macadami* from the Upper Greensand of the County Antrim.

Out of seventy-eight species of Cirripeds represented in the *Challenger* collection only nineteen had been previously recorded, and fifty-nine are named and described now for the first time. In 1854 Darwin gave the number of known Cirripedes as 147, and since then only some eighteen new species have been recorded.

Of the thirty-four genera of Cirripedia at present known the species of twenty-eight have never been observed at a depth greater than 150 fathoms. Two have been found from the shore to 400 fathoms (Alepas and Pœcilasma). Balanus occurs from the shore down to 510 fathoms. Dichelaspis ranges down to 1000 fathoms; and finally only two genera (Scalpellum and Verruca) have been observed at depths greater than 1000 fathoms. The occurrence of these two latter genera in the greater depths of the ocean coincides in a striking manner with their palæontological history, but Dr. Hoek has not been able to identify any of the recent species with the extinct forms described by Darwin, Bosquet, and Reuss. Of the genus Scalpellum only eleven species were known up to the cruise of the *Challenger;* over forty species were added to the list as the result of the cruise. The majority of the species are inhabitants of deep water; indeed Scalpellum appears to be the only genus of the stalked Cirripedia which is to be often met with at great depths. It is also worthy of note that the observation of Darwin made with regard to the number of specimens of Cirripeds during the Cretaceous period may be made for the recent species of Scalpellum: "The number of species is considerable, the individuals are rare." While the species found during the *Challenger* cruise amounted to forty-three, twenty-six of these are represented by a single specimen only; four are represented by two specimens; five by three; two by four; and only six species are represented by more than four specimens. The study of the complemental males found in some of the species of Scalpellum has given some very interesting results, but we are promised a more detailed treatment of the organisation of these little creatures in a supplementary memoir, which will deal with the anatomy of the group, and which will very shortly be published. In the account of *S. stroemii*, Sars, we find the following:—



Scalpellum darwinii.

"On opening a specimen of this species, dredged in August 1882 by H.M.S. *Triton*, it was found to contain within the mantle cavity a few large embryos; on microscopic examination these were found to have passed already the Nauplius-stage and to have arrived at the Cypris-stage. The exuviæ of the Nauplius-stage still adhered to the covering of the Cypris; still it was not easy to make out which parts had developed from the Nauplius-appendages."

The largest species of the genus known has been called *S. darwinii.* Only a single specimen of this splendid form was dredged during the *Challenger's* cruise, and of it, through the courtesy of Mr. Murray, we are enabled to give the woodcut illustration on the previous page. This specimen was found as represented attached to a manganese nodule; these nodules, according to Mr. Murray, are formed by concretionary depositions around shark's teeth, pumice, and other substances at the bottom of the sea; it was dredged at Station 299, December 14, 1875, lat. 33° 31′ S., long. 74° 43′ W., at a depth of 2160 fathoms, from a bottom of gray mud. Four large complemental males were found attached between the mantle and the scutum at a short distance from the apex of the valve and close to its occludent margin. Three specimens were on the left and one on the right side.

Of the genus Verruca, ten species, of which six are new, were found. They are among some of the most interesting forms of animal life collected during the Expedition, and prove that the number of recent species is much greater than had been to this supposed to exist, and that the genus has a true worldwide distribution. Of the six stations which yielded Verruca one belongs to the Northern Atlantic, three to the Southern Atlantic, one to the Pacific, and one to the Malay Archipelago. By these discoveries the range in depth has been immensely increased; the greatest depth known to Darwin for *V. strömia,* O.F.M., was 90 fathoms, but the six new *Challenger* species inhabit depths of from 500 to 1900 fathoms. Of the genus Balanus nine species are referred to, and five described as new; and of the genus Chthamalus one new species is described. This memoir is accompanied by thirteen plates.

The volume has been edited by Mr. Murray, and is one of the most important to the student of invertebrate forms yet published of these Reports.

GERMAN METEOROLOGY

Repertorium der Deutschen Meteorologie. Leistungen der Deutschen in Schriften, Erfindungen und Beobachtungen auf dem Gebiete der Meteorologie und des Erdmagnetismus von den Ältesten zeiten bis zum Schlusse des Jahres 1881. Von G. Hellmann. (Leipzig: verlag von Wilhelm Englemann, 1883.)

IN this goodly octavo volume of 498 pages, presenting an exhaustive catalogue of the meteorological literature of Germany from the earliest to the present time, Dr. Hellmann has done a service to science, the practical value of which it would be difficult to overestimate. The work is divided into three parts. The first part comprises the writings and discoveries, and is in two divisions. The first of these divisions gives the names of authors and the titles of their works; and the fulness and satisfactoriness of detail with which this is gone into may be seen by referring to "Dove," who was the prince of German meteorologists, and "Helmholtz," the latter contributing only one paper—on whirlwinds and thunderstorms—and the former 208 papers, embracing all departments of the subject. The principal events in the biography of each author are briefly indicated, together with the date of publication of each contribution and the work in which it appeared. The second division is an index of subjects comprised under meteorology, terrestrial magnetism, and atmospheric electricity; and the completeness with which this part of the work is done may be seen by a reference to "Barometer," the various papers relating to which are grouped under thirty heads. The heading "Astro-Meteorologie" shows that even the antiquities of the science have not been overlooked.

The second part gives a catalogue of stations, and is in two divisions—the first comprising stations and the different series of observations made at them; and the second, indexes of subjects and observers. The stations are arranged according to the different States of Germany where they are situated; and sections are set apart for stations the observations at which have been published *in extenso;* at which six or more observations have been made daily; stations for investigating forest meteorology, for weather telegraphy, and for international meteorology; high-level stations at heights of 1969 feet and upwards; and stations at which observations have been made for at least fifty years. To these is appended an index of observers' names and their stations.

The third part is historical, presenting an outline of the history of meteorological observations in Germany; a valuable chronological table from the eighth century downwards, detailing the more important facts in the history of meteorology and terrestrial magnetism; and the book closes with interesting statistics showing for the decennial periods beginning with 1480 the progress and extension of meteorological observations over Germany. A map is added showing the meteorological stations in the German Empire at the present time; and on the same sheet a small map showing the stations in Germany in 1781, including those established in connection with the Societas Meteorologica Palatina.

The extreme importance of this undertaking to all workers in meteorology, terrestrial magnetism, and atmospheric electricity, and the ability with which Dr. Hellmann has carried it through, make us regret with a strong feeling of shame the financial difficulty that was allowed to stand in the way of completing a similar catalogue of the meteorological literature of all nations. From Dr. Hellmann's letter to the International Meteorological Committee at Berne, dated July 20, 1880, it appears that all that was required to complete this great work was the raising of a sum not exceeding 1200*l.* As however there appeared to be no hope of this small sum being raised or even guaranteed, Dr. Hellmann, in a spirit and with an energy which cannot but call forth the warmest approbation of scientific men, set to work in the autumn of that year, and was in a position in May 1883 to sign the preface of the work now before us. No small praise is also due to Herr Engelmann, for the effective help he has given in its publication.

For want of such catalogues, the workers, not merely in meteorology, but in every department of science, are crippled, and the remark applies with peculiar emphasis in the case of those who are entering on the work of scientific research. Indeed, the waste of time and brain-work in carrying on scientific work no longer necessary because it has been already done is so great, and the consequent material loss to the nation so serious, that the time cannot be far distant when the Governments of this and other countries will have no choice, but yield to the demands made for a moderate annual grant towards defraying the expenses incurred in preparing and publishing these indispensable aids to all workers in science.

OUR BOOK SHELF

Berly's Electrical Directory. Third Edition. (London and New York, 1884.)

THIS work consists of three separate directories, separately paged, but bound up together; the first, of 228 pages, relates to British trades and professions connected with electricity; the second, of 273 pages, is devoted to similar matters from America; whilst the third is Continental. Of the last, 71 pages are French and Belgian, 12 German, and 3 relate to other countries, chiefly Russia. This arrangement, though convenient probably to the compilers, strikes us as being bad for many purposes. The American and French sections are particularly full of information. The British section opens with remarks on the progress made in electrical business during the past year, after which come various tables and formulæ. These are by no means satisfactory. In the formulæ for dimensions of units, many of the numbers which should have been printed as powers are given as simple multipliers. Though the table begins with C.G.S. units, and professes to describe those accepted by the British Association and the International Congress of 1881, the ohm is given as equal to 10^7 absolute units and the volt as 10^5, whereas the figures should respectively be 10^9 and 10^8. All this is very misleading. So also is the following statement:—"Calling gravitation the natural unit of force, the absolute unit of force will be $\frac{1}{9{\cdot}81}$th part of it." This statement ushers in the following definition:—"*Unit of Mechanical Effect* is the unit of force carried up through one centimetre, or $\frac{1}{9{\cdot}81}$ raised one centimetre." Is it possible that this chapter on formulæ has been translated literally from the pages of some French writer who was in the habit of using a mixed metre-gramme-second system instead of either the centimetre-gramme-second or the metre-kilogramme-second system? With the exception of the scientific part, the editing appears to have been carefully and soundly done, and the commercial information is very extensive.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

"The Unity of Nature"

IT was, I think, in the course of last year, or of the year preceding, that I ventured to remonstrate against the use sometimes made of your columns by Mr. G. J. Romanes for the purpose of inculcating his personal beliefs, and disbeliefs, on subjects which lie outside the boundaries of physical science.

The observations made by him in your paper of March 20 upon the book I have lately published ("Unity of Nature") show that in that remonstrance I committed an offence which Mr. Romanes has not forgotten or forgiven. Nevertheless I must repeat it; and this time I have the advantage of his own confession, that "the pages of a scientific journal are not suited to an examination" of those parts of my book which he has nevertheless denounced in your pages with unusual violence of language. If your pages are not suited to such an examination, neither can they be suited to comments which nothing but that examination could justify. The tone of these comments is a very clear proof of the necessity of our all keeping within the marches when we meet on neutral ground. Scientific facts and scientific hypotheses constitute that neutral ground. On the other hand, the bearing of these facts and of these hypotheses on questions of philosophy and of religion constitutes a separate region in which, if we meet at all, it must be outside the pages of a purely scientific journal. In that separate region it has always been my endeavour to argue without personal passion and without contumely towards opponents. I should be ashamed in any argument to display the animus which has in this case dictated the language of Mr. Romanes on subjects which, by his own confession, he has no right to drag into your pages. He may hold that the highest aim of the human intellect is to prove the mindlessness of nature. My book deals, and was intended to deal, with this philosophy; and I did not expect Mr. Romanes to like it. How much he dislikes it is remarkable. But he will find no passage in it which descends to the level of some of his comments.

Having dismissed, as irrelevant in your columns, the criticisms of Mr. Romanes on the "Unity of Nature" which have no connection with science, I now turn to some of those which have this connection, and are at least perfectly legitimate in their character.

Mr. Romanes is quite right when he says that I object to the "*newer philosophy*" which makes experience the source of instinct. In my view this theory is, in the strictest meaning of the word, nonsense, because experience is obviously a "synthesis of intuitions," and not the source of them. It is a plain fact that instinctive movements and instinctive sensations are the conditions precedent—the sole materials—of experience. Experience is nothing but the memory in living creatures of their own previous action on external things, and of the reaction of external things upon themselves. It is the combined consciousness of both which builds up what we call experience. But in every step of this process, whether of action, or of reaction, or of the combined memory of each, not one instinct only, but several instincts are concerned. Experience therefore is the result of instinct, and not the converse.

With this argument Mr. Romanes does not even attempt to deal.

He does, however, attempt to deal with my contention that instinct is always strictly correlated with organic structure, and that special instincts are always connected with "organs already fitted for and appropriate to the purpose." He says that my own case of the dipper ought to have taught me better; "for," he adds, "the dipper belongs to a non-aquatic family of birds, and *therefore* has no organs specially adapted to its aquatic instincts."

This argument, as an argument, is a *non sequitur*; and as a statement of fact is altogether erroneous. It is quite true that the dipper has not webbed feet. But it is not true that webbed feet are at all necessary for aquatic habits of a particular kind; nor is it true that the dipper is wanting in other peculiarities of structure which are most specially adapted to its peculiar aquatic habits and instincts. There are many birds which swim excellently well without webbed feet, as, for example, all the Gallinules, and some of the Tringidæ. The dipper does not need webbed feet, because it neither swims nor dives in deep water; and because on the other hand it positively needs feet free from web for grasping stones under rapid streams, as well as for grasping rock-surfaces in the places of its nidification. On the other hand, the structure of its wings, and above all the structure and texture of its feathers, are all specially modified and adapted to its aquatic habits.

It is for Mr. Romanes to prove, if he can, that the dipper once had an ancestor which began to dive in water, whilst as yet its wings had not a shape and a texture adapted to the purpose, and whilst its plumage was still pervious to water, and so was liable to be drenched and sodden.

Mr. Romanes protests against my suggestion that rudimentary organs may, sometimes at least, be the beginnings of a structure destined for future use, and not the relics of a structure whose use has been in the past. Yet in the same paper he himself suggests that the dipper may be on the way to having webbed feet, and only wants them now because it has "not yet had time to develop" them. But when these webs do begin to appear, they would naturally be small, and would appear to be rudimentary; so that in this stage they would exactly represent the "wholly untenable doctrine" which Mr. Romanes denounces as an "inversion of Mr. Darwin's teaching." As a matter of fact rudimentary organs on the way to future use can be identified in the aquatic larvæ of the Ephemeræ.

The truth evidently is that the theory of the origin of species by transmutation, involves of necessity a constant succession of structures which are on the wane, and another succession of structures which are on the stocks. Whether any particular structure now dissociated from use, belongs to the one or to the other class, is a question of evidence from associated facts. But the idea of some structures being on the rise, is an idea inseparable from the theory of evolution as taught by Darwin. Fully persuaded, as I am, that there is a very large amount of truth in that theory, I am equally persuaded that, as yet understood, it is incompetent to solve the most important phenomena of creation. In the hands of Mr. Romanes, and of many others, it is almost reduced to the repetition of mere verbal formulæ, under which anything and everything may be brought, only because they are empty of any definite meaning. The derivation of instinct from experience is an excellent example.

ARGYLL

Rain-band Spectroscopy Attacked Again

I HAVE just had the honour of receiving a copy of an essay read before the Philosophical Society, Washington, D.C., and printed in the *American Journal of Science* for the present month, wherein I read on p. 209:—

"The results of observations with the rain-band spectroscope are now called in question by many prominent meteorologists. In fact the unsatisfactory nature of the evidence may be easily shown to the satisfaction of any one possessing an instrument. If the spectroscope is first turned to the sky in any direction and afterward to a white wall fifty feet distant, it will be found impossible to distinguish between the appearance of the rain-band as shown by the whole atmosphere and by the layer fifty feet thick."

If this be the most damaging accusation that can be brought up, after the memorable correspondence in both NATURE and the *Times* during the autumn of 1882, there is hope of converting "the prominent meteorologists" yet.

For cannot they, as well as other men, see, that a white wall close to an observer in daylight, necessarily reflects the light, and with that, the spectrum, of the sky which is illumining it, solar lines and telluric lines and all!

Or if the worthy gentlemen still doubt, let them illumine their white wall at midnight with policemen's lanterns or Swan's incandescent lamps; and then I can promise them they will get out of it and the "layer of air fifty feet thick" in front of it, neither solar nor telluric spectrum lines in any kind of weather.

The Remarkable Sunsets

IN reply to inquiries sent out by me to Prof. John Milne of the University of Tokio, Japan, I am informed that no volcanic dust was known to have fallen in Japan during or after the Krakatoa eruption. He forwards, however, the following extracts, which may be of interest to your readers.

JOHN W. JUDD

Science Schools, South Kensington, S.W.

"*Japan Gazette, Friday, Sept.* 21, 1883.—Shortly after noon on August 30 the sun seemed to diminish in power, and a uniform yellow gray haze spread over the sky, gradually becoming more pronounced, and at two hours before sunset its rays were merged into a faint halo emerging from a globe of light no larger than the full moon. On Friday, August 31, at 8 a.m., sun the same. At 11 a.m. looked like full moon; could easily observe it with the naked eye. At intervals, faint clouds like puffs of smoke crossed the sun's face; they were enormously high. No wind; atmosphere dull and heavy, and neither heat nor light. September 1, the same. On Sunday, sun became as usual, and haze passed away. The Japanese were alarmed, and expected earthquakes."

Prof. Milne adds the note: "If this were due to Krakatoa, almost 2500 miles away, the speed of the dust must have been thirty miles an hour, assuming the date of the eruption to be 12 p.m. on August 26."

THE coloration of the sky in the neighbourhood of the sun, described by "B. W. S." in NATURE of March 27 (p. 503), has been repeatedly observed by myself from February 20 (or thereabouts) up to March 24. My first record of it is on February 24, when I describe it as a "rusty-red" tint. On other occasions I have called it "rusty brown" and "pale brick-red." Sometimes it has had a purplish or roseate hue. It has been chiefly seen between 10° and 20° from the sun (at a rough estimate), and only when the sun was hidden by a detached cloud. Frequently, when the sky has been clear, the intervention of a house or other object between the observer and the sun has revealed the presence of a hazy metallic-looking glare around the sun—an appearance not perhaps very remarkable in itself, but remarkable by its frequent repetition.

If, as seems probable, the explanation of these phenomena is to be found in a gradual subsidence of the reflecting matter which occasioned the remarkable sunsets, it will be well for observers to be prepared with suitable arrangements for catching what may fall. I have myself had in operation for some time past two separate devices for this purpose, the one intended for dry weather, the other for rain. In dry weather I expose a tray containing a number of glass slides, each with a drop of glycerine in a shallow cell, ready to be covered with this glass after sufficient exposure. For rain I use a 12-inch bell-glass supported in an inverted position on a three-legged stand, the legs partly buried in the earth, and the height such as to raise the receiving area of the glass to 30 inches above the soil. A rain-gauge is less suitable for the purpose, and experience has shown me the necessity of guarding against the introduction of particles of soil by the rebound of hailstones.

An investigation of this kind is difficult in the neighbourhood of a city, and it is much to be wished that observers living in isolated situations may be induced to undertake it.

It may be worth recording that on February 24, after an interval of several weeks, we had a striking recurrence of the sunset phenomena so often described. It was not perhaps the very finest example, but, as regards the primary glow, there had been nothing equal to it since January 12. Unfortunately I was not able to watch for the secondary glow. It is singular that at both the beginning and end of this series of phenomena there should have been outlying examples separated by some weeks from the rest. The first of the peculiar sunsets observed in this country appears to have been on November 9. Then I find no record until November 24. From that date (allowing for interruption by weather) they may perhaps be considered to have been continuous until February 2, becoming scarcely noticeable towards the last. Then, finally, after an entire absence of fully three weeks there comes, on February 24, a sunset which must be ranked amongst the finest of the series.

Clifton, March 31 GEORGE F. BURDER

REFERRING to the "decidedly unusual *pink tinge*" occasionally observed around the sun "when shining in a somewhat hazy sky, the colour being brought out with great distinctness if a light cloud happens to be passing across it" (see NATURE, March 27, p. 503), I would mention that, under the described circumstances, I have often noticed last winter a peculiar colour, to which I would apply the French term *pelure d'oignon* (onion skin), used to describe certain kinds of champagne. I offer this suggestion, as I know the value of precise and happily chosen terms, especially in the difficult matter of the terminology of colours.

O. S.

Heidelberg, Germany, March 29

Thread-twisting

THE habit of thread-twisting with the palm of the hand on the thigh is one which may be seen in every part of India at the present day; we think it can hardly be termed a rude method, or a savage art, though the Mohammedans, whose ancestors came not so very long ago from Central Asia, practise it as much as, or even more than, the Hindoos. As "J. S." observes in NATURE of March 20 (p. 478), it may be one of the survivals from a barbarous period which we have lost since the introduction of machinery. Perhaps some of your correspondents may be able to tell us whether it is in use in the Orkneys and the Hebrides, or elsewhere, where the people still spin their own wool.

COSMOPOLITAN

MEASURING HEIGHTS[1]

THE system of barometric hypsometry described in this treatise—first communicated in 1877 to the Philosophical Society of Washington—was suggested by the needs of the geographical surveys conducted by the Government of the United States in the mountainous region lying between the Great Plains and the Pacific Ocean. The system proposes a new method of observation and computation. It is not of universal application, but the range of work to which it is adapted is large and deserving the attention of the geographer.

The *method of observation* is as follows:—Two base stations are established—one high, the other low. Their difference in altitude is made as great, and their horizontal distance as small, as practicable. Each station is furnished with a barometer only, and observations are made at frequent intervals through each day. At each new station a barometer is observed, and no other instrument. The difference in altitude of the two base stations is determined by spirit level, and forms a vertical base by which all other intermediate altitudes are *computed as follows*:—The readings, being corrected for index error and temperature of instrument, are collected in groups of three, each observation at a new station being accompanied with the simultaneous observations at the two base stations. The resulting difference of heights of the lower and the new station is then computed by the following formula, in which if L, U, N represent the height of the lower, upper, and new stations respectively, and l, u, n the simultaneous corrected barometric readings at the same stations, and also let $B = U - L$, $A = N - L$, and $B - A = U - N$; then it is found approximately that—

$$A = B\frac{\log l - \log n}{\log l - \log u} + \frac{A(B - A)}{D}.$$

where $D = 490{,}000$, if A and B are reckoned in *feet*; or 149,349 if in *metres*. This formula consists of two terms —the first, or *logarithmic term*, is the principal one; the second, or *thermic term* (so called), is always very small in comparison with the first—so that it suffices to substitute for A in the second term the value of the first. The following example of computation further illustrates the formula:—

In August 1872 the simultaneous mean pressures at Sacramento, Colfax, and at Summit were 29·879, 27·475, and 23·336 inches respectively, and the altitude of Summit above Sacramento is 6989 feet. Required the altitude of Colfax above Sacramento. In this case:—

$$\begin{array}{ll} l = 29{\cdot}879 & \log l = 1{\cdot}47537 \\ n = 27{\cdot}475 & \log n = 1{\cdot}43894 \\ u = 23{\cdot}336 & \log u = 1{\cdot}36803 \end{array}$$

$$\log l - \log n = 0{\cdot}03643$$
$$\log l - \log u = 0{\cdot}10734$$

$$\begin{array}{lll} \log(0{\cdot}03643) & = -\,2{\cdot}56146 & \\ \log(0{\cdot}10734) & = -\,1{\cdot}03076 & \\ \hline \text{Difference} & = -\,1{\cdot}53076 & \\ \log B & = 3{\cdot}84441 & 6989 = B \\ \hline \text{sum} = \log(\text{first term}) & = 3{\cdot}37511 \ldots & 2372{\cdot}0 = \text{first term} = A \text{ nearly} \\ \log(B - A) & = 3{\cdot}6644 \ldots & 4617 = (B - A) \text{ (approximately)} \\ \text{colog}(490000) & = -\,6{\cdot}3098 \ldots & \\ \hline \end{array}$$

$$\text{Sum} = 1{\cdot}3493 = \log 22{\cdot}4 \ldots \text{the second term}$$

Required difference of altitude = 2394·4 feet.

The author, considering the direct calculation of the second term inconvenient, has calculated a table of double-entry showing the value of this term as a correction of the first term for every 100 feet of B and of the approximate value of A, which is appended. A graphic table is also appended (plate lxii.) for computation of this *thermic* correction. However, as the table of logarithms must be to hand, the direct calculation does not seem to present any particular inconvenience.

By thus abandoning the thermometer and psychrometer, and employing the barometer alone, the author reverts to elementary principles upon which all barometric measurements depend, and presents in his first chapter a review of the purposes and conditions of barometric hypsometry in general, and although not presenting anything new, is yet very interesting. The principle which underlies the measurement of heights by the barometer is exceedingly simple, but its application is fraught with difficulty. The law of the relation of altitude to atmospheric pressure is consequent on the law of the compressibility of gases, and is simply a certain multiple of the logarithm of the air-pressure. But there are numerous modifying conditions which must be considered in the application of this law. After describing the construction of barometers, of which the mercurial is both the oldest and the most accurate, the author passes to the consideration of the modifying conditions of the temperature and humidity of the atmosphere which are ever varying, so that the static order of densities is broken, currents are set in motion, and the circulation and the inequalities of temperature conspire to produce inequalities of moisture. Every element of equilibrium is thus set aside, and the air is rendered heterogeneous in composition, temperature, and density. Moreover, the disturbing factors are so multifarious and complex that there is infinite variety of combination and infinite variety of result. Approximate solutions of the problem are therefore only expected; and the author, after describing the disturbing factors—gradients, temperature, humidity—and the various devices for the elimination of the errors due thereto, and other general devices for diminishing hypsometric errors and the relative importance of different sources of error, arrives at the conclusion that the difficulties which inhere in the use of the barometer for the measurement of heights are so numerous and so baffling that there is no reason to hope they will ever be fully overcome. The best that can be done is to mitigate them, keeping in mind that the barometric method must not be so elaborate that its cost will approach that of the use of the spirit level. The problem, therefore, which occupies the attention of those who have occasion to use the barometer in extended surveys is how to secure the best result from a single observation at a new station combined with a series of observations at one or more base stations.

The author next proceeds in the second chapter to develop his *new method*, as explained above, and determines a mean value of the *thermic constant*, *D*. In Chapter III., on "Comparative Tests," various tables are given of the comparative results obtained by means of the new method and the ordinary and other empirical methods in use. This comparison shows the advantage of the new method in a reduction of one-half the error of the ordinary method, and one-fourth that of the empiric method. Nevertheless there is a considerable range of special cases in which the ordinary method can never be superseded.

Having shown that the new method is theoretically plausible and practically successful, the author considers in the fourth chapter the nature of possible improvements. This chapter, and the following fifth chapter on the limits of utility, and the sixth on the work of others, are more specially addressed to the students of hypsometry. This interesting work closes with a short chapter, the seventh, on the use of the table of the values of the *thermic term* —before-mentioned—and a supplementary note on devices to eliminate the influence of wind-pressure.

---

[1] "A New Method of Measuring Heights by Means of the Barometer." By G. K. Gilbert. Extract from the Annual Report of the Director of the U.S. Geological Survey, 1880-81. (Washington: Government Printing Office, 1882.)

It may be stated that of the seven plates referred to as illustrating this work, six are wanting in the copy now under notice.

ON A METHOD OF ESTIMATING THE STEADINESS OF ELONGATED SHOT WHEN FIRED FROM LARGE GUNS

IN October last it was stated in the newspapers that "at the request of Lord Alcester," and in the presence of the Lords of the Admiralty, "comparative trials of a Krupp gun and a 6-inch breechloader took place *greatly to the advantage of the former.*" . . . "The projectile used in the English weapon was 100 lb. with a 34 lb. charge, and that in the Krupp gun 64 lb. with a 14 lb. charge, *the results from the latter being far in advance of the former.*" If this statement be exact, the matter calls for the most careful consideration. In such a case the superiority of the Krupp gun must have arisen either from the higher initial velocity, or from the greater steadiness imparted to the shot by the Krupp gun, or probably from both these causes combined. The comparative merits of these or any other guns could be very readily settled by well-known methods of experimenting, at the expense of little more than the cost of 5 to 10 rounds of ammunition for each gun. There is no necessity for a repetition of the Armstrong and Whitworth competition, said to have cost some 30,000*l*.

Numerous experiments were made in this country in 1867-68 with guns of 3, 5, 7, and 9 inches calibre, to determine the resistance of the air to the motion of both round and elongated projectiles. Coefficients of resistance were then determined for all velocities between 900 f.s. and 1700 f.s. Additional experiments were made in 1878-79 with elongated projectiles alone, which gave the coefficient of resistance K corresponding to all velocities between 430 f.s. and 2250 f.s. But after this report had been printed, which contained general tables for both *time* and *space* within the above-named limits of velocity, it was decided to have additional experiments made with both lower and higher velocities. The final report of these experiments was published in 1880, which contained general tables for *space* and *time* for velocities between 100 f.s. and 2900 f.s. The values of K_v corresponding to the velocity v, as given in this report, will be hereafter referred to as the "tabular" values of K_v. The weight of a cubic foot of air was taken to be 534·22 grains.

In testing any new gun I would proceed, as in the above-named experiments, to measure the times occupied by the shot in passing over a succession of equal distances. These observations would readily give the velocity v of the shot at any point of its path, and also the corresponding coefficient of resistance K_v. Then according as the mean value of K_v derived from 5 to 10 rounds, was found to be *greater* or *less* than the tabular value of K_v, it would be evident that the gun on its trial gave a *less* or *greater* degree of steadiness than the average of the guns used in the experiments of 1867, &c.

Let us examine the relative value of these four guns in rounds where the middle velocity was about 1280 f.s.

Rounds 6-12, 124 and 126 were fired from the 3-inch gun, with projectiles of 9 lb., giving for K_{1280} respectively the values 136·5, 110·7, —, 114·5, 118·2, 121·0, 119·2, 111·7, and 111·2; the mean of which, 117·9, is 8·9 *higher* than 109·0, the tabular value of K_{1280}. Consequently this gun falls *below* the average in steadiness very decidedly.

Rounds 164-168 were fired from a 5-inch gun with projectiles of 47·68 lb., giving for K_{1280} respectively the values 110·2, 98·9, 91·0, 101·5, and 97·9; the mean of which, 99·9, is therefore 9·1 *below* 109·0, the tabular value of K_{1280}. Consequently these solid 5-inch shot had a very *high* degree of steadiness.

Rounds 148-153 were fired from the same 5-inch gun, but with hollow projectiles of 23·84 lb., giving for K_{1280} respectively the values 105·1, 113·4, 101·5, 105·4, 107·7, and 102·0; the mean of which, 105·9, is 3·1 *below* 109·0, the tabular value of K_{1280}. The steadiness of these shot was *above* the average, but inferior to that of the solid 5-inch shot.

Rounds 97-101 were fired from a 7-inch gun, with projectiles of 123·125 lb., giving for K_{1300} respectively the values 109·8, 118·7, 108·6, 117·6, and 117·5; the mean of which, 114·4, is 5·8 *greater* than 108·6, the tabular value of K_{1300}. The 7-inch projectiles were therefore *deficient* in steadiness.

Rounds 218-221 and 228 were fired from a 9-inch gun with projectiles of 250 lb. giving for K_{1280} respectively the values 110·4, 104·8, 126·0, 118·9, and 131·2; the mean of which, 118·2, is 9·2 *above* the tabulated value 109·0 of K_{1280}. The 9-inch shot were therefore very *unsteady*.

We thus arrive at the character of each of the experimental guns from the error in K_v. In the 3-inch gun the error was + 8·9; in the 5-inch gun (solid shot), − 9·1; in the 5-inch gun (hollow shot), − 3·1; in the 7-inch gun, + 5·8; and in the 9-inch gun, + 9·2.

Some experiments were made with projectiles provided with various forms of heads in 1866. Although the programme was never fully carried out, the rounds fired with hollow ogival-headed shot of one and two diameters were tolerably numerous. The two forms of shot were fired alternately, and gave the following values of K_{1400}.

Round	One diameter	Error	Round	Two diameters	Error
14	108·6	+0·1	15	108·0	+4·6
16	113·1	+4·6	17	—	—
18	109·6	+1·1	19	—	—
20	108·0	−0·5	21	103·5	+0·1
22	105·3	−3·2	23	104·6	+1·2
24	110·1	+1·6	25	99·1	−4·3
26	108·1	−0·4	27	100·8	−2·6
28	108·4	−0·1	29	103·0	−0·4
30	109·6	+1·1	31	104·0	+0·6
32	104·4	−4·1	33	104·2	+0·8
	10)1085·2	16·8		8)827·2	8)14·6
Means ...	108·5	1·7	Means ...	103·4	1·8

The tabular value of K_{1400} is 104·7, which was derived from experiments made with ogival-headed shot struck with a radius of one diameter and a half. The unit of K in the above cases corresponds to about the 1/50,000 of a second.

M. Krupp has recently circulated some tables which are based on coefficients, a little less than the tabular numbers above referred to, and about such as would have been obtained if I had used those coefficients only which were given by the most steady moving projectiles. Since 1868 there have been great improvements made in the manufacture of slow-burning powder, &c., which may have tended to give increased steadiness to the shot, and thus to reduce the resistance of the air slightly. Still I do not think it desirable at present to reduce my coefficients sensibly, because in all my experiments the velocities have been determined during the motion of the shot just after it had left the gun. But when the range of the shot is considerable, the direction of the axis of the shot must become inclined to the direction of the motion of the shot, and this must increase the resistance of the air. If it was thought desirable to reduce the coefficients of resistance throughout any range in a particular case by $\frac{1}{20}$th or $\frac{1}{10}$th, &c., this could easily be effected by multiplying $d^2 \div w$ by $(1 - \frac{1}{20})$, $(1 - \frac{1}{10})$, &c. For heavy shot the range should be extended much beyond 500 yards

The pamphlet alluded to above is entitled "Table de Krupp pour le calcul des vitesses restantes horizontales et des durées de trajet des projectiles oblongs. Essen, 1881." M. Krupp does not give any details of the experiments on which he professes to have founded his tables, or acknowledge any kind of assistance from any other author. He remarks that for a long time the resistance of the air was supposed to vary as v^2, then to depend upon two powers of v, and afterwards to vary as v^3 or v^4. Experiments have shown that these so-called laws of resistance are not good for all velocities. "Cette expérience devait le faire paraître utile de trouver une nouvelle méthod pour le calcul des vitesses restantes" (p. 16). And again, "Un tel tableau pour différences de vitesse de 10 cm. a été établi par l'usine Krupp au commencement de l'année 1880" (p. 18).

M. Krupp's tables are precisely the same as those that have been used in England since 1871, except only that French replace English measures, and that a small reduction of the English coefficients of resistance has been made throughout. Taking one of Krupp's examples (last page) 11/6/79, where d = 355 mm. = 13·977 inches; w = 525 kilos. = 1157·43 lbs.; commencing velocity 490 m.s. = 1607·64 f.s.; remaining velocity 415 m.s. = 1361·57 f.s., at distance 2384 m. = 7821·6 ft.; weight of 1 cubic metre of air = 1·200 kilos., M. Krupp finds from his table 411·8 m.s. for the remaining velocity instead of 415 m.s. given by his experiment. My table gives a remaining velocity of 405·7 m.s. But supposing we reduce the coefficients of resistance in the proportion 99·9 : 109·0 given by the experiments made with the 5-inch gun (solid shot), then we obtain 412·0 m.s. for the required remaining velocity, which is nearly the same as 411·8 m.s. obtained by the use of Krupp's table. Again, taking the experiment 6/8/79 with a projectile 400 mm. in diameter, commencing with a velocity 533·4 m.s., M. Krupp finds a remaining velocity of 447·0 m.s. by the use of his table, while I obtain 440·4 m.s. and 443·8 m.s. is given as the result of experiment. But if I reduce all my coefficients as before in the ratio 99·9 : 109·0, then my table gives 447·4 m.s. as the remaining velocity, which agrees with M. Krupp's calculations. Hence it appears that M. Krupp claims by these tables that his guns of 1880, on the average, give a degree of steadiness about equal to that given by the best of the four English experimental guns used in 1867-68. I have not much confidence in the accuracy of velocities measured at a distance of near one mile and a half from the gun by an instrument not specified, but I have used these data as a means of indicating to what extent the tables give different results. As a test of the tables I should much prefer a careful determination of the commencing velocity of the shot, and the time of flight to some known distant point, where all the times were measured by a *single* instrument.

For further information I beg leave to refer M. Krupp to (1) "Tables of Remaining Velocity, Time of Flight and Energy of various Projectiles, &c.," 1871; (2) to the *Proceedings of the Royal Artillery Institution*, Woolwich, September 1871, p. 382, &c.; (3) *Ib.*, April 1872, p. 1, &c.; (4) *Ib.*, December 1877, p. 250, &c.; (5) "Treatise on the Motion of Projectiles, &c.," 1873; (6) "Principles of Gunnery," by Major Sladen, R.A., 1879; (7) "Handbook for Field Service" (R.A.), 1878; (8) "The Construction of Ordnance, &c.," p. 359, &c., 1877; (9) "Reports on Experiments, &c., 84/B/2853," 1879; (10) "Final Report on Experiments, &c., 84/B/2909," 1880; and (11) and (12) "Manual of Gunnery for H.M. Fleet," 1880. And since that date my "General Tables" have been reprinted in four different books.

Since the above was written, I have noticed that the introducer of the Navy Estimates, 1884, remarked:—"*The old breech-loader* had been found to be of no more use than a muzzle-loader, and the Government had adopted a *gun twice as long* as the *old* form of breech-loader." I always understood that the profitable use of the new slow-burning powder required a *long* barrel, and that the breech-loading arrangement was introduced because it permitted the use of a longer barrel on shipboard than could be employed with muzzle-loading.

March 22 FRANCIS BASHFORTH

THIRD NOTE ON THE ELECTRICAL RESISTANCE OF THE HUMAN BODY

IN two previous communications last year, I showed that the amount of this important basis of rational electrotherapeutics had been enormously overstated. Since then I find it given in the new edition of Rosenthal's "Elektricitätslehre," published in the current year, as about 5000 ohms, and, to my surprise, so competent an observer as my friend Prof. Dolbear, in Lockwood's "Handbook of Electric Telegraphy," states it vaguely as from 6000 to 10,000 ohms. On the other hand, Count Du Moncel, in his paper on the conductivity of imperfect conductors in the *Annales de Chémie et de Physique*, vol. x., 1877, approaches more nearly to the real value in stating it from wrist to wrist to vary from 350 to 220 kilometres. This is probably the Swiss unit given in Clark and Sabine's tables as equal to 10·42 ohms or thereabouts. Both Rosenthal and Du Moncel furnish internal evidence that their excessive estimates were due to imperfect contact through the skin: for the former speaks of using fifty chromic acid elements of two volts E.M.F. each; whereas the current from this large battery, with proper contact, would be utterly unbearable to the patient, if not dangerous. The highest current I have seen employed was from twenty-two of these cells through less than 2000 ohms resistance. It was done against my advice, and produced a large carbuncular boil at the nape of the neck, where the negative pole was applied. I have since then completely modified my method of making the skin contacts, and no similar accident has occurred.

Even with a far smaller current, namely, that of eight Daniell cells and small platinum electrodes, of which the size is accurately given, namely, 4½ by 3 cm. (roughly, the length of two shillings side by side, and the breadth of a florin), Du Moncel produced a similar though much more serious accident. The current was passed at intervals for an hour and a half from wrist to wrist, the patient being a lady, and afterwards for shorter periods in the opposite direction. "On withdrawing the electrodes," says the writer, "to my great astonishment I found, on the parts of the wrists where my electrodes had been applied, very pronounced scars resembling burns produced by an acid or a caustic. These scars, to the number of three at the negative pole, were large and deep. At the positive pole they were very small, and thirty-two in number. During the first two days after the experiment no inflammation supervened, but on the third day it began about the negative scars, and it was necessary to have recourse to poultices, which were kept up for a month; even then the sloughs were not detached." It is satisfactory to find that no permanent harm was done; but it is evident that the excessive resistance recorded, amounting at times to 3500 ohms, was mainly due to this cause. It is perhaps not to be wondered at that the scientific Count should have relinquished this branch of his investigation.

With hands soaked in strong brine, and then enveloped in a thickness of flannel wetted with the same solution, bandaged surgically over this with a spiral strip of lead at least 30 cm. long and 5 cm. broad, no local accident has ever occurred to me, nor has any local pain been mentioned. But with ten bichromate cells in good order the shock felt at making and breaking circuit has often been considerable. Indeed my tall and athletic clinical clerk, Mr. Shackel, who kindly consented to act as a resistance, noticed that, when being tested from foot to hand (in his case a length of 7 feet) with 1027 ohms resistance, the opposite side of the body was jerked at these instants. In all recent experiments I have never exceeded this E.M.F., which is at the outside 20 volts, or about 18 volts as the cells run down.

In all cases hitherto named an ordinary battery current has been employed. In a paper read by me before the British Association at Southport, I named a rotating commutator and also one on the plan of a metronome which I had tried for the purpose of diminishing currents of polarisation by regular inversion. I preferred, however, the rapid manipulation of an ordinary commutating key with the fingers of the left hand until the "throw" of a damped galvanometer was all but extinguished.

At the Southport meeting, however, my friend, Dr. Oliver Lodge, suggested the use of alternating currents of induction, and a telephone in place of the galvanometer, and Prof. Lankester, the President of the Section in which my paper was read, kindly suggested that I should apply to the Royal Society for a grant in aid to purchase the expensive apparatus required for these experiments. The latter suggestion I at once acted on, and met with unconditional refusal on a printed form. Being thus thrown on my own small means, I proceeded to act on the former suggestion, and ordered an induction apparatus of an excellent London maker. But the British workman, if sure, is decidedly slow, and the instrument, though stated to be in a condition of forwardness, is not yet ready. In the meanwhile, in the pages of the *Electrical Review* for January 12, a diagram, description, and woodcut of a pretty little instrument designed by Prof. Kohlrausch of Wurzburg for the measurement of fluid resistances appeared; by his kindness I was put in communication with the firm of Hartmann and Co. of that town, the makers. They at once forwarded me the instrument, which proves to be beautifully made, and extremely moderate in price. This acknowledgment I owe to the Professor's courtesy towards a stranger, and their briskness in carrying out his wishes. Upon its details it is needless now to insist, it being practically a small induction-coil united to a metre-bridge of platinum-silver wire, with resistances of 1, 10, 100, and 1000 ohms, to be intercalated in the divided circuit. It emits a steady buzz of about 120 vibrations per second, which is reproduced in the telephone by methods well understood. In my first experiments I found the original and the phantom buzz difficult to separate. The former is easily lessened by mounting the apparatus on vulcanised rubber tubing and a solid support. The R. is read off the scale by inspection: towards the left hand or middle of the wire with great accuracy; towards the right-hand end the ohms get squeezed together. When I drew the plug of the 1000 R. my willing student-patient gave a jump out of his two brine baths and said he could not stand it. It was therefore necessary to use the 100 ohm plug. Even with this, however, the results were very remarkable. In this early period of my experiments two illustrative cases may be given. A female patient suffering from diabetes, but otherwise in good health, and able to walk about the ward, gave from foot to foot with an E.M.F. of 3·6 volts, a resistance of 1210 ohms; from right hand to right foot 1350 ohms; and from left hand to left foot exactly the same figure. With the induction current she gave from foot to foot only 473 ohms; from hand to foot 735 ohms on the right, and 750 ohms on the left, side. The difference was so great that at first I suspected instrumental error, but subsequent testings show that such is not the case. The discrepancy of 15 ohms between the two sides was clearly owing to my unfamiliarity with the telephone in place of galvanometer, and has materially lessened with greater experience.

A male patient suffering from dysentery, now perfectly well, gave from right hand to foot with a current of 3·6 volts a R. of 1580, with 6·2 volts a mean of 1510, with 18 volts a R. of 1366. Each observation was taken wice; the first and last agreeing exactly, the intermediate only differing from 1520 to 1500. This is impossible at times to prevent from the unintentional motions of the patient slightly shifting the level of the brine baths. With the same baths and poles the induction current gave only 590 ohms resistance.

In neither of these cases was there any morbid condition of the muscles tested. The distance was in each case from the external malleolus of the foot to the head of the ulna in the corresponding hand. In recording these results, I prefer, as on the former occasion, to give them at once in their rough state before waiting for a plausible explanation, or endeavouring to procure a fallacious agreement between the two methods. It is clearly not, as a writer in the *Electrical Journal* thought, a case of mere "cable-testing." What I stated then I now reaffirm, that there is some important difference of a physiological character between the human body as a conductor and ordinary fluid electrolytes.

No doubt, as Dr. Lodge suggests, "an alternating current ought to show too low a resistance, because of electro-chemical capacity, which it would treat like conductivity." But the difference is far too great for such an explanation, nor does it occur to this extent in saline solutions. I am at present engaged in testing its amount in physiological fluids, such as blood-serum, ascitic and ovarian effusion, and the like.

A beautiful metre-bridge on Prof. Kohlrausch's pattern, with platinum-silver wire of 3 m. long, has just reached me from Hartmann; with this I am using a "sledge" inductorium of Du Bois Reymond's with three different secondary coils of different lengths and fineness of wire. For the determination of the alternating currents passing I am using the small dynamometer with aluminium wire suspended coil which was shown before the Physical Society, and briefly described in NATURE.

This I shall check by a fine instrument now on its way from Wurzburg, with a single wire suspension and torsion head instead of the more sluggish bifilar method. Ultimately it may be necessary to use a quadrant electrometer.

Even at this stage it is obvious that the fact of the human body being about twice as permeable to induction as it is to low tension continuous currents is of great physiological and therapeutical importance.

W. H. STONE

INTERNATIONAL WEIGHTS AND MEASURES[1]

ALTHOUGH to some it might appear that the work of the Bureau at Sèvres is perhaps proceeding slowly, yet by reference to the two publications which have been issued under the authority of the Comité International it may be seen that the Bureau is doing its work thoroughly. The extent of the questions investigated is well shown in the first publication issued in 1881 (tome i.), which included papers by the director, Dr. Broch, on the force of gravity, the tension of vapour, the boiling point of water, and the weight of a *litre* of air; as well as independent investigations by Dr. Benoit on Fizeau's dilatometer; by Dr. Pernet, on thermometers; and by M. Marek, on weighing apparatus, &c.

The present publication (tome ii. 1883), to which we would now invite attention, contains accounts by Dr. Benoit of his expansion experiments; by M. Marek, on the methods and results of the weighings made at the Bureau from 1879 to 1881; and by Dr. Broch, on the expansion of mercury. In the experiments on the dilatation of standard measures of length, there has been followed a method attributed to General Wrede. It consists in the first instance in adjusting under two micrometer-microscopes a platinum-iridium bar, on which the length of the metre has been marked by means of two fine lines. The position of the lines at a constant temperature is then determined by the micrometers, the bar being placed for this purpose in a trough of water, the temperature of which is maintained constant by an improved automatic regulator. A second metal bar, whose rate of expansion is to be determined, is placed in a separate trough of water, the temperature of which differs considerably from that in the other trough. This trough is then also brought into position under the microscopes, and the positions of the lines on the second bar determined relatively to those on the first bar. This method has the advantage that the results are independent of any change in the distance between the axes of the two microscopes during the comparison of the two bars. The optical effect of the immersion of the bars in water was investigated by M. Krusper in 1872–73, who found it to affect the comparisons very little.

---

[1] "Bureau International des Poids et Mesures." *Travaux et Mémoires*, tome ii., 400 pp. Paris, 1883.

The comparing apparatus at the Bureau was originally made by M. Sörensen of Stockholm, but was subsequently altered and improved by the Geneva Society for the construction of physical instruments, under the directions of M. Turettini. The lines on the bars were illuminated by light reflected on to a small mirror fixed at an angle of 45° inside the microscope, a little above the object glass. The determinations of the errors of each micrometer-screw throughout its whole length, for even no micrometer-screw has yet been made in which appreciable errors may not be detected in its use, was made in accordance with methods followed by Drs. Foerster and Hirsch, and MM. Starke and Kammerer.

The thermometers used were constructed after the form adopted by the Bureau (tome i. p. B 8), and were made at Paris by M. M. Baudin and M. M. Alvergnat. It is satisfactory to find that to the important question of thermometers the Bureau has given much attention, as in such investigations errors of thermometers are of as great importance as the errors of the micrometer-microscopes, but are not, however, always so carefully attended to as they should be. The thermometers were calibrated after the methods suggested by Dr. Thiesen and M. J. Marek ("Repertorium der Carl," t. xv. 1879), and were corrected for "exterior pressure" to a barometric height of 760 mm. at 0° lat. = 45°, as well as for "interior pressure," or vertical position, the thermometers reading from 0°·02 to 0°·06 C. too high when placed in a horizontal position.

During the past years this apparatus has been used in determining the rates of expansion of the platinum-iridium metres deposited at the Bureau, which are intended hereafter to be the universal standards or prototypes of the metric system. The linear coefficient of expansion for 1° C. of the platinum-iridium was found to vary from 0·000008668 to 0·000008689, with a probable error of only ± 0·0000000075.

The high accuracy of the results obtained at the Bureau in the weighings there executed, have been already previously referred to, as they appeared in a separate form in 1881. In the present volume M. Marek gives the particulars of the experiments made by him in redetermining the density of mercury of the kind actually used in barometer tubes, taking the mean density of mercury as being comprised between that of perfectly dry mercury and of mercury exposed to moist air. Illustrations are given of the modes of purifying and of weighing the mercury. The density of four samples of mercury, as determined by weighing in water, was found after many experiments to be as follows :—

Mercury $A = 13{\cdot}595631 \pm 0{\cdot}000029$
" $B = 13{\cdot}595633 \pm 0{\cdot}000024$
" $C = 13{\cdot}595458 \pm 0{\cdot}000056$
" $D = 13{\cdot}595930 \pm 0{\cdot}000055$

In the paper, "Dilatation du Mercure," we find again that painstaking investigation and high accuracy which characterised the papers published in 1881 above referred to. The most exact observations on the dilatation of mercury are undoubtedly those of M. Regnault (*Mémoires de l'Académie des Sciences*, tome xxi. 1847); and it is to the mathematical reduction of these observations that Dr. Broch has now applied a critical examination, employing as his first coefficient of dilatation the value obtained by M. Wullner ("Lehrbuch der Experimental Physik," t. iii.) :—

$$d_t = 10^{-9} (181168 + 11{\cdot}554t + 0{\cdot}0211187t^2),$$

instead of that of Regnault—

$$d_t = 10^{-9} (179007 + 25{\cdot}232t).$$

By a reduction by the precise method of least squares, of the original observations to the latitude of 45° at the level of the sea ($B = 760$ mm.), there is now obtained for the cubic expansion of mercury the following formula, which we would recommend to the attention of those engaged in accurate work :—

$$1 + kt = 1 + 0{\cdot}000181792 \,.\, t + 0{\cdot}000{,}000{,}000175 \,.\, t^2 + 0{\cdot}000{,}000{,}0000035116 \,.\, t^3.$$

We note that for the current year the President of the Bureau is General Ibanez (Madrid), the Secretary being Dr. Hirsch (Neuchâtel), the Committee including MM. Dumas (Paris), Foerster (Berlin), Gould (Cordoba), Govi (Naples), Herr (Vienna), Hilgard (Washington), Krusper (Budapest), Stas (Brussels), Wild (St. Petersburg), and Wrede (Stockholm). This country is not represented on the Committee, our Government having decided not to take part in this international project.

LILÆA[1]

THE genus *Lilæa* was founded by Humboldt and Bompland for a very curious plant closely allied to our native *Triglochin*, which was first found by them in New Grenada. The present memoir, which has apparently only recently reached Europe, is one of the most elaborate studies probably ever made of the entire morphology, histology, and development of a single flowering plant, and is due to the unexpected discovery of the plant in 1875 in the Argentine Republic. The curious reductions of structure which are the result of a more or less aquatic mode of life have always made plants of this kind attractive to investigators.

The careful investigation of the structure of the flower throws some light on a point which has been much controverted, whether the stamen is ever an axial structure or not. *Lilæa* bears its flowers in a spike, and there are no less than three kinds :—(1) below, female; (2) in the middle, hermaphrodite; (3) at the top, male flowers. These latter consist of a single stamen in apparent direct prolongation of the floral axis. It is about these in the similar cases of *Naias* that discussion has arisen. Now Hieronymus contends that this stamen is really only pseudo-terminal, but that it consumes in its development the primitive meristem of the growing point, and so eventually occupies its place. He extends the same explanation to the cases of *Naias*, *Zannichellia*, *Casuarina*, *Brizula*, and others which have been held to support the axial origin of stamens. But as Sachs remarks ("Textbook," second edition, p. 541), the question cannot be settled wholly on anatomical grounds. And in *Lilæa* there can be no doubt that in the hermaphrodite flowers the stamens are lateral. In the male flowers he sometimes finds a lateral rudiment of a pistil; and this must be held to clinch the argument that the stamen is not really cauline, but always lateral and only pseudoterminal.

Lilæa has a fourth class of flowers, the adaptive origin of which is interesting. The whole plant is at first partially submerged—perhaps was once wholly so. The lowest flowers of the inflorescence are female, and seated in the axils of the sheathing leaves; but the style is enormously elongated so as to carry the stigma to the surface of the water for fertilisation. This recalls the habit of *Vallisneria*. But, as Mr. Bentham reminds us, the resemblances of *Hydrocharideæ* and of *Naiadaceæ* are essentially adaptive, and must not blind us to the real profoundly divergent affinity.

---

It is worth noting, as a hint to those interested in researches of this fascinating kind, that the investigations of Dr. Hieronymus were made partly on material preserved in a mixture of two-thirds alcohol and one-third glycerine, partly in an aqueous solution of salicylic acid (no further details are given). W. T. T. D.

PROFESSOR FLOWER

PROFESSOR FLOWER'S resignation of the office of Conservator of the Museum of the Royal College of Surgeons was received at the last meeting of the Council of that body, held on March 13, whereupon it was moved by Sir James Paget, seconded by Mr. Erichsen, and resolved unanimously:—"That the Council hereby desire to express to Mr. William Henry Flower their deep regret at his resignation of the office of Conservator of the Museum of the College.

"That they thank him for the admirable care, judgment, and zeal with which for twenty-two years he has fulfilled the various and responsible duties of that office.

"That they are glad to acknowledge that the great increase of the Museum during those years has been very largely due to his exertions and to the influence which he has exercised, not only on all who have worked with him, but amongst all who have been desirous to promote the progress of anatomical science.

"That they know that, whilst he has increased the value and utility of the Museum by enlarging it, by preserving it in perfect order, and by facilitating the study of its contents, he has also maintained the scientific repute of the College by the numerous works which have gained for him a distinguished position amongst the naturalists and biologists of the present time.

"And that, in thus placing on record their high appreciation of the services of Mr. Flower, the Council feel sure that they are expressing the opinion of all the Fellows and Members of the College, and that they will all unite with them in wishing him complete success and happiness in the important office to which he has been elected."

The conditions under which the Conservatorship of the Museum of the College will be held in future are at present under discussion, and will probably be decided at the next meeting of the Council on the 10th inst., when the office will be declared vacant, and candidates invited to send in their applications.

THE DEEP-SEA DREDGINGS OF THE "TALISMAN"—CRUSTACEA

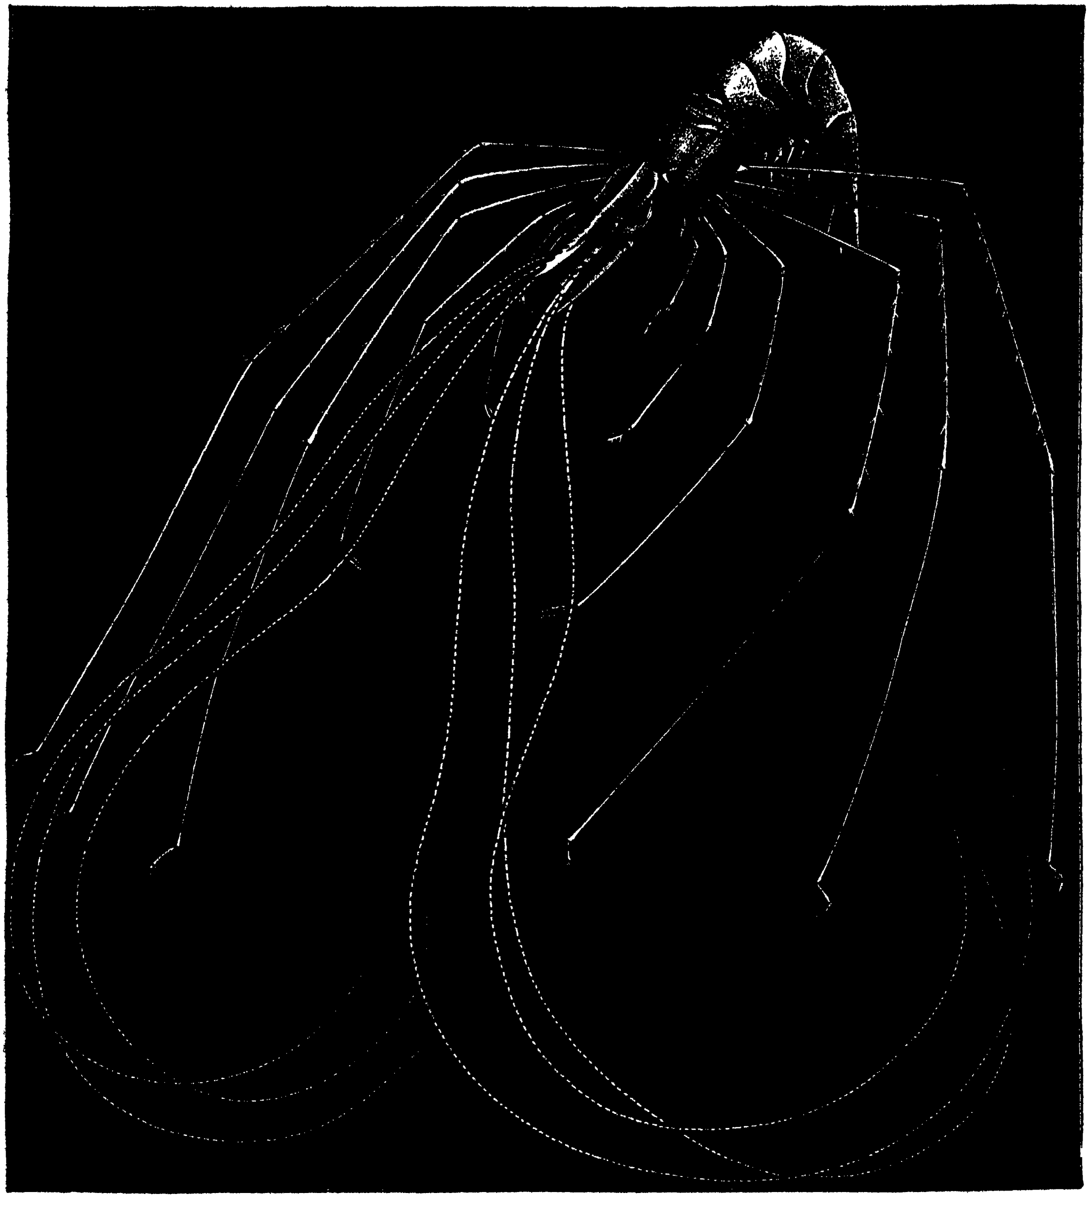
IN a previous article attention was called to some of the more remarkable of the deep-sea fishes taken during the recent cruise of the French frigate the *Talisman:* not less interesting were the numerous forms of Crustacea dredged during the same cruise, a fine collection of which were also on view at the Jardin des Plantes, Paris, as part of the spoils brought home after the voyage. From a survey of the specimens it is evident that these Crustacea are to be found at all depths of the ocean: some pass their lives floating on its surface, feeding thereon or amid the acres of Sargassum weed; while others live at depths of from 4000 to 5000 metres. The so-called swimming crabs which form a section of the Brachyura would seem to be extremely rare at great depths. Certain species taken during the *Talisman's* cruise are remarkable for their very extensive geographical distribution; thus, species of Batynectes which were found at depths of from 450 to 950 metres off the coasts of Morocco and about the Cape Verd Islands, seemed very closely related to the swimming crabs (Portunus) of our own seas, and again to be very nearly connected to species of the same genus collected at the Antilles, in the Mediterranean, and in the Arctic Ocean. Another section of the Brachyura, with sharp triangular bodies (Oxyrrhyncha), contains species which are to be met with at much greater depths; thus *Lispognatus thompsoni* (A. M. Edw.) was dredged off the coasts of Morocco from depths of between 600 and 1500 metres, and *Scyramathia carpenteri* was taken at the same place from a depth of 1200 metres. The former of these species has been found in the North Sea, and the latter has been taken off the north of Scotland and in the Mediterranean. The Crustacea intermediate by their forms between the Brachyura and the Macrura were found in abundance at very great depths, and the forms found seemed in great measure to belong to "transition" forms; so one was often surprised to find a form, which taken by itself appeared abundantly distinct, quite connected with others by numerous intermediary forms. Thus species of Ethusa, Dorippe, Homola, and Dromia seem to present such numerous shades of gradation as to perplex one completely in the difficult task of classifying these genera. Some of these forms are also very remarkable for their geographical distribution: a species of Dicranomia, described by Milne-Edwards from the Antilles, was found off Morocco, and *Homola cuvierii*, up to this thought to be peculiar to the Mediterranean, was found at the Azores and the Canaries. But the most remarkable instance of the geographical extension of which some genera are capable is furnished by some species of the family Lithodina. These Crustacea to this have been known as inhabitants of the Arctic and Antarctic regions, living in the littoral zone, but now they have been found under the tropics; the only difference being that in this latter locality they have contrived to find congenial conditions of life by abandoning their shallow-water life and betaking themselves to the cool depths of over 1000 metres. A fact like this is not without its interest, inasmuch as it shows how some forms can spread themselves from the frozen seas of the north to the seas of the tropics, and so from the region of one Pole to the other; altering their conditions of life as necessity demanded, and resuming their old habits when the opportunity to do so again occurred.

The Crustacea known as Hermit Crabs were found to extend to a depth of 5000 metres; as is well known, the terminal portions of the bodies of these Hermits are soft, not covered like the head and claws of the crab with a strong calcareous shell, and these animals have the habit of tucking the soft part of their bodies for security into the body-whorl of some empty shell; but at the great depths referred to shells suitable for this purpose are not to be found, and the hermit crabs inhabiting these depths must often be in great difficulties for material wherewith to cover themselves. In one specimen taken off Morocco this covering consisted of a living colony of a very pretty species of Epizoanthus.

Species of the family Galatheidea were found in profusion at all depths; but the colour of their body, generally that of a red or pink hue, was in the forms from the great depths of a uniform white. Some species were found which occupied the interior of those lovely siliceous sponges belonging to the genus Aphrocallistes. One new species, *Galathodes antonii*, was found at a depth of 4000 metres, and another, from the same depth, with its abdomen coiled twice upon itself, has been also described by A. M. Edwards as new (*Ptychogaster formosus*).

Of the group of Eryonidæ a considerable number of both genera and species were dredged. Of these, those belonging to the genera Polycheles, Wilmoesia, were from depths of from 4000 to 5000 metres, and the wonderful transparency of the forms permitted the whole internal viscera to be distinctly seen. Some species of Pentacheles were evidently allied to the fossil forms of Eryon.

Of the Crustacea belonging to the group of Macrura, the one to which the crayfish and shrimps belong, many were taken at very great depths. Off the Cape Verd Islands, from a depth of 500 metres, a thousand individuals of a new species of Pandalus were taken. Among the most remarkable of all of these forms is the one which, through the courtesy of the editor of *La Nature*, from which journal this notice is in part translated, we are enabled to give the accompanying illustration. Named *Nematocarcinus gracilipes* by Alphonse Milne-Edwards, it was, when taken fresh from a depth of 850 metres, of a splendid rose colour. The extreme length of its antennæ will at once attract attention, and tno less remarkable are the wonderfully attenuated feet, of which the third, fourth, and fifth pairs are longer than the first and second. The eyes are large, but the eye-stalks are not elongated. In another member of this group, *Glyphus marsupialis*, the female had the lateral portions of the abdominal segments developed so as to form a pouch-like receptacle, in which the eggs were deposited.



Nematocarcinus gracilipes (A. M. Edw.).

When trying to draw conclusions from the phenomena presented by the numerous forms of Crustacea collected during the *Talisman* cruise, one is struck by the strange diversity in these phenomena. While some of the species are blind, others have well-developed organs of vision; while in some the eye-stalks are flexible, in others they are immovable; while in some there is a very marked transparency of the integuments and a decided softness of the muscular tissues, in others neither of these facts is at all apparent. Some of the deep-sea Crustacea are beautifully phosphorescent, and in certain species this phosphorescence is not diffused but is limited to some special areas of their bodies, and in a new species, *Acantephyra pellucida* (A. M. Edw.), the feet are adorned with phosphorescent bands. We of necessity know so little of the habits of these new, strange forms, that it would be premature to draw scientific conclusions from their structure.

THE SOCIETY FOR THE BIOLOGICAL INVESTIGATION OF THE BRITISH COASTS

THE meeting which we previously announced as about to be held for the purpose of inaugurating a new society having the above title, took place last Monday in the rooms of the Royal Society, Prof. Huxley being in the chair. The meeting was large and influential. Among those present were the Duke of Argyll, the Earl of Dalhousie, Lord Arthur Russell, Sir Lyon Playfair, M.P., Dr. W. B. Carpenter, Sir Joseph Hooker, the Hon. Edward Marjoribanks, M.P., Sir John Lubbock, M.P., President of the Linnean Society, Mr. J. Blake, M.P., Sir George Nares, Dr. John Rae, Sir Joseph Fayrer, Capt. Verney, R.N., Prof. Flower, Prof. Ewart, Dr. John Evans, Prof. Bonney, Dr. Spencer Cobbold, Mr. John Murray (of the *Challenger* Office), Dr. J. Gwyn Jeffreys, Dr. Günther, Prof. Moseley, Mr. G. J. Romanes, Mr. H. C. Sorby, Mr. Francis Galton, Mr. Brady, Prof. Crofton, Mr. Dawson Williams, Prof. St. George Mivart, Mr. Busk, Dr. Sclater, Dr. Dodson (Netley), Mr. Thiselton Dyer, Mr. H. C. Burdett, Prof. Donkin, Dr. John Murie, librarian of the Linnean Society, Mr. W. H. Dallinger, Dr. A. Geikie, Mr. E. Forbes Lankester, Mr. Saville Kent, Mr. M'Lachlan, Dr. Herbert Carpenter (of Eton), Prof. Jeffrey Bell, Mr. Frank Crisp, and Prof. Ray Lankester. Letters regretting inability to attend were read from Lord Derby, the Marquis of Hamilton, Sir Thomas Dakin, Mr. Chamberlain, Mr. Burdett-Coutts, Mr. R. W. Duff, M.P., and Dr. Dohrn.

Prof. Huxley, in opening the proceedings, began by observing that the object with which the meeting had to deal was not in his hands, but in those of Prof. Lankester, who had requested that the Royal Society should foster an undertaking which promised well for the progress of science. The establishment of marine biological stations had been undertaken during the last few years by most of the civilised countries, and was, indeed, a necessary result of the great change which had taken place in the aims of biological science. The study of development began about half a century ago, and the ramifications of that inquiry, which had been extended to the mode of becoming of all live things by Mr. Darwin, had caused a complete change in the methods of biological research. In order to investigate the living being it was now no longer deemed sufficient, as in the days of our great-grandfathers, to observe its outside, or even, in the days of our grandfathers, to examine its anatomy. We have now to trace its developmental growth from the egg, and we are able to do so with a thoroughness of which no one in his young days could have had any conception. Such was one good reason for founding an institution of this kind from a purely scientific point of view. But there was another reason from another point of view which was practical. We had great fisheries and great fishery interests, and up to within the last thirty years legislation with reference to them was almost entirely haphazard, owing to our ignorance of the habits, modes of life, reproduction, and so on, of marine animals, which were economically useful. If we are to have any considerable improvement in our legislation in this respect, our arguments and reasonings with a view to it must rest upon sound and exact observation. In conclusion, he wished to say with special emphasis that there was no possibility of any rivalry between the society which it was now proposed to found and another society the formation of which was announced a few days ago by H.R.H. the Prince of Wales. That society was, in the ordinary sense of the word, practical. He trusted that when both societies were established, so far from there being any conflict between their aims, they would work in concurrence to a common end.

The Duke of Argyll said the resolution which had been placed in his hands was—"That in the opinion of this meeting there is an urgent want of one or more laboratories on the British coast, similar to those existing in France, Austria, Italy, and America, where accurate researches may be carried on, leading to the improvement of zoological and botanical science, and to an increase in our knowledge as regards the food, life, conditions, and habits of British food fishes and mollusks in particular, and the animal and vegetable resources of the sea in general." The fact of their being called together to form a voluntary society to carry out these objects implied a discovery on the part of those who had taken a leading part in this matter that the work was not likely to be taken up by the Government. He was afraid that in this respect the British Government had always stood rather behind those of other countries, whether monarchical or republican. There were other agencies by which facts about food fishes would be obtained, and he instanced the researches of the President of the Royal Society, and a valuable paper recently contributed by Prof. Ewart upon one of the most important questions connected with food fishes—the spawning of the herring. When further researches of this kind should be forthcoming, it can scarcely admit of doubt that, by making us acquainted with the life-history and habits of the herring, they will serve to improve the herring fisheries. He had himself good reason to appreciate the importance of acquiring information of this kind, for in the vicinity of his own residence the fishing community was suffering distress on account of the herring having abandoned Loch Fyne without any one being able, in the present state of our knowledge, to assign the cause. Moreover, the opposition which was raised to ground-trawling in Loch Fyne, on the supposition that the practice is destructive of herring spawn, has been shown by such researches to be without any justification—the spawn having been found to adhere closely to the sea-bottom. But great as would be the probable economic nature of a marine biological station in the improvement of our fisheries, he thought that the chief object in promoting this society should be that of promoting the interests of biological science. Enlarging upon the importance of this science, he concluded by observing that the branches of it which would fall to the lot of this society to cultivate would have the advantage of avoiding contact with the question of vivisection; for he supposed that even the most susceptible of anti-vivisectionists would scarcely have their feelings touched by physiological experiments on jelly-fish.

Sir Lyon Playfair, M.P., in seconding the resolution, dwelt upon the anomaly that a country which depends so much upon its fisheries as Great Britain should hitherto have been the only Great Power which had not founded a zoological station. He then proceeded to enumerate some of the economic advantages which had been secured by such institutions elsewhere, especially in America.

Lord Dalhousie and Prof. Flower also supported the motion.

Dr. W. B. Carpenter moved:—"That it is desirable to found a society, having for its object the establishment and maintenance of at least one such laboratory at a suitable point on the coast, the resources of the laboratory its boats, fishermen, working-rooms, &c., being open to the use of all naturalists under regulations hereafter to be determined."

Sir John Lubbock, as President of the Linnean Society and a trustee of the British Museum, in seconding this motion said he thought they owed their thanks to Prof. Lankester for the efforts he had made to found the proposed society.

Dr. Günther supported the resolution, which was passed.

Sir Joseph Hooker moved:—That this meeting does hereby agree to constitute itself such a society under the title of "The Society for the Biological Investigation of the Coasts of the United Kingdom." He dilated upon the importance of such a society to the interests of botanical science. The motion was seconded by Prof. Moseley, who appropriately called attention to the fact that most, if not all, life upon this planet was littoral in origin, and afterwards spread on the one hand to the deep sea and on the other to the land.

On the motion of Sir William Bowman, F.R.S., it was resolved that gentlemen whose names follow be requested to act as a provisional council and report to an adjourned meeting to be held on Friday, May 30, as to the constitution and organisation of the society and other matters, and in the meantime have power to admit suitable persons to the membership of the society; further, that Prof. Lankester be asked to act as secretary and Mr. Frank Crisp as treasurer *ad interim*. Those named were the Duke of Argyll, the Earl of Dalhousie, Lord Arthur Russell, the Lord Mayor, the Prime Warden of the Fishmongers' Company, the President of the Royal Society, the Presidents of the Linnean, Zoological, and Royal Microscopical Societies; Dr. W. B. Carpenter, F.R.S.; Mr. W. S. Caine, M.P., Mr. Frank Crisp, Mr. Thomas Christy, Mr. Thiselton Dyer, F.R.S., Prof. Flower, Mr. John Evans (treasurer of the Royal Society), Dr. Albert Günther, F.R.S., Sir Joseph Hooker, Prof. Michael Foster (secretary of the Royal Society), Prof. Ray Lankester, F.R.S., Prof. M. Marshall, Prof. Moseley, F.R.S, Mr. John Murray, F.R.S.E., the Rev Dr. Norman, Mr. George J. Romanes, F.R.S., Prof. Burdon Sanderson, F.R.S., Dr. Sclater, Mr. Adam Sedgwick, Mr. Percy Sladen, Mr. H. C. Sorby, F.R.S., and Mr. Charles Stewart, F.L.S.

Mr. G. J. Romanes, in seconding the motion, took occasion to observe that in his opinion one of the most important functions of the society when formed would be that of conducting researches upon invertebrate physiology. He was sure he would be but carrying with him the assent of all physiologists when he said that it is to the invertebrate forms of life that we must now look for the elucidation of many of the most fundamental problems connected with life-processes. It is in the Invertebrata that we meet with life in its least compounded state, and therefore in the state best suited to observation and experiment directed towards the solution of these fundamental problems. The sea is the great magazine of invertebrate life, and if the rich stores of material therein presented have been hitherto almost entirely neglected by physiologists, the explanation may be found in the fact that physiological research can only be conducted in well-equipped laboratories, which have been of but comparatively recent institution upon the sea-coasts of Europe and America.

Prof. Ray Lankester then moved a vote of thanks to the President of the Royal Society for taking the chair, and said it had been estimated that from 6000*l.* to 10,000*l.* would be required to start the project. He invited immediate subscriptions, payable *ad interim* to the treasurer, Mr. Frank Crisp, 6, Old Jewry, E.C. Sir Joseph Fayrer seconded the motion, and the President having briefly replied, the proceedings terminated.

NOTES

IN the death of the youngest and one of the most accomplished of the Queen's sons the cause of education has sustained a loss. The Duke of Albany knew well what science meant, and on several occasions publicly expressed his sense of its value in respect of the nation's welfare, and the necessity for its introduction into our systems of education. There can be no doubt that had he lived he would have rendered service to the best interests of the country. It is so rarely that princes have the tastes and leanings of the late Royal Duke that we could ill afford to lose him.

THE organising committee of Section F (Economic Science and Statistics) have arranged the following programme of subjects for discussion at the Montreal meeting of the British Association. The subjects will be distributed over the four or five days which will probably be at the disposal of the Section. Group I. Population: (1) Emigration; (2) Census results; (3) Distribution of wealth and condition of the poor. Group II. Land: (4) Agriculture; (5) Land laws; (6) Forestry. Group III. Trade: (7) Manufactures, shipping, and foreign markets; (8) Internal communication by land and water. Group IV. Finance: (9) Monetary system; (10) Public debts (Governmental and Municipal). Writers have been engaged for most of the subjects in the above programme.

WE regret to announce the death, at the age of sixty-seven years, of Mr. Nicolas Trübner, the well-known publisher, who has done so much to place within the reach of the English public some of the best works in German philosophy, science, and learning. He will be missed by a wide circle of friends, among whom are many men of science, English and foreign.

THE Prince of Wales has formally urged upon the Corporation and the Livery Companies to lend still further aid to the City and Guilds of London Technical Institute, which is greatly in need of funds; and the Corporation proposes to vote a further sum of 1000*l.* provided the Livery Companies subscribe the rest of the 20,000*l.* needed by the Institute.

AS usual there was some pleasant talk at the Civil Engineers' dinner last week; Prof. Huxley in replying to the toast of "Science," said there was one educational aspect which was extremely instructive and important, and that was the insensible and almost unconscious education in science which was carried on upon the masses of the people by the great work of engineers and mechanicians. The work of the engineer and all who were applying the teachings of science was surrounding the population with the symbols of scientific faith.

MR. W. SAVILLE KENT, F.L.S., F.Z.S., has been appointed Inspector of Fisheries to the Government of Tasmania, and proceeds shortly to the scene of his new duties. The more extensive introduction and distribution of the Salmonidæ already acclimatised in Tasmanian waters, and the resuscitation by artificial culture of the once prolific but now greatly depleted oyster fisheries, are among the special subjects that will engage the attention of the newly appointed Inspector. A systematic investigation of the marine fauna, with the view of turning to profitable account those edible, indigenous forms which are as yet but little utilised for economic purposes, will likewise be initiated. It is to be hoped that the Colonial Government will recognise the fitness of the opportunity that now presents itself of establishing in this quarter of the antipodes a well-equipped if small marine observatory for the artificial cultivation and scientific observation of the habits and developmental phenomena of the many interesting types peculiar to this region, and of which, as yet, biologists possess little or no knowledge. Mr.

Saville Kent's reputation as a marine zoologist, and the experience he has already gained as naturalist to various of the large public aquaria of this country, peculiarly qualifies him for the conduct of original investigation in this new field, which could not fail to yield important results for both the interests of science and the fishing industries of Tasmania.

THE Institution of Naval Architects is meeting this week. The session was opened yesterday under the presidency of the Earl of Ravensworth. The papers down for yesterday were:—On the Riachuelo, by J. D'A. Samuda; description of the electrical launch built last year, by A. F. Yarrow; on the vibration of steam vessels, by Otto Schlick. To-day the following papers will be read:—On cross curves of stability, their uses, and a method of constructing them, obviating the necessity for the usual correction of the differences of the wedges of immersion and emersion, by William Denny, F.R.S.E.; the use of stability calculations in regulating the loading of steamers, by F. Elgar, Professor of Naval Architecture, University of Glasgow; on a new method for calculating, and some new curves for measuring the stability of ships at all angles of inclination, by M. Daymard; on some points of interest in connection with the construction of metacentric diagrams, and the initial stability of vessels, by P. Jenkins; on the combustion of fuel in furnaces of steam boilers by natural draught and by air supplied under pressure, by J. Howden; on the application of hydraulic machinery to the loading, discharging, steering, and working of steamships, by A. B. Brown; cast steel as a material for crank shafts, &c., by J. F. Hall; repairs to steamship machinery, by Andrew K. Hamilton. To-morrow the following are set down for reading:—Contributions to the solution of the problem of stability, by L. Benjamin; on the uses of Amsler's integrator in naval architecture, by Dr. A. Amsler; on the comparative safety of well-decked vessels, by Thomas Phillips; the graphic calculation of the data depending on the form of ships required for determining their stability, by J. C. Spence; description of Alexander Taylor's stability indicator, for showing the initial stability and stowage of ships at any displacement, by A. Taylor; some considerations relating to the riveting of iron ships, by H. H. West; on the ventilation of merchant steamers, by J. Webb; on water brakes, by Capt. F. J. Heathorn, R.A.; on improvements in apparatus and means for indicating the position of a ship's helm, by J. E. Liardet.

THE Geographical Society of Bremen publishes in vol. vii. part 1 of its *Deutsche Geographische Blätter* an interesting paper, by Dr. A. H. Post, on the development of family life among mankind from an original "matriarchal" condition. He brings forward some new evidence collected by Dr. C. A. Wilken in the Dutch East Indies, showing the existence of Malay families consisting of mothers and their children, to which the fathers do not belong as members at all, being in fact only visitors. Dr. Post, tracing the stages of progressive change under the influence of landholding and the union of individuals in states, which in the course of ages converted matriarchal into patriarchal society, expounds with much clearness the theory which has arisen in the last few years out of the works of Bachofen and McLennan. Some of this clearness arises no doubt from ignoring difficulties, but a sketch of this kind does not involve the responsibilities of a full-grown treatise.

THE International Health Exhibition will be opened by the President, the Prince of Wales, on Thursday, May 8, at 3 p.m.

THE death is announced of Dr. George Engelmann, the well-known botanist, who died at St. Louis on March 3, aged seventy-five. Also of Dr. Siegfried Aronhold, formerly Professor of Natural History at the Berlin Technische Hochschule, who died at Berlin on March 13.

NEWS from the Austrian traveller, Eduard Glaser, who had fallen dangerously ill, states that he has recovered, and left for Haschid on February 6, a part of Arabia hitherto unexplored by Europeans.

M. GABRIEL DE MORTILLET, Conservateur of the Museum of National Antiquities at St. Germain, has begun to issue a new monthly journal, *L'Homme*, entirely devoted to anthropology.

M. FREMY, Director of the Museum of Paris, has published a pamphlet defending the establishment against the Central Administration, which is desirous of appointing a director. Up to the present time the director has been nominated by his fellow professors. This liberal mode of nomination was established by the National Convention in 1793. It is probable that an effort will be made in the present session to extend this privilege to other establishments, as the Observatory and the Conservatoire des Arts et Métiers.

M. FREMY is desirous of establishing on the coast a marine laboratory in connection with the Museum of Paris. It is thought the money may be granted for establishing one in Algeria.

THE motion proposed by Admiral Mouchez to sell the Paris Observatory ground, has been defeated before the Academy of Sciences by a large majority. Only two members, MM. d'Abbadie and Faye, voted with the Admiral.

A CORRESPONDENT referred last week to the changes which have been introduced into the examinations for admission into the Royal Military College, and the subject was brought up in the House of Lords last Thursday by Lord Salisbury. "The change with respect to natural science," he said, "was much to be regretted, because there was no body of men to whom a knowledge of science could be more useful, and conduce more to their happiness, especially when it was considered that they had to pass their time in various parts of the world, often with no adequate employment for their spare hours." The Earl of Morley in reply said that "by the new scheme greater importance was given to modern languages and mathematics, less importance to science, and the English paper had been excluded from Class I. The object of these changes was to improve the examinations, and to encourage the subjects which must be taught. In drawing up this scheme the War Office had been in constant communication with the Civil Service Commissioners, and with many gentlemen interested in education. The main purpose of these examinations was to test the results of general education, and for that purpose the subjects themselves had, as far as possible, to be of a general nature. That constituted one of the evils of the present system. He did not think it was necessary, or even desirable, in framing a scheme of this kind to confine themselves to the curriculum of the public schools. It was, no doubt, a matter of regret that during the last five years the number of successful candidates who came direct from the public institutions to the Royal Military College had diminished rather than increased. He did not wish to speak harshly of the race of private tutors. Some of them were extremely able and ingenious, but as a rule their whole object was mark-making. These tutors did not require their pupils to read the books on which they were examined, but by an ingenious process of analysing their contents all the questions that could be put to them could almost be exhausted. But cram did not last, and it was no substitute for education." The Duke of Cambridge said that "the great object of the examination was to put forward such a syllabus that all young persons educated at the public schools of the country should be able to enter Woolwich or Sandhurst direct without going through the hands of the crammer. What was wanted to bring about this result was a general education which they could say every young gentleman ought to have to fit him for any sphere in life which he might intend to adopt. It would be time enough to teach military subjects when the candidates for the army got into the military schools. Up to that time their education should be general, and not special. The proposed change was entirely with the view of inducing the public schools, such as Wellington, Marlborough, and others, besides Eton and Harrow, to co-operate with the authorities in the endeavour to get rid of cramming." The Marquis of Salisbury believed that "nothing would ever get rid of cramming so long as there was a system of competitive examination. Cramming belonged to competitive examination. He ventured to say that the Government were pursuing their object in rather a dangerous way. If there was a difference between the great public authorities and the public schools, the former should lead. With respect to the question of English literature, he did not understand why boys should not be expected to get a general knowledge of it in the same way that they were expected to have a general knowledge of Latin literature. In France and Germany the language, literature, and history of the country were systematically studied, but we seemed to treat them as matters of no importance, or as things which might be learnt in the nursery, or accidentally in conversation after leaving school."

THE Ninth Annual Meeting of the members of the Sunday Society was held at 9, Conduit Street, W., on Monday last, Prof. W. H. Corfield, M.D., in the chair. The annual report, which was read by Mr. Mark H. Judge, Honorary Secretary, set forth the work of the Society during the past year. It referred at considerable length to the action taken in the House of Lords, and pointed out that the policy embodied in the resolution proposed this year by Lord Thurlow at the request of the National Sunday League differed from that advocated by Lord Dunraven and other representatives of the Sunday Society in both Houses of Parliament. Statistics of the Society's Sunday Art Exhibitions were given. The movement in the provinces had been successful at Newcastle-on-Tyne, the Public Library there having been opened on Sundays by the Town Council. His Grace the Duke of Westminster was elected President of the Society.

Two shocks of earthquake were felt at San Francisco in the afternoon of March 25. The series of earthquakes which began on the 25th ult. continues in the south of Hungary. In Vukovar some slight shocks were again felt on March 27 at 11 p.m. On the night of the 29th about sunset a pretty severe shock of earthquake was felt at Sinope and other places in the neighbourhood. In the town of Costamboul some old buildings fell, but no lives were lost.

THE Easter Monday and Tuesday excursion of the Geologists' Association this year will be to Lincoln; on Saturday, April 26, there will be an excursion to Guildford.

THE number of high-level meteorological stations has been recently increased by the opening of a station at Poni, on the Suram Pass of the Great Caucasus.

MR. CHARLES SMITH, Fellow and Tutor of Sidney-Sussex College, Cambridge, to whose valuable treatise on "Conic Sections" we have already drawn attention, has prepared a new elementary mathematical work which will bear the title, "An Elementary Treatise on Solid Geometry." It will be published almost immediately by Messrs. Macmillan and Co.

THE additions to the Zoological Society's Gardens during the past week include two Malbrouck Monkeys (*Cercopithecus cynosurus* ♀ ♀) from West Africa, presented by Messrs. G. Somerford and G. A. Zobel; an Axis Deer (*Cervus axis* ♀) from India, presented by Mr. L. B. Lewis; a Bosman's Potto (*Perodicticus potto*) from West Africa, presented by Capt. Grant Elliott; a Common Squirrel (*Sciurus vulgaris*), British, presented by Mr. P. Aug Holst; three Herring Gulls (*Larus argentatus*), European, presented by Mr. S. Aloof; a Rose-crested Cockatoo (*Cacatua moluccensis*) from Moluccas, presented by General Rundall, R.E.; a Grecian Ibex (*Capra ægagrus*), South-East European, presented by Mr. Thomas B. Sandwith; a Smooth Snake (*Coronella lævis*), British, presented by Mr. W. H. B. Pain; a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, a Rose-coloured Pastor (*Pastor roseus*) from India, deposited; a Leopard Tortoise (*Testudo pardalis*) from South Africa, an Egyptian Cobra (*Naia haje*) from Africa, purchased; a White-fronted Lemur (*Lemur albifrons*), a Vulpine Phalanger (*Phalangista vulpina*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE DOUBLE-STAR α HERCULIS.—Smyth, in his "Cycle of Celestial Objects," attributes to Sir William Herschel the discovery of the duplicity of this star; but the companion was detected two years earlier than Sir William's first observation, and under somewhat curious circumstances. It was perceived by Maskelyne while observing the meridian passage on August 7, 1777, and only seven days later Christian Mayer, also observing the transit of the star with his mural quadrant, noted it to be double. The particulars are detailed in Mayer's work, "De Novis in Cœlo Sidereo Phenomenis," published at Mannheim in 1779. He had communicated to Maskelyne a number of his results bearing upon the double-stars; and the Greenwich astronomer, in replying towards the end of 1777, relates that he had observed a similar phenomenon in α Herculis on the date given above, "et videns valde obstupui," he remarks, since he had so often observed the star on the meridian without perceiving the companion. Maskelyne considered it of the sixth magnitude, the principal star being estimated a third; the latter he judged to be reddish, and the companion pale; Mayer, who discovered the smaller star on August 14, called it a seventh or eighth magnitude.

Adopting Sir George Airy's intervals for the transit-wires in Maskelyne's instrument, we find from a number of transits of the two components—

For about 1778·2 ... $\Delta\alpha$ ... + 0·324s., $\Delta\delta$ ... − 2″·80.

And hence the angle of position 120°·8, and the distance 5″·47.

Mayer's observations extend from August 14, 1777, to August 26, 1779. His differences of right ascension vary from 0·75s. to 0·2s., and those of declination from 6″ to 1″·8, while his estimates of the magnitude of the smaller star vary from 6 m. to 8·9.

Sir William Herschel's first measures were made on August 29, 1779. Taking means of those made between this date and 1783·252, we find—

Position, 1782·36 ... 116°·9 Distance, 1780·33 ... 4″·88.

VARIABLE STARS.—Mr. Burnham, in a note to No. 545 of his recently published Catalogue of 748 double-stars, remarks: "The principal star is strangely wanting in many of the star catalogues." It was observed by Lamont in zone 364, and estimated 5 m.; it does not occur in Lalande, D'Agelet, or Bessel. On Bremicker's Berlin map it is marked 7 m., and it is 6 m. in Harding's Atlas. In the *Uranometria Argentina* it is called 6·3; Gould has no note upon it. We have also the following estimates:—

1879·345	Burnham	6·5
— ·549	Stone (Cincinnati)	7·5
— ·575	Burnham	6·5
1880·442	Stone	6·0
— ·520	Burnham	5·5
1881·383	„	6·5
— ·578	„	6·8

The star may perhaps vary from about the fifth to the seventh magnitude, but systematic observation is wanted to decide. Its position, brought up from Lamont to 1885·0 is in R.A. 17h. 8m. 46·9s., N.P.D. 104° 27′ 4″.

D'Agelet 5057 (a star to which attention has been already called in this column) deserves frequent examination. It was observed by D'Agelet on July 26, 27, and 29, 1783, being twice noted 6 m. and once 6·5. It was not observed either by Lalande or Bessel, but in the *Durchmusterung* we find it estimated only

9·4. Its place for 1885·0 is in R.A. 19h. 27m. 35·5s., N.P.D. 72° 29′ 54″.

Nos. 2577–78 of the *Astronomische Nachrichten* contain the late Prof. Julius Schmidt's results of observations of variable stars made at Athens in 1883, which were communicated about a fortnight before his sudden decease.

ON THE AURORA BOREALIS IN ICELAND

AS considerable doubt has hitherto prevailed as to the form and nature of the aurora borealis in Iceland, I have decided to pass the winter here in Reykjavik, in order to study the phenomenon on principles which I followed during my sojourn at Kautokeino last winter, 1882–83 (NATURE, vols. xxvii. p. 394, and xxviii. p. 397).

I arrived here about the middle of October last, and began my regular observations on November 6; and although the series of observations as yet is brief, and, through very unfavourable weather, not so complete as might be desired, I believe that a few preliminary remarks on this phenomenon may not prove without interest, particularly as the appearance of the aurora borealis here is somewhat different to what we might expect and what is generally assumed.

Weather more unfavourable than I have encountered since my arrival it is impossible to imagine. A sky nearly always cloudy, rain, snow, and storm following upon storm—such have its chief characteristics been. A clear sky is quite an exception, and when it occurs there is a wind blowing so keen and cutting that no human being can walk out of doors for any length of time. Iceland is, no doubt, not favoured with very congenial weather, but such a winter as the present must, according to the dwellers here, be considered as quite an exceptional one.

I have shown in Table I. the average cloud calculations of each evening hour (the observations begin generally at 5 p.m., and continue until two or three hours after midnight) from November 6 to January 28. Here 5 indicates the hour from 5h. to 5h. 59m., &c. The scale is the usual one, viz. from 0 (clear) to 10 (cloudy).

TABLE I.

Hour	5	6	7	8	9	10	11	12	13	14	15	Average
Clouds	8·06	7·72	7·51	7·83	7·90	8·10	8·24	8·0[illegible]	7·39	8·29	8·66	7·91

If an average of the nebulosity on each evening be taken, each value of the scale will fall on the number of days shown in Table II. The former are also calculated in per cents. of the total days (83).

TABLE II.

Clouds ...	0	1	2	3	4	5	6	7	8	9	10
Days ...	2	8	2	1	4	1	1	9	9	15	31
Per cent.	2·4	9·6	2·4	1·2	4·8	1·2	1·2	10·8	10·8	18·1	37·3
	14·5			7·2			22·9			55·4	

These figures speak so plainly for themselves that any comment is needless.

Through Iceland being situated in the zone of the terrestrial magnetism, it might be assumed that the aurora borealis attained a high degree of development and splendour here; but this has not been the case this winter, in Reykjavik at all events, even allowing for the unfavourable weather. The auroræ here are generally faint and wanting in force; it is only seldom that there is any energy in the movements, and but rarely that the forms are sharply defined, while the outlines are dim and vague.

There have therefore only been a few occasions on which I have been able to effect somewhat satisfactory measurements with the auroral theodolite of azimuth and the height. The aurora doubtless often reaches far up on the sky, and even travels far down on the southern horizon, but the force of light is very small. In spite of the circumstance that Reykjavik lies—judging by the appearance of the aurora borealis on the horizon—much nearer to the auroral maximum zone than Kautokeino, the appearance of the auroræ in the two places cannot be compared. There was activity, force, and colour; here is vagueness, uncertainty, and want of character. Only once—on January 25—I observed an aurora during one hour which was a true Arctic one, with defined, elegant outlines, intense play of colour, and bold movements.

The more extensive auroræ which I saw in Kautokeino generally finished by the bands or streamers changing into luminous clouds, which again shortly afterwards assumed the wave-like motion I have called "coruscation," and which often lasted for hours, flooding the entire heavens. This form of the aurora borealis *I have not observed on a single occasion here*, which appears to me to be a very remarkable circumstance. Extensive auroræ finish here through the simple vanishing of the light or by the changing of the forms into faint, luminous clouds consisting of stripes (north-east to south-west), or vague, cloudy bands which by degrees lose in energy and finally die away.

Any real corona I have not seen as yet, and the usual colours, viz. red and green, I have only noted on six occasions.

On forty of the eighty-three evenings I have effected observations there have been auroræ, which is rather a high figure when the unfavourable weather conditions are taken into consideration. But the aurora is, however, not always present when the sky is clear or nearly so; on the contrary, it is not nearly as frequent here as in Kautokeino. This will be understood from Table III., which has been framed on the assumption that all observations were equally divided over the twelve hours, viz. from 4h. to 15h., which also shows that in every hour there was observed one hundred times either aurora or clear sky without aurora. The lower figures show in per cents. when the sky was without aurora.

TABLE III.

Hour	4	5	6	7	8	9	10	11	12	13	14	15
W	75	72	77	88	91	97	89	83	63	53	62	33
o	25	26	23	12	9	3	11	17	37	47	38	67

In consequence of the great magnetic declination in Iceland, viz. about 40° N.W., the points of culmination of the arcs and bands fall far outside the astronomical meridian, and their direction is nearly north-east to south-west. From the measurement of twenty arcs, partly on the north, partly on the south horizon, I have certainly only obtained an azimuth of 22°·4 W., but I do not accept this as any definite result before more complete observations are in my hands.

The intensity of the aurora borealis here I have defined approximately in Table IV. by four degrees, viz. from one to four. From the total determinations of intensity for every hour when no aurora is visible, in spite of clear sky, being determined by 0, the following average figures are obtained:—

TABLE IV.

Hour	5	6	7	8	9	10	11	12	13	14	15	Average
Intensity	0·90	0·76	1·04	1·26	1·45	1·05	0·82	0·59	0·40	0·44	0·03	0·95

From these figures a decided maximum of intensity is manifest between 9h. and 10h.

As regards the position of the auroræ on the sky and the relative frequency of the various forms, I append a tabular list of observations. The abbreviations made in the same are these:—

H N.	Aurora stands near the northern horizon, *i.e.* the magnetic north.
l N.	,, ,, low in the north.
N.	,, ,, in the north (to a height of about 45°).
N h.	,, ,, on the northern horizon (to a height from the horizon about 70°).
N h—Z.	,, ,, on the northern horizon to zenith.

Further, *Z* indicates through or on both sides of the zenith *S*, south; *S Z*, south of zenith; *S h*, south horizon; *t*, over the whole sky; ÷, with the exception of; *N* + *S*, auroræ in the north and south (but not in zenith); 0, no aurora. Below *N′* I have collected the values of *H N*, *l N*, *N*, *N h*, and *N h—Z*; and under *S′* those of *S Z*, *S h*, and *S*; and under *t′* the others. with the exception of 0.

Table V. gives percentally, assuming an evenly divided time of observation, a view of the position of the auroræ in the sky.

Table VI. shows the relative appearance of the various forms calculated percentally on the same basis as in the previous tables. Here *I* indicates one arc; *I*=, several arcs; *II*, a band; *II*=, several bands; *j*, diffused; *s*, streaming; *js*, simultaneously diffused and streaming, or a variety between the two; *III* isolated streamers, or bunches of streamers; *V*, luminous clouds

On the valuable isochasme chart, in which Prof. Fritz has denoted the increasing frequency of the aurora borealis northwards, the maximum zone of the phenomenon falls far south of Iceland. I must, however, first explain what my definition of the word maximum zone is at present. It is a line passing across the places where the aurora not only appears and is most frequently visible, *provided the weather permits*, but where it also, as a rule, appears in zenith, or as often on the northern as the southern hemisphere. According to this definition, the correctness of which I think can neither be disputed nor doubted, Iceland lies, at all events this year, as was the case with Kautokeino and Bossekop last year, considerably south of the

I hope to be able to demonstrate this in a more conclusive manner still on a future occasion, when the winter is over and the numerous exact determinations of the southern border of the aurora borealis will be discussed.

The reason why the maximum zone lies so far south on Prof. Fritz's chart may be sought, perhaps, in the circumstance that the climatic conditions of Iceland to a great extent reduce the number of auroræ which an ordinary observer, who only casually or on particular occasions looks at the sky, may observe. That the maximum zone of the aurora does not really fall across the part shown in the chart is also distinctly apparent from what I learnt of its appearance at the Färoe Islands during my sojourn there.

It may perhaps be superfluous to state that neither here nor in any other place have I heard the mystic auroral *sound*. Neither has it ever been heard by any of the Icelanders I have as yet met with.

Shortly before leaving Copenhagen last autumn I spoke with a celebrated Danish *savant*, who had some years ago spent some time in Reykjavik, and who told me that he had on several occasions seen auroræ descend below and in front of the mountain Esja, about 2500 feet in height, and lying six to seven English miles away (NATURE, vol. xxix. p. 337). I was delighted with the prospect of being able to see a similar phenomenon, as, although my observations in the plane Bossekop-Kautokeino, previously referred to, had greatly contributed to strengthen my belief in the height of the aurora borealis being 100 km. or more above the earth (NATURE, vol. xxix. p. 412), I would with pleasure have accepted a proof so tangible pointing in another direction. I regret to say that my expectations have not been fulfilled. This is not because the aurora has not been in close proximity to Esja, as, the mountain lying to the north-east from this place, nearly all arcs and bands rise with their eastern end up behind and run above it, but *never have I been so fortunate as to see any auroral light descend to the top of the mountain or in front of its steep sides.* Even the highest-lying clouds are also, in Iceland, *below* the plane of the aurora borealis.

In connection with this point I may further mention that the faint luminosities referred to by Prof. Lemström above the mountain-tops at Sodankylä, and in other places (NATURE, vol. xxvii. p. 322), as well as phenomena of a similar nature have, I venture to assert, never been observed here. I have continually had my attention directed to this point, and there are several mountains here, but I have never been able to trace the slightest indication of such a phenomenon.

I brought with me the necessary apparatus and appliances for effecting such experiments as Prof. Lemström pursued on some mountains in Northern Finland for the production of an artificial aurora borealis, and shortly after my arrival I came to the conclusion that the above-mentioned mountain Esja was the most advantageous for such. Its great height, steep fall into the sea, and short distance from the town, were advantages such as no other spot in the district offered, but as I only brought with me 1000 m. of insulated wire—telegraph-poles with insulators cannot be employed in consequence of the nature of the ground—and wished to conduct the wire from the top of the mountain down to the sea at its foot, I was obliged to wait until I obtained more wire by the steamer at the end of November. Since then the execution of this plan has been attempted a number of times; men, boats, and horses have been ready, and everything prepared, but every time the unfortunate weather has frustrated the same. Even in the middle of summer the Esja is a mountain difficult to ascend, and at this time of the year it would be very dangerous to undertake an ascent with the heavy wires, insulators, and poles, without the weather being remarkably quiet for several days.

I intend, however, very shortly to make another attempt, and should this fail I will select a more distant but much lower and more unfavourably situated mountain-top. I will only add that a few days after my arrival I fixed one of Prof. Lemström's "utströmnings" apparatus—with 200 points—on the flat roof of a stone tower, 30 to 40 feet in height, and which lies free and isolated on a height in the vicinity of the town; but the same has up to the present, in spite of numerous trials, given no result whatever. Any current between the points and the earth cannot be traced, and of any luminous phenomena above them there has not been the faintest appearance. SOPHUS TROMHOLT

Reykjavik, February

ON THE NATURAL AND ARTIFICIAL FERTILISATION OF HERRING OVA[1]

IN 1862 Prof. Huxley arrived at the conclusion that herring visit our shores in order to spawn twice a year, some schools arriving during the autumn, while others make their appearance during the winter. The herring which spawn during the autumn chiefly frequent banks on the east coast, while those which spawn during winter are most abundant on the west coast. A report of the Scottish Fishery Board referring to the east coast spawning beds was published in NATURE on November 29 last. The present paper deals chiefly with the Ballantrae spawning bed, which lies off the coast of Ayrshire.

In 1862 Prof. Allman made some investigations for the Scottish Fishery Board, and succeeded in dredging and hatching what was considered herring ova; but since then, although important results have been obtained by the German and American Commissioners of Fisheries, little or nothing has been done in this country.

When examining the Ballantrae Bank the author of this paper succeeded in dredging several specimens of herring ova attached to stones, seaweed, and sea-firs. These stones coated with eggs varied from 6 inches to 1½ inches in length, and from 4 inches to 1 inch in breadth, but in all cases the eggs were attached to a comparatively smooth surface, and they were arranged either in low cones or in comparatively thin layers one or two eggs deep. The eggs on the sea-firs were always attached in small clusters about half an inch in diameter around the stems. On examining the spawn found on the stones and seaweed, embryos at various stages of development were at once visible, some of them apparently only three days old, while others had distinct eyes, and from their violent movements and their size seemed almost ready for hatching. Some of the egg-coated stones were taken to the University of Edinburgh, where the eggs hatched on March 15, eight days after their removal from the spawning ground, and to-day (March 17) they are three-eighths of an inch in length, extremely active, and swimming freely about in the water.

---

[1] Abstract of a paper read by Prof. J. Cossar Ewart, M.D., at the Royal Society, March 27. Communicated by the Author.

By taking soundings over the Ballantrae Bank in various directions, it was ascertained that it consisted of rock, stones, shells, and coarse sand, and that the depths varied from 7 to 13 fathoms. The outer edge of the bank shelved at most points rapidly until a depth of 17 fathoms was reached, and at this depth the bottom consisted of fine, soft mud. While on the east coast spawning grounds examined during the autumn the surface temperature in most cases varied from 53° F. to 55° F., and the bottom temperature from 52° F. to 54° F., even at a depth of 40 fathoms, the temperature at the Ballantrae Bank varied from 42°·8 to 43°·8 F. at the surface, and from 43°·5 to 42°·8 F. at the bottom. The corresponding surface temperature, however, on the east coast during the week ending March 8 was from 2° to 3° F. lower than at Ballantrae.

According to previous observers—

"When spawning takes place naturally, the eggs fall to the bottom and attach themselves." "But at this time the assembled fish dart wildly about and the water becomes cloudy with the shed fluid of the milt. The eggs thus become fecundated as they fall, and the development of the young within the ova sticking to the bottom commences at once."

Mr. Mitchell, in his book on "The Herring," referring to the once famous spawning bed off Dunbar, states that—

"About August 30 the shoals began to deposit their spawn a short distance from the harbour, and on September 3 the fishermen found that a very large body of herrings remained fixed to the ground in the progress of spawning, the ground being of a rocky or stony nature."

While many fishermen believe that herring spawn on hard ground, some believe that they also spawn on a clayey bottom; and while some think they spawn near the bottom, others affirm that they spawn near the surface. Having secured at Ballantrae a large number of live herring, some of the largest and ripest males and females were placed in a large wooden tank into which a number of stones and a quantity of seaweed had been previously introduced. After the fish had been about two hours in this tank, the stones and seaweed were examined. Although a few eggs were attached to both stones and seaweed, it was quite evident that the eggs had not been deposited in the same way as those found on the stones dredged on the previous day; but we were not surprised that only a few isolated eggs were found on the stones, because the fish had been disturbed every few minutes by the pouring of water into the tank.

On reaching Rothesay the hatching boxes and live herring were at once transferred from H.M.S. *Jackal* to the tanks—a tank into which comparatively little light entered being selected for the ripest and most vigorous herring. In about half an hour after they were introduced a large full herring was seen moving slowly about the bottom of the tank with four other fish making circles around her at some distance from the bottom. Appearing satisfied with a particular stone which she had evidently been examining, she halted over it and remained stationary for a few minutes about half an inch from its surface, the tail being in a straight line with the tank and the pectoral fins near or resting on the bottom.

While in this position a thin, beaded ribbon was seen to escape from the genital opening and fall in graceful curves on the surface of the stone, so as to form a slightly conical mass almost identical with a cluster on one of the stones dredged at Ballantrae. As this little heap of eggs increased—some falling to the left side one moment, while others fell to the right the next, according to the currents in the water—the males continued circling round her at various distances, while the other females in the tank remained apart. The males remained from 8 to 10 inches above the bottom of the tank, and formed circles varying from 18 inches to 2 feet 6 inches in diameter. Some of the males were swimming from right to left, others from left to right; and although there was no darting about, no struggling amongst themselves, there was a peculiar jerking of the tail as they performed their revolutions. Soon the object of this peculiar movement was sufficiently evident. Three or four times during each revolution each fish expelled a small white ribbon of milt, which varied from half an inch to three-quarters of an inch in length, and was nearly a line in breadth across the centre, but pointed at both ends, and somewhat thinner than it was broad. These delicate ribbons slowly fell through the water, sometimes reaching the bottom almost undiminished in size, but in most instances they had almost completely dispersed before the bottom was reached. In this way the whole of the water about the female became of a very faint milky colour, and practically every drop of it was charged with sperms, as was afterwards ascertained. It will thus be seen that there is no attempt whatever on the part of the males to fertilise the eggs as they escape from the female. While the female is depositing the eggs at the bottom, the males concern themselves with fertilising the water in the neighbourhood, and it will be observed that the males are careful to guard against the influence of currents by forming circles around the female and shedding milt on the way. It matters little how the currents are running, they are bound to carry some of the milt towards the eggs, the milt, like the eggs, sinking though not adhering to the bottom.

This then is the natural process of depositing and fertilising the ova of the herring in comparatively still water. When the female had deposited a certain number of eggs at any given spot, she moved forward in a somewhat jerky fashion without rising from the bottom, and as she changed her position the males changed theirs, so that the female was always surrounded by a fine rain of short sperm ribbons. A specimen of *Hydrallmannia* sent from Eyemouth seems to indicate that the female moves about amongst sea-firs and seaweeds in exactly the same way as she does amongst stones. On each stem of the colony there is a cluster of ova about the size of a small grape, and all the clusters had reached on arrival the same stage of development as if they had been deposited about the same time and by the same fish.

This method of depositing and fertilising the eggs accounts, I think, for all the eggs, or at least for a very large percentage of those found attached to sea-firs, seaweeds, and stones, containing developing embryos.

When a female was depositing her eggs, she was very easily disturbed; whenever anything was introduced into the tank she at once darted off. When strong currents were made, she at first seemed to apply herself nearer to the bottom, to make sure, as it were, that the spawn would get fixed before it could be carried away; but when the currents were further intensified she at once changed her position, and arrested the escape of the spawn. A spawning female was held immediately under the surface of the water so as to cause the spawn to escape. When this was done the spawn escaped in long ribbons consisting of a single row of eggs. So firmly do the eggs adhere to each other that in perfectly still water the ribbon was sometimes over a foot in length before it broke. When it had only about two feet of water to travel through, it fell in wide loops at the bottom, but when it had to fall over three feet the chain broke up into numerous segments which formed an irregular pattern on the bottom. From experiments made, it seems the further the eggs have to fall and the longer they are in contact with the water before they reach the bottom, they are more widely dispersed, and have all the less adhesive power. When the eggs are expressed in water moving rapidly in various directions, the chains soon break into short segments, and the individual eggs and the small groups are often carried a considerable distance before they reach the bottom.

A number of flat stones and pieces of seaweed were obtained, and a spawning female held over them at different distances in still water, in water with gentle currents, and in water with strong currents. In this way we obtained groups of eggs which mimicked in a very striking manner all the arrangements of the eggs on the stones and seaweeds dredged on the Ballantrae Bank. When gently pressed, a beaded ribbon consisting of a single row of eggs always escaped; when there were no currents, it formed a conical heap; when in a gentle current, the ribbon fell in irregular loops, the elements of which rearranged themselves so as to form a flattened cone; but when strong currents acted on it the ribbon was broken into fragments and only a few eggs succeeded in fixing themselves to the objects introduced. When the currents were strong, the males were seen not only to swim nearer the bottom but to expel longer ribbons of milt, which reached the bottom before getting dispersed and remained visible sometimes for ten minutes. On gently expressing a male under the water it was never possible to expel so fine or so short portions of milt as escaped naturally, but it was extremely easy expelling a ribbon from 18 inches to 3 feet in length, measuring 2 lines across and 1 line in thickness. Such ribbons fell to the bottom and remained almost unchanged for nearly two hours; they then assumed a segmented appearance, and in about three hours and a half had all but disappeared.

Eggs were allowed to escape into a vessel containing fine sand, and into another containing mud. The eggs after being fertilised underwent the early stages of development, but either owing to their moving freely about with the sand particles or owing to their getting coated over with the sand and mud their development was arrested. I have not yet determined finally if the development is arrested when the eggs are detached while development is proceeding, but this seems extremely probable.

When at Ballantrae I noticed that the trammel nets secured often more males than females. Mr. Wilson, fishery officer at Girvan, informs me that the ripest fish are caught in the trammel nets, while most of the unripe fish are obtained in the drift nets, and that at the end of the fishing season there are about three males taken for every two females, indicating not necessarily that the males are more abundant than the females, but rather that the males remain longer on the spawning ground; and Mr. Wilson believes that herring prefer quiet water free from strong currents when spawning, and that when the weather is fine the herring remain long upon the bank and deposit their spawn leisurely, but when there are strong currents they either hurry the spawning process or disappear into deep water.

As to artificial fertilisation and hatching I found, after many experiments at Ballantrae, that the best results were obtained when both the male and female were held under water while the milt and ova escaped, *i.e.* when the natural process of spawning is followed.

An ordinary wooden tub was obtained and filled with sea-water. Into this a small quantity of milt was expressed, the male being held completely under water while the milt escaped. A glass plate was then held about four inches beneath the surface of the water, and, the female herring being held about one inch beneath the surface, by gentle pressure the eggs readily escaped in the characteristic narrow beaded ribbon, and, by moving the fish over the surface of the glass, either a close or an open network could be formed. At first, where one loop crossed another, the eggs were two or more layers thick, but, either owing to the weight of the eggs or the gentle currents set up in the water, before a few minutes had elapsed, the eggs formed a single and almost continuous layer, the network arrangement having disappeared. The plate was then allowed to rest for two or three minutes at the bottom of the tub, and a few short ribbons of milt were again introduced. After moving the plate once or twice across the top of the tub in order to wash off any scales that were adhering, it was placed either in a hatching or a carrying box. Many thousands of ova treated in this way contain extremely active embryos, which are expected to hatch on March 22 or 23.

Prof. Ewart exhibited a number of specimens showing herring eggs attached to stones, seaweeds, and sea-firs, and some of the herring fry hatched on March 24 from the eggs artificially fertilised on March 8.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The electors have awarded the Radcliffe Travelling Fellowship after examination to Mr. J. E. Blomfield, B.A., late Natural Science Demy of Magdalen College, and now of University College Hospital, London. The Fellowship is of the annual value of 200*l.*, and tenable for three years provided that the Fellow travels abroad for his improvement in the study of medicine. This is the fourth time in the last five years that this prize Fellowship has been won by a student of Magdalen College.

CAMBRIDGE.—From the report of the last Local Examinations it appears that the answers in pure mathematics exhibited considerable improvement, while in applied mathematics the work was inferior, and much of the teaching in statics was imperfect, and not based on mathematics. In chemistry great inequality was shown, some centres sending uniformly good work, others being very inferior. The practical work is better done than the theoretical. The teaching of experimental physics is still very ineffectual in its results. In the senior paper in electricity and magnetism only two of the candidates showed any proof of accurate knowledge or scientific training.

In biology the answers were, on the whole, not good, yet at some centres candidates did extremely well. In botany vegetable physiology showed improvement, but floral diagrams are not sufficiently used. In zoology the candidates seemed to have no idea of the relative value of facts. In physical geography a marked absence of scientific method was noticeable in the answers; great ignorance of meteorological terms used in most daily papers was manifested.

The Cambridge Local Lectures have made good progress in the past session, much good having resulted from the conference of local committees and lecturers held last year. In a number of centres local associations have been formed for putting the lectures on a permanent basis. At Derby an Artisans' Higher Education Society has been formed, the subscription being very low. At the Midland Railway works the large mess-rooms have been utilised in giving short lectures to arouse interest among the men, Prof. Teall lecturing on chalk, Mr. Bemrose on the transit of Venus, Mr. Heycock on digestion, respiration, &c., and the men have always been appreciative. In the Newcastle district much eagerness has been shown by pitmen to attend the lectures, often at great personal cost and inconvenience. The cost, indeed, is so great as to form an obstacle of serious magnitude, and it is found that the desire for lectures is such that the overcoming of financial difficulties would lead to an enormous extension of the work. Efforts are being made to get the rules of the Trades Unions altered so as to enable them to contribute towards the cost of the lectures.

It is now proposed to constitute an examination in French or in German as the additional subjects required of candidates for honours degrees, unless the candidates choose rather to pass the General Examination for the B.A. degree. This change would be welcomed by the large number of students to whom the study of works in French and German would be an important aid in their Tripos subjects.

SCIENTIFIC SERIALS

THE *Journal of Botany* for March contains the conclusion of Mr. T. Hick's valuable paper on protoplasmic continuity in the Florideæ. In quite a number of distinct genera belonging to this class he has now traced connecting threads between the protoplasm from cell to cell. He regards these threads as permanent and essential structures, normally present in all parts of the thallus from the oldest to the youngest, not restricted to special localities and special cells.—Some details of the life-history of a rare and little-known British plant, *Lithospermum purpureo-cæruleum*, are contributed by Mr. Jas. W. White.

American Journal of Science, March.—Experimental determination of wave-lengths in the invisible prismatic spectrum, with plate, by S. P. Langley.—The Quaternary gravels of Northern Delaware and Eastern Maryland, with map, by Frederick D. Chester. From a careful survey of this region the author infers that the peninsula became depressed at least 350 feet towards the close of the Glacial period, when the estuary thus formed received the discharge of the Delaware River, which pushed its way across the present States of Delaware and Maryland to the head of the Chesapeake. By this current and the subsequent distributing action of the waves the red gravel was deposited. Later on the land began to rise, the violence of the flood was abated, and the northern glacier gradually broke up. During this period the Philadelphia Clay was deposited, and the boulders distributed over the estuary by the icebergs from the glacier. The land continuing to rise, the shoal gravels were piled up by the waves and tides, the river began to assume its present channel, and the Delaware and Chesapeake were finally parted.—On the identity of scovillite with rhabdophane, by G. J. Brush and S. L. Penfield.—A theory of the recent sun-glows, by H. A. Hazen. The author attributes the phenomena to the presence of watery vapour, ice crystals, or frozen water particles under a peculiar form in a rarefied atmosphere at a low temperature.—On the topaz and associated minerals found at Stoneham, Maine, by George F. Kunz.—A contribution to the study of the geology of Rhode Island, with map, by T. Nelson Dale.—On the crystalline form of the supposed herderite from Stoneham, Maine, by Edward S. Dana.

SOCIETIES AND ACADEMIES

LONDON

Chemical Society, March 20.—Dr. W. H. Perkin, president, in the chair.—The following gentlemen were elected Fellows:—F. W. Brown, H. Cave, F. W. Fleming, E. E. Graves, A. E. Lewis, J. E. London, G. A. Parkinson, S. Smith, G. Tunbridge, T. U. Walton.—The following papers were read:—Note on the preparation of marsh gas, by Dr. J. H. Gladstone and Mr. A. Tribe. In 1873 (*Chem. Soc. Journ.* xi. 682) the authors described a reaction in which pure marsh gas was obtained by the action of the copper-zinc couple on methyl iodide in the presence of alcohol. The loss of the methyl iodide was considerable, 23 to 50 per cent. In the present note the authors describe a slight modification by which this loss can be prevented. It consists essentially in passing the gas evolved through a vertical tube twelve inches long filled with the copper-zinc couple.—On the action of dibrom-α-naphthol upon amines, by R. Meldola. The author has investigated the action of dibrom-α-napthol upon anilin, orthotoluidin, paratoluidin, and α-naphthylamin. With anilin a body was obtained which proved to be β-naphthoquinonedianilide; similar bodies were obtained with toluidin, &c. This reaction therefore furnishes a simple method of obtaining these quinoneimides in large quantities. The author also discusses the bearing of this reaction on the constitution of these bodies.—Note on the existence of salicylic acid in the cultivated varieties of pansy and in the Violaceæ generally, by A. B. Griffiths and E. C. Conrad. The authors state that they have extracted salicylic acid from the leaves, stems, and roots of the pansy; apparently none exists in the flowers.

Zoological Society, March 18.—Prof. W. H. Flower, F.R.S., president, in the chair.—Mr. Tegetmeier exhibited specimens showing a variation in the colour of the feet of the pink-footed goose (*Anser brachyrhynchus*).—A communication was read from Sir Richard Owen, K.C.B., on the extinct birds of the genus *Dinornis*, forming the twenty-fifth of his series of memoirs on the subject. The present paper gave a description of the sternum of *Dinornis elephantopus*.—Mr. J. B. Sutton, F.Z.S., read an account of the results of his investigations of the more important diseases which affect the carnivorous animals living in the Society's Gardens.—Mr. J. W. Clark, F.Z.S., exhibited and read an account of three skulls of a sea-lion from the east coast of Australia. The largest, that of an adult male, had been exhibited, together with the stuffed skin, at the Fisheries Exhibition last year, where it had been named *Arctocephalus cinereus*, Gray. The object of the paper was to trace the history of the species for which the name *Otaria cinerea* had been suggested by Péron in 1816, and to show, by comparison with the type skull at Paris, that these specimens had been rightly referred to.—A communication was read from the Rev. O. P. Cambridge, in which he gave descriptions of two new genera of spiders proposed to be called *Forbesia* and *Regillus*.

Physical Society, March 22.—Prof. Guthrie, president, in the chair.—The President announced that a meeting of the Society would be held on May 10 at Birmingham, by invitation. The next meeting will be on April 26.—Prof. S. P. Thompson then read a paper by himself and Mr. C. Starling on Hall's phenomenon. The authors had not agreed with Hall's explanation of his observed effect, and last year undertook experiments to investigate its nature. They employed a strip of tinfoil gummed on a mahogany board with vaseline, which, being soft and a non-conductor, answers well for this purpose. A top-shaped electromagnet with a pointed pole was used on one side of the strip to try the effect of a pointed pole. The current was obtained from accumulators. They found that the equipotential lines in the strip, which before magnetisation ran straight across the strip, were slightly curved on either side of the pointed pole after magnetisation. This curving was interpreted as a reduction of resistance in the strip at the pole, and subsequent tests of the resistance of the strips in a magnetic field confirmed this view. Iron strips, however, showed a slight *increase* of resistance. It was also found that an effect similar to Hall's was got by placing the pointed pole so that this change of resistance was not symmetrical with respect to the points in the strip to which the galvanometer was connected. But inasmuch as the effect was not reversible by reversing the magnetism, it was not Hall's effect, which they failed to obtain with the narrow pointed pole. In their experiments thermo-electric effects were eliminated, and their results, though different, do not clash with those of Mr. Bidwell.—A paper by Mr. Herbert Tomlinson on the same subject was read by Prof. Reinold. The author drew attention to a similarity between Hall's table of results and one of his on the effects of mechanical stress on electrical resistance.—Mr. Shelford Bidwell read a note on Hall's effect in tin, in which he showed that a small extension and a greater extension produced opposite thermo-electric effects in tin wires.—In answer to Prof. Guthrie and Mr. Walter Baily, Prof. Thompson stated that the change of resistance he had observed was sub-permanent, and died away in about half an hour. He believed it to be producible on the strip when no current traversed it.—Prof. S. P. Thompson then read a paper on some propositions in electromagnetics, giving a connected series of explanations throwing light on the laws of electromagnetics, and based on a practical experiment.

Royal Microscopical Society, March 12.—Rev. H. W. Dallinger, F.R.S., president, in the chair.—Mr. Glaisher introduced Mr. Dallinger to the meeting on taking his seat for the first time as president, and the latter made a short address in acknowledgment.—Mr. J. Mayall, jun., described the improved Nelson-Mayall lamp, in which the burner could be brought down very close to the table; also Boecker's improved freezing microtome.—Mr. Crisp exhibited Schieck's microscope with fine adjustment made by tilting the stage at one end; also Watson's rotating stage, Collin's set of fish-scales, and a slide of a hydroid polyp with extended tentacles, mounted by Mr. E. Ward.—Notes were read: On a multiple eye-piece by Mr. E. H. Griffith, in which eye-lenses of different powers were mounted on a rotating disk; by Col. O'Hara on some peculiarities in the form of blood-corpuscles; and a communication from a Microscopical Society recently formed at San Francisco, and consisting of ladies.—A paper was read by Mr. T. B. Rosseter describing some peculiar annular muscles in *Stephanoceros*; also by Prof. Reinsch, who stated that he had found bacteria and non-cellular Algæ to exist in considerable numbers on almost all copper and silver coins which had been for some time in currency; also by Mr. G. Massee on the formation and growth of cells in the genus *Polysiphonia*, being a further contribution to the evidence on the continuity of protoplasm through the walls of vegetable cells; also by Prof. Abbe on the distance of distinct vision, in which he pointed out the erroneous inferences which had arisen from the practice of expressing the amplifying power of a lens by reference to a fixed distance of vision (10 inches, or 250 mm.).—Some new forms of cells devised by Mr. Wilks and made by Mr. E. Ward for mounting without pressure in balsam were also exhibited and described.

Royal Meteorological Society, March 19.—Mr. R. H. Scott, F.R.S., president, in the chair.—Messrs. W. Baily, M.A., W. L. Blore, A. L. Ford, H. Leupold, A. F. Lindemann, F.R.A.S., and Rev. E. B. Smith were elected Fellows of the Society.—The President read a paper entitled brief notes on the history of thermometers. He stated that the subject had been handled in a comprehensive manner by M. Renou a few years ago in the *Annuaire* of the French Meteorological Society, so that he should merely mention some of the leading points. The name of the actual inventor of the instrument is unknown. The earliest mention of it, as an instrument then fifty years old, was in a work by Dr. R. Fludd, published in 1638. Bacon, who died in 1636, also mentions it. The earliest thermometers were really sympiezometers, as the end of the tube was open and plunged into water, which rose or fell in the tube as the air in the bulb was expanded or contracted. Such instruments were of course affected by pressure as well as temperature, as Pascal soon discovered. However, simultaneously with such instruments, thermometers with closed tubes had been made at Florence, and some of these old instruments were shown at the Loan Collection of Scientific Apparatus at South Kensington in 1876. They are in the collection of the Florentine Academy, and in general principle of construction they are identical with modern thermometers. Passing on to the instrument as we now have it, Mr. Scott said that most of the improvements in construction in the earliest days of the instrument were due to

Englishmen. Robert Hooke suggested the use of the freezing point, Halley the use of the boiling point, and the employment of mercury instead of spirit, and Newton was the first to mention blood heat. Fahrenheit was a German by birth, but was a *protégé* of James I., and died in England. Réaumur's thermometer in its final form owes its origin to De Luc, while the centigrade thermometer, almost universally attributed to Celsius, was really invented by Linnæus. Celsius's instrument had its scale the reverse way, the boiling point being 0°, and the freezing point 100°. Mr. Scott then gave a brief account of some of the principal forms of self-registering and self-recording thermometers.—After the reading of this paper the meeting was adjourned, in order to afford the Fellows and their friends an opportunity of inspecting the exhibition of thermometers and of instruments recently invented. This exhibition was a most interesting one, and embraced 136 exhibits. The thermometers were classified as follows: (1) standard, (2) maximum, (3) minimum, (4) combined maximum and minimum, (5) metallic, (6) self-recording, (7) solar radiation, (8) sea, (9) earth and well, (10) thermometers used for special purposes, (11) thermometers with various forms of bulbs, scales, &c., and (12) miscellaneous thermometers. In addition to these there were also exhibited various patterns of thermometer screens, as well as several new meteorological instruments, together with drawings, photographs, &c.

Anthropological Institute, February 26.—Edward B. Tylor, Esq., F.R.S., vice-president, in the chair.—It was announced that Dr. Walter H. C. Coffin, Dr. Emil Riebeck, Miss H. M. Hargreaves, and Miss Helen E. Pearson had been elected Members of the Institute.—The Rev. R. H. Codrington read a paper on the Melanesian languages. In the term Melanesia the author included (1) New Caledonia, with the Loyalty Islands; (2) the New Hebrides; (3) the Banks' and Torres' Islands; (4) Fiji; (5) Santa Cruz and the Reef Islands; (6) the Solomon Islands. The object of the paper was to set forth the view that the various tongues of Melanesia belong to one common stock, and that this stock is the same as that to which the other Ocean languages belong—Malayan, Polynesian, the languages of the islands that connect Melanesia with the Indian Archipelago, and Malagasy.—A paper by the Rev. Lorimer Fison, on the "Nanga," or sacred stone inclosure of Wainimala, Fiji, was read by Dr. Tylor. The author explained the constitution of the Nanga, and described the ceremony of initiation and other rites connected with it.

March 11.—Prof. Flower, F.R.S., president, in the chair.—The election of W. Ayshford Sanford was announced.—Mr. A. L. Lewis read a paper on the Longstone and other prehistoric remains in the Isle of Wight.—Mr. W. J. Knowles read a paper on the antiquity of man in Ireland. The author exhibited a series of flints discovered by him at Larne and other parts of the north-east coast of Ireland, some of which he believed to have been dressed in imitation of certain pear-shaped nodules or hammer-stones found at the same spot, while others showed more evident signs of human workmanship. One large chipped implement was found in what appeared to be true, undisturbed boulder-clay, and hence the author contended that the implements he exhibited were not only older than the Neolithic Age in Ireland, but older even than those previously known as Palæolithic, and that they carry the age of man back into the Glacial period.—A paper by Admiral F. S. Tremlett on the Cromlec of Er Lanic was read.—A paper by Mr. Henry Prigg on a portion of a human skull of supposed Palæolithic age from near Bury St. Edmunds was read. The author exhibited the fragment, which consisted of portions of the frontal and right and left parietal bones, and also two flint implements found in the same locality.

DUBLIN

Royal Society, February 18.—Section of Physical and Experimental Science.—G. Johnstone Stoney, F.R.S., in the chair.—On Mr. J. J. Thomson's theory of electricity, by Prof. G. F. Fitzgerald, F.R.S. After explaining Mr. Thomson's theory, Prof. Fitzgerald pointed out that it seems very unlikely that electrified bodies *in vacuo* would not attract or repel one another, inasmuch as experiments seemed to show that the only effect of matter between electrified bodies was to alter the specific inductive capacity of the space, and so Mr. Thomson's theory was more probable as an explanation of how gases had a specific inductive capacity different from unity. In a communication on the mechanical theory of Crookes' force made to the Society in 1878 he had shown that a polarisation of the motions of the molecules in a gas of a particular kind would produce the same stresses as are required to explain electrostatic actions. He explained how a suitable polarisation of the motions or positions of the superficial molecules of a conductor, due to their being on the surface of separation of a constant and variable electric potential, was probably the cause of electrostatic attractions. He pointed out that the ordinary hypothesis that molecules act on one another by means of the ether, and so transmit mechanical stress across intermolecular layers of ether was an assumption of precisely the same kind at intermolecular distances as Maxwell's theory of electricity was at molar distances, and expected that a suitable strain of the superficial molecules of a body would transmit a stress through the ether. Prof. Fitzgerald explained a particular hypothesis as to the nature of this polarisation of the superficial molecules on the vortex theory of atoms, which, however, seemed subject to the very serious objection that it appeared at first sight as if two oppositely electrified planes would tend to move bodily in one direction. The hypothesis was founded on the fact that when two vortex rings are going in the same direction, and one following the other, they attract; but if going in opposite directions they repel one another. The polarisation supposed was that an electrified surface had the superficial molecules all turned in one way, preferably negatively electrified bodies with the faces of the vortex atoms outwards, and positively electrified bodies with their backs outwards. He described how contact-electricity, thermo-electricity, and electro-chemical actions might be explained on this hypothesis. This hypothesis was put forward more as an illustration of how a polarisation of the superficial molecules of a body might produce attractions and repulsions than as an hypothesis that really explained electrostatic actions.—On Prof. Osborne Reynolds's mechanical illustrations of heat engines, by Prof. G. F. Fitzgerald, F.R.S. After explaining Prof. Osborne Reynolds's beautiful illustrations, he described three arrangements, one by setting a chain rotating in loops and nodes, one by a balanced centrifugal pendulum, and the third by a pair of masses running on a revolving radius, by means of which all the operations in Carnot's cycle might be illustrated, and explained how to arrange that temperature should be represented by the angular velocity of the rotating masses, and how by means of a chain passing over a pulley in the second case, and by a chain drawn off a table in the third case, it was easy to arrange that the masses should expand when given energy at a constant velocity. He explained how an arrangement in which the masses when not rotating would rest in any position represented an ideal gas in which no internal work is spent in expansion. Prof. Fitzgerald described how by means of a dynamo driven from a battery, a self-acting engine of this kind could be arranged which would show when it was absorbing and when giving out energy. He explained that it was easier to work these models when promiscuous agitation was represented by rotatory motion than when it was really promiscuous, and that it was for this reason rotatory motion was adopted. Mr. Stoney, in some remarks he made on this communication, explained how necessary it was that the energy be really promiscuous, in order that it be subject to the second law of thermodynamics, showing how it would be possible to get a region in which all the radiant energy was plane polarised to radiate into a hotter similarly polarised region without allowing the latter to lose any heat by radiating any of its original energy. He proposed to do this by means of a plate of quartz that rotated through 90° the plane of polarisation of the radiant energy that passed through it, and by a doubly refracting prism, thus admitting heat energy into the second region that was polarised at right angles to that originally there, while the polarised radiant energy that escaped back again was returned into the region it came from, being bent out of the path of the entering energy by the doubly refracting prism.—Prof. Fitzgerald exhibited a lecture balance. In this arrangement a beam of light fell parallel to the axis of the balance on a mirror attached at 45° to this axis, so that the reflected ray turns through the same angle as the balance. The balance was provided with an arrangement by which its stability could be altered very much, so as to be suitable for either rough or delicate weighing. As the difference of weights in the pans of a balance is proportional to the tangent of the angle of deflection, a vertical scale uniformly divided showed by the position of the spot of light the difference of the weights in the pans in a manner that could be easily read by a large class.

Section of Natural Science.—V. Ball, F.R.S., in the chair.—Gerrard A. Kinahan read a paper entitled "Notes on the Coal-fields of the North-West Territories of Canada."

Cambridge

Philosophical Society, March 10.—Mr. D'Arcy W. Thompson, B.A., Trinity College, was elected a Fellow.—The following papers were communicated:—Continuation of observations on the state of an eye affected with astigmatism, by Sir G. B. Airy. The paper consisted of a continuation of observations already recorded in the publication of the Society. The author gave tables of the distances from the cornea of the left eye at which a luminous point appears respectively as a horizontal and a vertical straight line. The observations have extended from the year 1825 to the present time.—On the measurement of the electrical resistance between two neighbouring points on a conductor, by Lord Rayleigh. In some experiments described in a recent paper read before the Royal Society, the author had occasion to arrange a set of resistance coils so that the difference of potential between two points on a circuit through which a current is flowing shall be exceedingly small and yet known to a high degree of accuracy. In the present communication the method is applied to determining the difference of potential between two neighbouring points on a conductor through which the same current is flowing. The resistance coils are adjusted until the difference of potential measured by the current produced in a galvanometer of comparatively high resistance is the same in the two cases. The method has been applied by Messrs. Ward and Shackle at the Cavendish Laboratory to determine the value of a small resistance of about 1/200 of a B.A. unit, and is capable of very great accuracy.—On dimensional equations and change of units, by Mr. W. N. Shaw.

Sydney

Linnean Society of New South Wales, January 30.—C. S. Wilkinson, F.G.S., president, in the chair.—The President delivered an address on the progress of science in Australia during the past year, and concluded by a general account of the geology of the country from an economic point of view.—The following papers were read:—Supplement to the Descriptive Catalogue of the Fishes of Australia, by William Macleay, F.L.S., &c. This paper contains references to, or descriptions of, 157 species of fishes not mentioned as Australian in the previously printed catalogue. The species here described for the first time are from the pens of Dr. Klunzinger, Dr. Günther, Messrs. De Vis, Ramsay, Macleay, and R. M. Johnston. The total number of Australian fishes now amounts to 1291 species.—On some new Batrachians from Queensland, by Charles W. De Vis, M.A. This paper contains descriptions of three new species of frogs, collected at Mackay, by Mr. H. Ling Roth, and named by the author as follows:—*Limnodynastes lineatus*, approaching *L. peronii*, but distinguished by shorter hind limbs, and continuity of dorsal stripes; *L. olivaceus*, and *Hyla rothii*.—On plants indigenous in the immediate neighbourhood of Sydney, by Mr. Haviland. This, the sixth of the series, gives an account of some species of the genus *Darwinia*, showing the supposed manner of fertilisation, and explaining, to some extent, the prevalence of the species *D. fascicularis*, notwithstanding the great disproportion between the fertilised and the fertilising flowers.—Studies on the Elasmobranch skeleton, by William A. Haswell, M.A., B.Sc.

Paris

Academy of Sciences, March 24.—M. Rolland in the chair.—Influence of the density of explosive gaseous mixtures on pressure; isomerous mixtures, by MM. Berthelot and Vieille.—Separation of gallium from boric acid, by M. Lecoq de Boisbaudran. This concludes the series of exhaustive experiments conducted by the author for the purpose of obtaining the complete separation of gallium from all other known elements. A final communication is promised on the separation of gallium from tartaric acid, taken as a type of organic substances whose presence might affect several of the reactions indicated during the course of the foregoing studies.—On the concordance of some general practical methods, based on apparently opposite principles, for determining the tensions in a system of points connected by electric links and kept in equilibrium under the action of external forces, by General L. F. Menabrea.—Observations of Saturn and Uranus made at the Observatory of Nice, by M. Perrotin. These observations were made under unusually favourable conditions by Messrs. Norman Lockyer, Thollon, and Perrotin on March 16 and 18. The outer ring of Saturn appeared to consist of three distinct rings slightly diminishing in breadth outwardly, and each apparently made up of numerous subdivisions. Uranus, seen on the 18th, presented in some respects the general aspect of Mars, with dark spots towards the centre, and a white speck like the pole of that planet at the angle of position 380° on the edge of the disk. Mr. Lockyer, who was present at the sitting, read a telegram from M. Perrotin announcing a repetition of the observations on March 23 under equally favourable conditions.—Note on the polar spots in Venus, observed at the Meudon Observatory, by M. E. L. Trouvelot. These spots seem to be permanent, although varying greatly in brilliancy, and often rendered invisible by the distance of the planet towards superior conjunction.—On the thrust of a mass of sand with horizontal upper surface against a vertical wall, in the neighbourhood of which its inner angle of friction is assumed to be slightly increased according to a definite law, by M. J. Boussinesq.—On the extension of the theorems of Pascal and Brianchon to surfaces of the second order, by M. A. Petot.—On a probable cause of the discrepancies found to exist between the electromotor force of voltaic piles and the theoretical results of thermochemical observations, by M. G. Chaperon.—Note on the action exercised by polarised light on cellulose solutions in Schweizer's fluid, by M. A. Levallois.—Remarks on a case of dimorphism observed with the hyposulphite of soda ($NaO,S_2O_2,5HO$), by MM. F. Parmentier and L. Amat.—Researches on the sulphites and bisulphites of soda, by M. de Forcrand.—On the dissymmetric chloro-iodurretted and bromo-iodurretted ethylenes, by M. L. Henry.—Experimental researches on the influence of extremely high pressure on living organisms, by M. P. Regnard. These experiments were conducted by means of the press of MM. Cailletet and Ducretet, yielding pressures of 1000 atmospheres and upwards. Soluble ferments were unaffected by extreme pressure; starch at 1000 was changed to sugar; algæ at 600 were decomposed, and the carbonic acid liberated; infusoria, leeches, and mollusks at 600 were rendered insensible, but recovered when the pressure was removed; fishes with swimming bladder resisted 100, became insensible at 200, and succumbed at 300. These results show interesting coincidences with the phenomena observed by the naturalists of the *Talisman* at various oceanic depths.—On the action of cold on microbes, by MM. R. Pictet and E. Yung. Many inferior organisms resisted temperatures of from −70° to −130° C. for several hours. Others were either killed or lost their germinating functions.—On peritoneal transfusion, by M. G. Hayem.—On the medullar mechanism of paralyses of cerebral origin, by M. Couty.—Anatomical description of the fœtus of a gorilla recently brought from the Gaboon, by M. J. Deniker.—On the anatomy of the *Peachia hastata* discovered by Gosse in 1855, by M. Faurot.—On the structure of the auditory organ in *Arenicola grubii*, Clap., by M. Et. Jourdan.—Anatomy of the muscles in the abdomen of the bee, by M. G. Carlet.—Note on a deposit of gold at Peñaflor in Andalusia, by M. A. F. Berlin

Physiological Society, February 29.—Dr. Weyl spoke about the secretion in man of nitric acid, which he had analytically proved, and which, by administration of ammonia, he was able quantitatively to increase. After it had been experimentally established that a direct transference of albumen into urine was impossible, it was recognised that the formation of urine was no oxidising process of the albumen, but was effected circuitously by the formation of amido-compounds, whose introduction into the animal body increased the quantity of the secreted urine. The formation of urine took place through alimentation of the simplest amidinous matters, ammonia increased the secretion of urea. Similar to the action of ammonia was that of a carbonate of ammonia, as also when combined with organic acids, while from hydrochlorate, sulphate, and mineral acid salt, the ammonia did not become transformed into urea. On perusing the literature of the subject, Dr. Weyl found that in all experiments the ammonia was never wholly transformed into urea, but that there was always a residue of from 10 to 40 per cent. which was not represented in the urine. This residue of ammonia, he conjectured, was consumed in the animal body, and he therefore made search in animals to which he had given ammonia, for the presence of nitric acid. Rabbits not being adapted for precise experiments in connection with the transmutation of matter, he experimented on dogs, but always failed to discover any nitric acid in their urine. Even when he had given these animals nitrates, no nitrates could be found in their urine. He now tried experiments on men, and soon ascertained that in their case nitric acid was a perfectly normal product of secretion. The quantitative determinations, even where no nitrate was administered, yielded from 400 to 600 mgr. of nitric acid in the contents of the urine. The quantity of nitric acid varied with the nourishment, and by the use of vegetables could be considerably increased. To test the accuracy of his conjecture regarding the fate of the ammonia not converted into urea, he took with a uniform regulated diet citrated ammonia in doses of from six to eight grammes, and found in two series of experiments a very marked increase of the nitric acid in the urine—in one case, for example, of from about 500 to over 800 mgr. This constant presence in no inconsiderable quantities of nitric acid in the urine of man ought, in experiments connected with the change of matter, to be carefully attended to. Historically, Dr. Weyl observed that more than thirty years ago Bence Jones had made the assertion that in the animal body ammonia was oxidised into nitric acid. He was, however, unable to substantiate this proposition without raising objections.—Prof. Kronecker reported on the discovery of a coordination centre in the movements of the ventricles of the heart, made by Herr Schmey, a student in his department of the Physiological Institute, and which he (Prof. Kronecker) had repeatedly verified. In an examination of the changes in the dimensions of the heart in the process of contraction, needles were thrust in the most various directions into the heart of a dog after it had been laid bare, an operation which, as was known by experience, had no influence on the movements of the heart. When in this operation the needle came upon a certain small spot on the lower border of the upper third of the *septum cordis*, the ventricles of the heart at once ceased to beat, and, diastolically dilated, fell into fibrillar convulsions, which were soon followed by the death of the ventricles of the heart. It was not possible by any appliances to restore the ventricles to their normal action. The vestibules continued to beat normally, but the ventricles no longer discharged their blood, and soon, in consequence of the palsy of the heart, general death set in. This instantaneous death of the heart through a prick in a particular part of the septum—the stoppage thereby produced of each coordinate contraction of the muscles of the heart—was up to the present wholly without analogy. What approached nearest to this fact was the well-known phenomenon that a compression of the coronary artery produced in a short time a cessation of pulsation and fibrillar convulsions. On withdrawing the compression, however, the pulsations of the ventricle were resumed. In the case of a prick, on the other hand, the effect followed altogether much more quickly, quite instantaneously in fact, and the ventricles, not able again to discharge their functions normally, were for ever motionless. This phenomenon Prof. Kronecker explained in the following manner. By the prick of the needle a coordinating centre in the movements of the ventricles of the heart, having its seat at the spot in question in the septum, was touched and destroyed. The finding of this centre afforded the physiological key to the riddle not unknown in surgery, that many very slight heart-wounds, pricks of needles, for example, which did not even penetrate, produced sudden death. It was now the task of anatomical investigation to demonstrate the existence of this centre now experimentally proved to exist. Prof. Kronecker and Herr Schmey have demonstrated this important experiment to the satisfaction of the Society.

VIENNA

Imperial Academy of Sciences, January 17.—M. Tüllig, on a new mode of telephonic transmission of sound (sealed packet).—J. Kachler and F. V. Spitzer, on Jackson's and Menke's method of preparing borneol from camphor.

January 31.—W. Biedermann, contributions to general nerve and muscle physiology (xiv. communication), on the heart of *Helix pomatia*.—G. von Niessl, on the astronomical relations at the meteoric fall of Mocs (Transylvania) on February 3, 1882.—L. Koller, on some general laws relating to knot-combinations.—A. Lustig, on the degeneration of the olfactory epithelium of rabbit after destruction of the olfactory lobes.—F. Zehden, attempt to explain the sunspots.—J. Hann, on the results of the meteorological observations made by Major von Machow at Pungo Andongo and Malunge in the interior of tropical South-West Africa in the years 1879–80.

February 7.—J. Odstrzil, on the mechanism of gravitation and inertia.—R. Benedikt and K. Hazura, on morin.—E. Goldstein, on the influence of conducting surfaces within the second stratum of the kathode light of Geissler's tubes.—S. Exner, on the innervation of the larynx.

February 14.—E. Hering, contributions to general nerve and muscle physiology (xv. communication), on the positive after-variation (*Nachschwankung*) of the nerve-current after electrical stimulation.—J. Klemencics, researches on the relation between electrostatic and electromagnetic measure.—F. von Hochstetter, seventh report of the Prehistoric Commission on its work during the year 1883.—R. von Wettstein, on the laws of growth of plant organs.

March 6.—J. Singer, contribution to a knowledge of the motor functions of the lumbar cord of the pigeon.—J. Redtenbacher, synopsis of the larvæ of Myrmeleoideæ.—J. H. List, on calyx-cells in the vesicle epithelium of the frog.—K. Zulkowsky, on coloured combinations of phenol with aromatic aldehydes.—F. von Hochstetter, reports of the Prehistoric Commission on the researches carried out in Moravia by J. Szombathy and W. Müller.—E. von Marenzeller, contribution to a knowledge of Adriatic annelids (iii. paper).—V. von Ebner, on the planes of solution of calcareous spar and aragonite.—H. Pitsch, on the value of Fermat's rule for the propagation of light in double refracting media.—Von Barth and M. Kretschy, on picrotoxin.—J. Herzig, studies on quercetin and its derivatives.—E. Häckel, gramina nova, vel minus nota.—A. Rosoll, contributions to the histochemistry of plants.—A. Adamkiewicz, on new stainings of the spinal cord.—F. K. Ginzel, researches on eclipses, especially on ascertaining empiric corrections of the orbit of the moon.

March 13.—E. Hering, contributions to general nerve and muscle physiology (xvi. communication), on the variations of nerve-current caused by unipolar stimulation in tetanisation.—C. Puschl, on the second axiom of mechanical theory of heat and on the behaviour of water.—K. Olzewski, on the liquefaction of hydrogen.—On the density of liquid oxygen, by the same.—On the point of solidification of some gases and liquids, by the same.—G. Adler, on the energy in the electrostatic field.—C. Goldstein, on the passing of electricity through vacua.

group but feebly developed in this region.—Mr. R. Bowdler Sharpe read the description of three rare species of Flycatchers, viz. *Alseonax minima*, *Lioptilus abyssinicus*, and *Lioptilus galinieri*. Mr. Sharpe also described an apparently new species of Nuthatch discovered by Mr. John Whitehead in the mountains of Corsica, and proposed to be called *Sitta whiteheadi*—Mr. G. E. Dobson, F.R.S., read a paper on the myology and visceral anatomy of *Capromys melanurus*, of which rare mammal specimens had been lately obtained for him by Mr. F. W. Ramsden, H.M.'s Consul at St. Jago de Cuba. The well-known division of the hepatic lobes into minute lobules in *C. pilorides* from the same island was shown not to exist in *C. melanurus*, which otherwise closely resembled the former species, and this character could therefore no longer be considered a generic one.

EDINBURGH

Royal Society, March 3.—Sir W. Thomson, hon. vice-president, in the chair.—Sir W. Thomson communicated a paper on the efficiency of clothing for maintaining temperature. He showed that if a body be below a certain size, the effect of clothing will be to cool it. In a globular body the temperature will only be kept up if the radius be greater than $\frac{k}{2e}$, where k is the conductivity of the substance and e its emissivity.—Prof. J. Thomson read a paper on the law of inertia, the principle of chronometry, and the principle of absolute clinural rest and of absolute rotation. In this paper the author proceeded to discriminate between what men can know, and what men cannot know, as to rest and motion in unmarked space. For example, men have no means of knowing or imagining whether a ball existing in space is in motion or at rest; nor have they any means, if it be in motion, of knowing or imagining any one direction, rather than another, as being the direction of the straight line from the place that was occupied by its centre at any past instant to the place occupied by that centre at present. There is then an essential difficulty as to our forming a distinct conception either of rest or of rectilinear motion through unmarked space. He discussed, in connection with this, the statement set forth by Sir Isaac Newton, under the designation of the first law of motion, that *every body continues in its state of resting or of moving uniformly in a straight line, except in so much as, by applied forces, it is compelled to change that state.* A most important truth in the nature of things, perceived with more or less clearness, was, he said, at the root of that enunciation; but the words, whether taken by themselves, or in connection with Newton's accompanying definitions and illustrations, were inadequate to give expression to that great natural truth. He proceeded to explain the character of mutual motions, which can in any sense be regarded as uniform rectilinear mutual motions. He gave, under the title of the law of inertia, an enunciation which he offered as setting forth, by a better expression, all the truth which is either explicitly stated, or is suggested by the first and second laws of motion in Sir Isaac Newton's arrangement. In connection with the law of inertia he gave further statements bringing out expressions of the principle of chronometry and the principle of "directional fixedness" or of absolute clinural rest, and of absolute rotation.—Sir W. Thomson described a modification of Gauss's method for determining the horizontal component of terrestrial magnetic force and the magnetic moments of bar magnets in absolute measure.—Mr. Thomas Muir gave a paper on the phenomenon of greatest middle in the cycle of a class of periodic continued fractions.

March 17.—Robert Grey, vice-president, in the chair.—Messrs. Peach and Horne, of the Geological Survey of Scotland, communicated a paper on the Old Red Sandstone volcanic rocks of Shetland.—Mr. P. Geddes gave the first two parts, mathematical and physical, of a paper on the principles of economics.—Prof. Crum Brown communicated a paper by Prof. Michie Smith on an integrating hygrometer.

DUBLIN

University Experimental Science Association, March 18.—On the boiling-points of the haloid ethers, by F. Trouton.—On a new test for gallic acid, by A. E. Dixon, B.A. The crimson-red colour which Dr. Sidney Young had noticed on adding a solution of cyanide of potassium to a solution of gallic acid, and which a few minutes' rest or gentle warmth causes completely to disappear, is probably due to oxidation. For although when shaken in contact with the air the colour reappears, it will not do so when shaken in an atmosphere of hydrogen, nitrogen, or carbon dioxide. On re-exposure to the air, with agitation, the colour may be brought back. The red colour is not dissolved out by alcohol, ether, or chloroform; neither does it afford any characteristic absorption-spectrum.—On Ayrton and Perry's electrometers, by G. F. Fitzgerald, F.R.S.—An electro-magnet for use in analysis was exhibited by J. Joly, B.E. The electro-magnet is sealed into a test-tube to enable it to be dipped into solutions containing perruginous particles.

PARIS

Academy of Sciences, March 31.—M. Rolland in the chair.—Remarks on the third volume of the "Annals of the Bureau of Longitudes," presented to the Academy by M. Faye.—On a proposed classification of comets according to their direct or retrograde motion, by M. Faye.—Note on the form of the nucleus of the Pons-Brooks comet, by M. Faye.—On the specific heat of gaseous elements at very high temperatures, by MM. Berthelot and Vieille.—Note on the origin of sugar of milk, by M. Paul Bert. From experiments made on goats the author infers that the sugar of milk is produced by the mammary secretion of the superabundant sugar formed by the organisms after parturition, most probably in the liver.—On a new species of fossil Sirenian found in the Paris Basin, by M. A. Gaudry.—On the correspondence between two different species of functions of two systems of quantities correlated and equal in number, by M. Sylvester.—Separation of gallium; separation from organic substances, by M. Lecoq de Boisbaudran.—On a modified form of lightning-conductor, by M. A. Callaud.—Results of experiments with a new ventilating system worked by centrifugal force, by M. L. Ser.—Observations made at the Meudon Observatory on the planet Mars, by M. E. L. Trouvelot.—Approximate calculation of the thrust and surface of fracture in a homogeneous horizontal mass of earth supported by a vertical wall, by M. J. Boussinesq.—On Gyldén's differential equation:—

$$\frac{d^2 x}{d t^2} = \phi_0 + x \phi_1 + x^2 \phi_2 + \ldots + x^m \phi_m + \ldots$$

Mer.—On the diffusion of christianite in the ancient lavas of the Puy-de-Dôme and the Loire Basin, by M. F. Gonnard.—Note on the origin of certain phosphates of lime found in mass in the limestones of the Secondary series, and of certain iron ores belonging to the class of globular ores, by M. Dieulafait.—On the solar halos observed at Saint Maur on the morning of March 29, by M. E. Renou.—Note on the presence of manganese in the wines of Grave, by M. E.-J. Maumené.

Berlin

Physical Society, March 7.—Prof. Neesen, by means of different glass tubes, demonstrated certain phenomena of Kundt's dust figures produced by experimenting with deep tones. Busied with an examination into the cause, not yet explained, of the transverse ridgings in sounding-tubes, Prof. Neesen has, instead of the high tones of longitudinally-vibrating tubes, tested deeper tones, which are kept up in the column of air of the glass tubes by an electric tuning-fork. In the course of this investigation he made very beautiful observations in many tubes of dust-whirls roaming hither and thither, now to one side, now to the other. In other tubes, again, these whirls came to light either with great difficulty or but imperfectly. It would therefore appear that the material of the tubular wall exercised some influence on the production of those whirls. The speaker had yet, however, come to no definite result respecting the cause of the transverse ridges.—Dr. Kœnig supplemented the experiments he communicated at the last sitting of the Society, on the sensitiveness of normal eyes for variations of colour between the wave-lengths of 640 and 430. This he had so far done, inasmuch as he had tested the influence of light-intensity on the sensibility in question. Seeing, as was well known, that light-intensity, in this part of the spectrum especially, mounted very rapidly from the line C to the line D, and again sank from the maximum beyond D down to F, it would be possible that the differentiating sensibility arrived at in the former experiments was in large part conditioned by the differences of intensity. The cooperation of intensity was now in the new experiments partly excluded as a factor in this way, that the spectrum was observed through an absorbing medium whose maximum of absorption stood at D, so that the curve of light-intensity between C and D rose with much less rapidity, ran horizontally for some distance, and then sank to D. The measurements, being carried out as in the former experiments, yielded the result that the differentiative sensibility under the conditions mentioned had undergone very little alteration, and that, consequently, light-intensity had no influence on the range that had been arrived at.—Prof. von Helmholtz reported on a theoretic treatise he had laid before the Berlin Royal Academy, in which he had taken in hand the task of explaining, in accordance with mechanical principles, thermal movements, and more particularly Carnot's law. He attained his object by means of the rules bearing on stationary movements, as they were calculated for a vortex revolving without friction and with great velocity, or for a fluid moving without friction in a closed circular canal. The equations for these stationary movements derived from mechanics corresponded with those derived from Lagrange's law for thermal movements.

Physiological Society, March 14.—Prof. Lucae gave an address on the subject of subjective auricular sensations and their treatment. He showed by examples that the idea that subjective auricular sensations, and in particular the generally known one of singing in the ears, had a somatic cause, such as stoppage of the external acoustic duct or of the Eustachian tube, was not in accordance with experience. Both on himself and on persons of musical culture he had determined the pitch of the singing or whistling sound, and had found it equal to the proper tone of the external acoustic duct. This circumstance, together with several other facts, led him to the conjecture that the singing in the ears was caused by a tetanus of the tensor tympani, which set the air over the membrane of the tympanum in continuous oscillation. In cases of suffering from this distemper, of which the speaker cited a number of examples, the subjective auricular sensations were to be divided into such as were intensified and such as were abated by external sounds. Both kinds were to be regarded as phenomena of abnormal resonance, and were accompanied by different degrees of hardness of hearing down to deafness. The treatment of these subjective sensations, so far as they were simple tones and noises, and not the subjective hearing of words or of anything outside the hearer (disturbances psychological and beyond the scope of his address) consisted, in the opinion of the speaker, an opinion based on manifold personal experience, in subjecting the sufferers, for progressively longer periods of time, and for as many as two to three minutes at once, to a certain constant tone of the tuning-fork. In such a case Prof. Lucae used deep tuning-forks with such as heard subjective high tones, and *vice versâ*. With the cessation of the subjective noises the deafness also usually disappeared, and the sufferers recovered a permanently normal state in this respect. An explanation of this phenomenon the speaker thought might be found in the analogy of other sensations in which abnormal excitement in one part of the sensory nerves was relieved by the excitement of neighbouring nervous parts.—Prof. Munk reported on a treatise sent for insertion in the *Verhandlungen* by Dr. Gad, a foreign member. Contrary to the opinion on the subject hitherto entertained, Dr. Gad in this treatise proved that in the spinal marrow of frogs, even under the seventh nerve-root, there were reflex centres in operation. By cutting through the spinal marrow, below this spot, reflex convulsions from the toes upwards are produced, not only on the same but also on the opposite side. In other experiments on frogs the spinal marrow was cut through beneath the medulla-oblongata, and the upper part of the spinal marrow as far as the second vertebra carefully prepared and laid on filtering paper saturated with strychnine. On stimulating the frog at the lower extremities reflex movements were seen to pervade the whole body, but in the region of those sections of the spinal marrow treated with strychnine, flexor spasms were observed, though it is well known to be a special characteristic of the strychnine spasm that it exclusively attacks the extensor muscles. In this way was demonstrated the existence of conducting tracks rising from the reflex centres situated in the lowermost part of the spinal marrow up to its topmost parts. If these latter, again, were electrically stimulated, no flexor movement could be started from the spot which before, under the operation of strychnine, had generated exterior reflections. Between this part of the spinal marrow and the motory nerves there must therefore lie ganglia.—Following up his communication at the last sitting, on the presence of nitric acid in urine, Dr. Weyl brought before the Society a series of chemical reactions tending to demonstrate that nitric acid could exist and be substantiated in an oxidised solution along with urea.

tials which appeared in these columns a short time ago, but with some additional matter, must, from the clear explanation of the principles involved in the different methods of measurement, take a high position as an educational work, and, from the care with which details of manipulation are in many parts described, form a valuable laboratory guide.

The author begins by explaining Gauss's method of finding the horizontal intensity of the earth's magnetism. Instead of describing an "instrument-maker's" magnetometer, and showing how with this expensive luxury *H* may be determined, he gives simple, clear, and full directions for constructing, with such common materials as are to be found in any laboratory, all that is necessary for making this determination with great accuracy.

A description of the tangent galvanometer in some of its forms and an explanation of some of the units naturally follow. Here, by treating each unit separately with many illustrations depending on the aspect from which they are viewed, the author has succeeded in giving them a reality which students often find it difficult to believe they possess.

The next two chapters are devoted to a description of the construction and graduation of Sir W. Thomson's "Graded Galvanometers." These instruments possess so great a range, and are, when used carefully in the laboratory, so accurate and convenient, though rather delicate for an engine-room, that an exact description from headquarters of their construction, of the precautions which must be observed in their use, and of the means of graduating them is especially valuable.

The various methods employed in measuring any resistance from that of a thick copper rod to that of a piece of gutta-percha are given, and in many cases explained by numerical examples.

The methods by which the energy due to direct or to alternating currents may be measured is explained—in the latter case on the assumption that the current strength varies harmonically with the time.

The chapter on the measurement of intense magnetic fields is especially interesting, for the methods given, depending on the use of suspended bits of wire attached by threads to pendulum weights, or equally simple and easily contrived devices, show how the experimenter may in many cases be independent of the elaborate work of the instrument-maker. C. V. B.

Field and Garden Crops of the North-Western Provinces and Oudh. By J. F. Duthie, B.A. F.L.S., Superintendent of the Saharanpur Botanical Gardens, and J. B. Fuller, Director of Agriculture, Central Provinces. Part 2. With Illustrations.

As a work of reference it will be very valuable, for it contains well-arranged details of some of the more important crops under cultivation, and the information is well and systematically arranged. Care has been taken in each case to secure a complete but still a concise statement, which is sufficient to guide the cultivator in all the specialities of management necessary to secure successful results. A good drawing illustrates each crop treated of, and its several cultivated varieties, and with these we have carefully-prepared descriptions of each plant in succession, and its general history. The districts within which the cultivation can be successfully extended are also set forth with great clearness and precision. For accuracy of details, in a very accessible form, this work leaves little to be desired.

A Treatise on Higher Trigonometry. By the Rev. J. B. Lock. (Macmillan, 1884.)

This is the promised complement to the same writer's "Treatise on Elementary Trigonometry," which we noticed very favourably in these pages at the time of its appearance (vol. xxvi. p. 124). It is concerned principally with series, the errors which arise in practical work, and the use of subsidiary angles in numerical calculations.

A short chapter on the use of imaginaries is justified by the position this subject holds in the London University Examinations, and no apology is needed for the space assigned to an account of, and a collection of exercises upon, the hyperbolic sine and cosine. We have read the text carefully, and though almost of necessity there are numerous typographical mistakes, only one or two (for $2a\cos 2\theta$, p. 127, line 3, read $a\cos 2\theta$) will inconvenience a student. In addition to the numerous examples in the text, there are fourteen specimen papers from Cambridge and other examinations.

The only article to which we take exception is § 9, the proof of which may be, if we mistake not, considerably simplified. The book can be confidently recommended to the use of advanced pupils in our schools, and will meet the wants of most students in our Universities.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

Teaching Animals to Converse

You did me the honour some weeks ago (January 3, p. 216) to insert a letter of mine, containing suggestions as to a method of studying the psychology of animals, and a short account of a beginning I had myself made in that direction.

This letter has elicited various replies and suggestions which you will perhaps allow me to answer, and I may also take the opportunity of stating the progress which my dog "Van" has made, although, owing greatly no doubt to my frequent absences from home, and the little time I can devote to him, this has not been so rapid as I doubt not would otherwise have been the case. Perhaps I may just repeat that the essence of my idea was to have various words, such as "food," "bone," "water," "out," &c., printed on pieces of cardboard, and after some preliminary training, to give the dog anything for which he asked by bringing a card.

I use pieces of cardboard about 10 inches long and 3 inches high, placing a number of them on the floor side by side, so that the dog has several cards to select from, each bearing a different word.

One correspondent has suggested that it would be better to use variously coloured cards. This might no doubt render the first steps rather more easy, but, on the other hand, any temporary advantage gained would be at the expense of subsequent difficulty, since the pupil would very likely begin by associating the object with the colour rather than with the letters; he would, therefore, as is too often the case with our own children, have the unnecessary labour of unlearning some of his first lessons. At the same time the experiment would have an interest as a test of the condition of the colour-sense in dogs. Another suggestion has been that, instead of words, pictorial representations should be placed on the cards. This, however, could only be done with material objects, such as "food," "bone," "water," &c., and would not be applicable to such words as "out," "pet me," &c.; nor even as regards the former class do I see that it would present any substantial advantage.

Again, it has been suggested that "Van" is led by scent rather than by sight. He has no doubt an excellent nose, but in this case he is certainly guided by the eye. The cards are all handled by us, and must emit very nearly the same odour. I do not, however, rely on this, but have in use a number of cards bearing the same word. When, for instance, he has brought a card with "food" on it, we do not put down the same identical card, but another with the same word; when he has brought that, a third is put down, and so on. For a single meal, therefore, eight or ten cards will have been used, and it seems clear, therefore, that in selecting them "Van" must be guided by the letters.

When I last wrote I had satisfied myself that he had learnt to regard the bringing of a card as a request, and that he could distinguish a card with the word "food" on it from a plain one, while I believed that he could distinguish between a card with "food" on it, and one with "out" on it. I have no doubt that he can distinguish between different words. For instance, when he is hungry he will bring a "food" card time after time until he has had enough, and then he lies down quietly for a nap. Again, when I am going for a walk and invite him to come, he gladly responds by picking up the "out" card and running triumphantly with it before me to the front door. In the same way he knows the "bone" card quite well. As regards water (which I spell phonetically so as not to confuse him unnecessarily), I keep a card always on the floor in my dressing-room, and whenever he is thirsty he goes off there, without any suggestion from me, and brings the card with perfect gravity. At the same time he is fond of a game, and if he is playful or excited will occasionally run about with any card. If through inadvertence he brings a card for something he does not want, when the corresponding object is shown him he seizes the card, takes it back again, and fetches the right one.

No one who has seen him look along a row of cards and select the right one can, I think, doubt that in bringing a card he feels that he is making a request, and that he can not only perfectly distinguish between one word and another, but also associate the word and the object.

I do not for a moment say that "Van" thus shows more intelligence than has been recorded in the case of other dogs; that is not my point, but it does seem to me that this method of instruction opens out a means by which dogs and other animals may be enabled to communicate with us more satisfactorily than hitherto.

I am still continuing my observations, and am now considering the best mode of testing him in very simple arithmetic, but I wish I could induce others to cooperate, for I feel satisfied that the system would well repay more time and attention than I am myself able to give. JOHN LUBBOCK

High Elms, Down, Kent

"The Unity of Nature"

I REGRET that the Duke of Argyll should have been led by anything that I have written to make some of the remarks which appear in this week's issue of NATURE (p. 524). If a reviewer in a signed review cannot express freely his opinion upon a book without its being suggested that he is actuated by secondary and sinister motives, I fancy that few men of common honesty would care to continue the work of reviewing. Moreover, in the present instance the imputation of animus seems to me specially unjustifiable. I had almost forgotten the correspondence in NATURE to which the Duke alludes, but on now referring to it again I can only see that, if it was provocative of animus, there was assuredly no reason for the animus to have arisen on my side (see NATURE, vol. xxiv. pp. 581 and 604; vol. xxv. pp. 6 and 29). But, to ignore so unworthy a charge, and one which I can only suppose to have been made under a sense of irritation, I must explain that the Duke is under a wrong impression when he assumes that my objection to his advocacy of Theistic belief is due to what he regards as my aversion to Theism. As I have never been in the habit of "using your columns for the purpose of inculcating personal beliefs and disbeliefs on subjects which lie outside the boundaries of physical science," I shall not do so now. But in view of the slender grounds on which the Duke has felt himself entitled to infer that I "hold that the highest aim of the human intellect is to prove the mindlessness of nature," I feel it is desirable to correct the inference. For this purpose it is not needful that I should publish my "personal beliefs and disbeliefs." It is only needful to say that my previous remarks will be found to have been directed, not against the cause of Theism, but against its champion in the Duke of Argyll. Had my sympathies been more on the side of the materialists than they happen to be, the Duke of Argyll might not have found so much reason to quarrel with my "dislike" of his advocacy.

I may now turn to the Duke's remarks on those of my criticisms which he deems legitimate. Taking first the case of rudimentary organs, I quite agree with the statement that the question whether any particular structure now dissociated from use is to be regarded as "on the stocks or on the wane" is "a question of evidence from associated facts." Therefore it was that I said in my review that no illustration could be more unfortunate than the one which was chosen by the Duke as an example of rudimentary structures possibly on the stocks. For if the rudimentary organs which occur in the Cetacea admit of being supposed of doubtful interpretation in this matter, it is clear that in no case could the "evidence from associated facts" of structure and affinity be of any value. But in reality this evidence is nearly always so cogent that the difficulty suggested by the Duke is of a purely imaginary kind: evolutionists have no need ever to be puzzled in deciding whether a given structure is on the stocks or on the wane. Thus, for instance, let us take the cases which are adduced by the Duke himself. No evolutionist could be insane enough to imagine that the papillæ on the roof of the mouth of the giraffe are the remnants of whalebone, seeing that the whole structure and all the affinities of the animal are opposed to the inference that its ancestors were aquatic mammalia. Or, if we take the case of webbed feet, even if the dipper had begun to develop them, no evolutionist in his senses would infer that these incipient structures were remnants of structures once more fully developed, seeing that all the other structures and affinities of the bird prove that it belongs to a non-aquatic family. Cases of this kind actually occur in such birds as the grebe and the coot, where even apart from structure and affinity it is easy to see that the little piece of web must be regarded as a growing and not a dwindling organ, seeing that the birds are so strongly aquatic in their habits.

Considering next the Duke's remarks on instinct, I did not attempt to deal with the argument to which he refers, because I could not perceive that there was any argument to be dealt with. His view is a mere assumption to the effect that instincts are divinely implanted intuitions independent of experience; and to deny that experience, *in successive generations*, is the source of instinct is not to meet, by way of argument, the enormous mass of evidence which goes to prove that such is the case. Even within the limits of my review I should have thought there was evidence enough to have disposed of this denial.

As for the special case of the dipper, I only mentioned it in my review because the Duke lays great stress upon it in his book. No doubt better cases occur of newly-acquired instincts not yet associated with correlated structures, and in all such cases (whether good, bad, or indifferent), it is not a *non sequitur* mode of argument to say that, on the theory of the transmutation of instincts, the appropriate organs have not been developed, because, looking to the affinities of the animal, we are entitled to infer that time enough has not yet been allowed for their development. Again, I deny that it is for me, or for any other evolutionist, to prove that the ancestors of the dipper did not present those lesser modifications of structure which, according to the Duke, are now correlated with the aquatic instincts.[1] By "proof" he no doubt means the display of the ancestral form, and not the study of allied species. Proof of this kind is not attainable, but neither is it required. The question whether instincts are fixed intuitions or admit of being modified by accumulative experience with natural selection—*i.e.* whether they are or are not subject to evolution—is a question that does not require to be settled on the narrow basis of any one particular case. And if we take a broad view of all the instincts known to us, the combined weight of their testimony to the fact of transmutation is simply overwhelming.

London, April 4 GEORGE J. ROMANES

The Remarkable Sunsets

THE remarkable *red sunsets* and after-glows, about which so much has been written of late, still continue here, but in a less intense form. A remarkable one occurred last night, and while watching it I determined to send you a brief account of my experiences in the matter. It is of little use going into descriptions of the appearances which are now well known, but the one which occurred last evening was unusually fine. It was a stormy wild evening, with black clouds all around, except in the west, where, from about 10° above the horizon to near the zenith, it was quite clear, and of a pale orange glow. A quarter of an hour after sunset three immense rays through rifts in the cloud bank sprang up almost suddenly, and took quite an intense crimson lake colour, which lasted about ten minutes.

Our brightest displays occurred in October and November last, and frequently bathed the whole landscape in a deep crimson glow. These skies were often still more gorgeous in the morning, and on some occasions were so wonderful as to be styled *frightful* by some observers. I witnessed one of these sunrises from an altitude of 3000 feet in January, and it was almost an *awful* sight. The view to the east was over about thirty miles of plains to distant mountains; a low mist hung over the low ground, and the surface appeared slightly rolling as seen from above. The sky half an hour before sunrise was so intensely red, almost to the zenith, that it gave this mist the appearance of a sea of blood. Every object, tree-trunks, fern-trees, bushes, rocks, and the cottages about the hills, was of a similar lurid colour; still there was not yet sufficient light to read by comfortably. This display reminded me of the wonderfully red aurora witnessed in Australia on April 5, 1870, when the red light was so intense that ordinary newspaper type could be read by it at ten o'clock on a moonless night, the type appearing as if set in a blood-red sheet. This was the first time I recorded the *red spectrum line* of the aurora, and I think was one of the earliest observations of this fact.

---

[1] I say "according to the Duke," because, according to Mr. Darwin, "in the case of the water-ouzel the acutest observer, by examining its dead body, would never have suspected its sub-aquatic habits" ("Origin of Species," 6th ed., p. 142).

Some of the recent sunsets have looked very much like an aurora in the west, and faint traces of stratification lent additional similarity; indeed on one night early in December, the *after-glow* merged into a beautiful aurora, and silver streamers were seen before all the red glow had disappeared.

From all over Australia reports of wonderful sunsets and sunrises have been sent to me. In one case the *red glow* was reported as margined by an immense *black bow* stretching across from north-west to south-west. On several occasions these glows prolonged the twilight considerably, and a correspondent at Urana, in New South Wales, described one occasion where approaching darkness after one of these sunsets at length compelled him to leave off watering his garden, but suddenly the light increased again sufficiently to induce him to resume his work; and he states that a similar accession of light—each time fainter—occurred on that same evening.

The season over the south of Australia especially, but all over the continent, has been remarkable, and, so far as this colony is concerned, unprecedented in my thirty-three years' knowledge of the climate. January, February, and March are usually our dry, hot months; this year they have been wet and cold ones. The average rainfall for January has been 1·60 inches; this year it was 4·75 inches. For February the average is 1·95 inches, and up to this date (the 27th) it has been also 1·95 inches. The mean temperature for January was 3°·5 below the average, and for February 2° below. Stormy, squally, wintry weather has predominated, with now and then a very hot or a tropical day for a change.

Even before the Krakatoa outburst the northern parts of Tasmania had become subject to prolonged *earth tremors*, with now and then a decided earthquake shock. These disturbances still continue, and appear to be extending northwards, for on the 15th of this month a shock was felt at Gabo Island, at the south-east extremity of Australia, and a very severe one again on the 17th, when a curious and sudden barometric disturbance, not unlike that at the time of the Java catastrophe, was shown on our barographs.

While on this subject it may be as well to state that Mr. Barrachi, one of my assistants, while at Port Darwin determining the difference of longitude between that place and Singapore in March 1883, saw sunsets, followed by after-glows, which prolonged the usual short twilights to a very considerable extent, and he states they were equally remarkable with those witnessed here. They only occurred either just before or just after very heavy rains.

Referring to the various hypotheses which have found their way into print explanatory of the unusual phenomena attending sunrise and sunset since August 1883, the belief that they have been in some way brought about by the Krakatoa eruption appears to be generally accepted, and while some doubt may be thrown on this assumption by records of equally remarkable chromatic effects at both sunrise and sunset and about the sun at other times of the day prior to the eruption, it must be admitted at present that the volcanic eruption has strong claims to credence.

There can be no doubt that, whatever the prime cause, the effects are due to the presence in the higher regions of our atmosphere of a *form of matter* not usually there, at least to such an extent. Now this matter, or *form of matter*, may, as far as we know, be due to Krakatoa, to the earth's orbit traversing streams or regions pervaded with extremely fine meteoric dust, or to any other cause that might either introduce new or alter the form of existing matter.

It is well known in the laboratory that certain chemical combinations and mechanical mixtures will exist as such, but in a most unstable form,—a concussion or sharp sound, an electric spark, &c., either breaks them up or brings about a change of form so as to present altogether different physical properties. Now it is also well known that at the time of the Krakatoa eruption barometric pressure was spasmodically affected all over the world. Everywhere where barographs have been recorded this fact appears. This atmospheric shudder, undoubtedly originating at Krakatoa, was, I have reason to believe, conveyed rapidly from the centre through the higher and more tenuous regions of atmosphere, but affected the lower strata in its passage. This would perhaps account for the immense distance—thousands of miles—over which, it has been widely reported, explosions were heard about the time of the occurrence of the outburst.

Now if we assume that on the peripheral regions of our atmosphere *gases* and *forms of matter* exist in not very stable combinations or mixtures, it requires no great stretch of our imagination to picture the result of this great atmospheric shudder bringing about an alteration in the form or proportion of matter, and consequently such a change in its optical properties as to produce the unusual and remarkable effects which have been so universal. ROBT. J. ELLERY

Melbourne Observatory, February 27

UNDER date of January 14 I named the bark *C. Southard Hurlburt* as having observed the glow on September 3. She was dismasted in a cyclone August 8, and came to Honolulu for repairs. On the former date she was in about lat. 17° N., long. 125° W. The captain's wife, Mrs. Davis, described the phenomena to me as extremely brilliant.

Only last week I learned from Hon. H. M. Whitney, Postmaster-General, that on September 5 Mrs. Whitney and himself distinctly observed the sun's disk before setting to be *green*. His residence was an exception to most of ours in Honolulu, from which trees cut off a view of the horizon. My wife spoke much that night of a strange green cumulus, seen by her ten minutes before calling me to observe the portentous masses of colour pouring out all over the sky.

I beg special attention to my former remark of the "earth-shadow sharply cutting off" the upper rim of the first glow. This was very manifest in the strong heavy glows of September, showing clearly that the first glow directly reflected the sun's rays, while in the after-glow which had no defined upper rim, but continued much longer, the haze reflects only the light of the first glow. This bears on estimates of the height of the haze.

Observers here are well agreed that during November there was a very great abatement of the glows, amounting almost to a cessation, although the whitish corona was always well developed through the day. Early in December the glows were renewed, and for six weeks continued quite as brilliant as during October. They are now somewhat abated, although quite uniform nightly. In September and October they were extremely unequal, as well as varying in position of greater colour, south or north of west.

As this revival of our glows closely followed their general diffusion over Europe and the United States, I suggest that this was the arrival in force by slow marches of the main body constituting the great *cone* of vapours, which, falling into the atmosphere in September, covered like a pall the Indian Ocean and Peninsula, down the extended western slope of which cone the light upper vapours were sent by the westward thrust of the earth's rotation, to find speed in their downward slide to carry them at once around the tropical belt as a light advance guard (as set forth in my letter of January 14). As the September haze became gradually dissipated, so the later December arrivals are wasting away. S. E. BISHOP

Honolulu, January 30

AT Fanning's Island, long. 159° 22′ W., lat. 3° 52′ N., on September 4 last, the proprietor, Mr. Greig, states that the sun and sky had an extraordinary appearance; the sun "looked like a copper kettle." Lurid colours covered the sky. Great fears were felt for the safety of his schooner, the *Jennie Walker*, which sailed three days before.

From the master of the *Jennie Walker* I learn that on September 4 he was in long. 155° 28′ W., lat. 8° 20′ N., sailed from Fanning's Island three days before. At 5 p.m. noticed strange appearance in the sun, which was greenish. Strange colours over the west and around the sky at sunset. The sun was green at setting. Thought bad weather was portended. Never saw such appearances before.

Both parties are positive that the schooner was *three* days out when their fears were thus excited. She sailed September 1. No entry in ship's log of the above phenomena.

Honolulu, February 20 S. E. BISHOP

ANOTHER note relative to these phenomena:—"*August* 20, 1861.—Earthquake at Naples. At Castellamare the water is so discoloured, that although the calm has been complete, we fear some subterranean perturbation. The heat is intense. At the same time the atmosphere presented a very peculiar appearance. There are no clouds, and during the whole week a thick mist has enveloped the city and coast, and *the sun when setting is as red as blood.*"—(*Moniteur* du 29 Août, 1861.)

Meteorological Bibliography

I REJOICE to see the well-earned tribute which you have paid to Dr. Hellmann's excellent "Repertorium der Deutschen Meteorologie," and as a worker in the same field I trust that you will permit me to add that I agree with every word which your reviewer has said as to its excellence.

My object in writing is merely to point out that, thanks to the liberality of the United States Government, we may hope soon to have, not a perfect catalogue, but one which will be extremely useful, especially if, as I hope, the United States Government adopt my suggestion and endeavour to arrange with Dr. Hellmann for the incorporation of the first part of his "Repertorium" with the materials already forwarded to them.

Your reviewer is perfectly right in urging the absolute necessity of steps being taken to index and classify the multitudinous publications now appearing. Dr. Hellmann in his "Repertorium" says that 800 publications upon meteorology appear annually, or more than two each day, hence the impossibility of any one keeping abreast of the entire literature.

As regards the catalogue which I had the pleasure of sending to the United States last autumn, I annex an abstract of the description which I gave at the Southport meeting of the British Association in case you may think it of sufficient importance to be worthy of a place in NATURE. Dr. Hellmann's "Repertorium" only reached me just before my catalogue was shipped, hence the absence of reference to it in the annexed paper.

62, Camden Square, N.W., April 4 G. J. SYMONS

On the Completion of the European Portion of the Preliminary Meteorological Catalogue, by G. J. Symons

The author commenced by giving a few illustrations of the large amount of time and energy which has been wasted by meteorologists, owing to their not knowing what had previously been done, sometimes even in their own country, but most frequently in other parts of the world; and he pointed out that with the modern development of meteorological work and of meteorological literature, some effort, upon a large scale, to deal with this evil was imperatively necessary.

Mr. Symons described the catalogue which he had formed during the last twenty or twenty-five years, by extracting (from many thousand catalogues issued by dealers in second-hand books in most of the capitals of Europe) all the titles of works on meteorology or kindred subjects. He also described the important publication, by the Royal Society, of its "Catalogue of Scientific Papers," and showed wherein the two agreed, and how largely each supplemented deficiencies in the other.

He then explained the steps which Prof. Cleveland Abbe had taken in preparing his card catalogue, and the arrangements whereby a copy of Mr. Symons's catalogue was to be prepared and forwarded to the United States for incorporation with Prof. Abbe's.

Mr. Symons then stated the additions which had been made to the original proposal, and that the following catalogues had been subsequently incorporated, each giving *approximately* the number of titles set against it, viz.:—

Prof. A. Poëy's	MS.	6000
Ronald's	Printed	3000
Struve's Pulkova	Printed	3000
Meteorological Society	MS. and printed ...	2000
Houzeau's Belgian	Printed	2000
Soc. Météor. de France ...	MS.	1500
Royal Observatory, Greenwich	MS.	500
Fineman's Swedish...	Printed	500
	Total about	18,500

Of course a great many of these were duplicates, but every catalogue contained titles which were not in any of the others, and altogether they have undoubtedly added very largely to the value of the work; it is impossible to state how largely, nor is it material in a case wherein the assistance rendered has been almost as great as the catalogue, and as diverse as the languages dealt with.

The precise number of titles forwarded is not known, but is probably about 20,000. Prof. Abbe's catalogue is understood to contain about 10,000, but probably there will be a few thousand common to both catalogues, and therefore the preliminary catalogue, which the United States Signal Office, under the direction of General Hazen, will proceed to prepare for publication, will probably contain the titles of more than 25,000 books and papers upon meteorology.

Mr. Symons remarked, in conclusion, that the catalogue must not be regarded as complete. It was impossible to make it perfect—it could not be perfect as regarded the past until every public and private library in the world had been searched. It could not be perfect for the present, because every day new works appeared in different parts of the world, and all could not be simultaneously inserted. Nor would his part of it bear bibliographical criticism, for he was not a bibliographical expert, and his chief aim had been to give information useful to working meteorologists.

Ice Volcanoes—Mountain Rainbow

THE past winter has been unusually cold and stormy in Ontario, and, as a result, an uneven strip of ice 100 to 200 yards wide has accumulated along the lake shore, sometimes forming mounds twenty or thirty feet high. Many of these mounds are conical, and have a crater-like opening communicating with the water. In stormy weather every wave hurls a column of spray and ice fragments through the opening. The ejecta freeze fast as they fall, and add to the height of the cone. In high winds the coast seems fringed with miniature volcanoes in active eruption. After a time the crater becomes clogged with ice, and the volcano may be looked on as extinct. Often a second crater is formed just to seaward of the first, and growing upon its ruins.

Mr. J. A. Fleming mentions in your issue for January 31 (p. 310) a circular rainbow seen from a hill-top against mist. I saw the same phenomenon three years ago near the Lofoden Islands, as a fog was breaking. It was noticed and admired by other passengers on the steamer also. Each saw his shadow enlarged upon the mist, and with the head surrounded by a brightly coloured halo or rainbow. The beautiful sight disappeared after a few minutes as the fog thickened again.

Thread-twisting

IN reply to "Cosmopolitan's" question in NATURE (vol. xxix. p. 525), I have been many years in Orkney, but do not remember to have seen the women twisting thread with "the palm of the hand on the thigh," but the fishermen there twist the short lengths of horsehair line called "snoods," which when united together form fishing lines of different strengths, in this manner.

The women of the North-American Indians always twist the short threads of sinew with which moccasins and leather clothes are sewn in this way: The sinew is torn up or divided into thin filaments slightly moistened by being drawn between the lips, then twisted between palm and thigh. J. RAE

Kensington, April 5

IN reply to "Cosmopolitan's" query as to the occurrence of the habit of thread-twisting with the palm of the hand on the thigh in other lands than India, I may say that I have observed the same mode of operating upon paper in Japan very frequently. The paper used there is tough and fibrous, and a Japanese is never at a loss for card to tie a parcel with if he has paper beside him. I have seen the spindle-whorl in actual use in upland districts, and it was employed even in Tokio very recently.

Henry Faulds

Laurel Bank, Shawlands, Glasgow, April 7

Colony of Cats

It may interest those of your readers fond of cats to know that a colony of cats live and breed under the wooden platform of the Victoria Station of the District Railway. They may be seen crossing the rails right in front of trains, and considering the enormous traffic, and the consequent noise and vibration, it certainly does seem remarkable that such naturally timid animals as cats should live amidst such unnatural surroundings. It may tend to show the plasticity of the animal creation generally in adapting itself to surrounding conditions. A female cat may have taken refuge there originally, and hence the railway domestication of the animals.

George Rayleigh Vicars

London

Earthworms

Seeing the correspondence on this subject, I am led to give the following fact, which affords a further proof of the necessity of a vegetable deposit being formed previous to the existence of earthworms as stated by Mr. Melvin (vol. xxix. p. 502). A field two years ago was converted into a garden, and on account of bad cultivation, and by reason of each crop being altogether removed for several years in succession, no worms were there, but after the application of a large quantity of stable manure worms have appeared by hundreds, and their castings after rain afford ample proof of their activity. Transformation of vegetable mould combined with animal refuse into available food for plants is here made evident.

J. Lovell

Driffield, April 7

"The Axioms of Geometry"

Prof. Henrici, in Nature, vol. xxix. p. 453, considers Hamilton's proof of Euclid I. 32 invalid; and asserts that from his reasoning it would follow that the sum of the three angles of a spherical triangle equals two right angles. I venture to differ from him for the following reason:—The only thing which Hamilton requires to be granted is that when a moving *straight* line slides along a *fixed* straight line its *direction* is unchanged. This axiom will, I suppose, be granted by every one. Of course it is not true that in every case rotation is independent of translation. But Hamilton's proof does not require it to be true in every case, but only in the case of a *straight* line. Hence I maintain that Hamilton's reasoning is perfectly correct, and his proof valid.

Edward Geoghegan

Bardsea, March 26

GEOLOGY OF CENTRAL AFRICA

The following extract from a letter received by Mr. Geikie from Mr. Henry Drummond, who is at present exploring the Lake region, may interest our readers:—

"*Maramoura, Central Africa, November* 1, 1883

"I have now completed a traverse from the mouth of the Zambesi, by way of the Shire highlands, in a north-west direction, until the line joins Mr. Joseph Thomson's route, about half way between Lakes Nyassa and Tanganyika. I have filled in the geology so far as is possible in a single survey, and hope thus to be able to extend the sketch geological map, begun by Thomson, for some distance south and west. I may still further extend this by an expedition to Lake Bangweolo, after the rainy season, but there are circumstances which may make it necessary for me to leave for home in February or March. Perhaps the most interesting thing I have to note is the discovery here of a small but rich bed of fossils. The strata alluded to consist of light coloured limestones and shales, with beds of fine gray sandstones, and the fossils include plant, fish, and molluscan remains. Plants are the most scarce, but fish-scales and teeth exist in vast numbers. Unfortunately whole fish are extremely rare, and after three or four days' search I have only succeeded in securing two or three indifferent specimens. The mollusks, on the other hand, are obtainable in endless quantity, and are in fine preservation. Indeed there is one small bed of limestone entirely made up of these remains, all, however, belonging to a single species. From the general character of the beds I am inclined to think they are of lacustrine origin. These fossiliferous beds are *the only sedimentary rocks* I have crossed between the mouth of the Shire—say 130 miles from the coast—and the centre of the Nyassa-Tanganyika plateau. At the point where I crossed them they are not more than a couple of miles in breadth, and are flanked on either side by granite and gneiss. They lie at a short distance from Lake Nyassa, and are probably part of the Mount Waller series. This series stretches for some short distance along the north-west shore of the lake, but is apparently of no great extent. These deposits may possibly throw some light on the problem of the lake.

"As regards the controversy between Mr. Thomson and Mr. Stewart about (1) the Livingstone Mountains, and (2) the bed of iron between the lakes, I should say that on both points both explorers are right from their own point of view.

"Mr. Stewart had only been dead a few days when I reached the north end of Nyassa. It was a great disappointment and blow to me, as I looked forward to much help from him. No one living possesses anything like his knowledge of the physical geography of this part of the interior."

CHINESE PALÆONTOLOGY

PALÆONTOLOGY is not a study that commends itself to the attention of Chinamen. With archæology the case is different. That is a pursuit which within historical limits the Chinese follow with enthusiasm. Every one who possesses any pretensions to culture, and who can afford to indulge the inclination, collects all that is old from cracked china to coins. So prevalent is this taste, and so keen is the competition for objects bearing the stamp of age, that a flourishing trade, such as rivals the celebrated traffic in "antiquities" carried on at Jerusalem, exists in fabricated antiques for the benefit of inexperienced native collectors and foreign purchasers. But natural antiquities are, speaking generally, left unnoticed, or if thought of for a moment are hastily explained by random conjectures. Topsy's celebrated explanation of her existence is about on a par with the guesses which are hazarded by the most learned Chinamen to account for palæontological phenomena. Science has always a borderland of unsolved questions, but in China this borderland exceeds in extent the territory of knowledge in the possession of the people. They have no aptitude for palæontology, and few writers make any reference to it. Among the rare exceptions to this rule is Ch'ên Kwah of the Sung Dynasty (A.D. 960-1127), who, in an interesting work entitled "Notes from a Dreamy Valley," has collected a number of facts on natural antiquities as well as on other matters. His knowledge is not deep, but when we remember that Voltaire accounted for the presence of marine shells on the top of the Alps by supposing that pilgrims in the Middle Ages had dropped them on their way to Rome, a great deal may be forgiven a Chinese writer of the eleventh century.

The Chinese have so completely lost sight of the possibility of the existence in China of any civilisation but their own that when they meet with traces of earlier man they attribute them either to blind chance or to supernatural causes. In this way when Ch'ên Kwah met in the course of his investigations with flint and bronze implements he at once adopted the common opinion of his countrymen, which is the same as that which was prevalent in Europe a couple of centuries ago, that they were thunderbolts shot down by the God of Thunder in the explosions of his wrath. In confirmation of this theory Ch'ên states that though these implements are found all over the country they are more plentiful in districts, such as Lui-chow in the province of Canton, where thunderstorms are more than usually prevalent. In shape, he tells us, they resemble axes, knives, small hammers several pounds in weight, skewers or nails, and other pointed implements. In colour they vary, some being yellow, some green, and some black. Some of the axe-shaped stones are bored with two holes, but the majority are not pierced, and implements of the same shape are found in bronze and iron.

Speaking within his own knowledge he only describes the circumstances of the discovery of two stone axes, both of which he tells us were found beneath trees. In one case, at Sin-chow, in Hupeh, after a severe thunderstorm in which, like Prospero, the God of Thunder had

"rifted Jove's stout oak,
With his own bolt,"

a stone axe was found at its roots; and on another occasion at Sui-chow, under precisely similar circumstances, a shepherd-lad found a "fire stone in the shape of an axe." As in the only two cases about which Ch'ên speaks from personal knowledge the axes were found beneath trees, it is not unnatural to suppose that they are more frequently found in that position than elsewhere; and this becomes interesting when we find it stated by Mr. Rivett Carnac in a valuable paper published in vol. lii. of the *Proceedings* of the Bengal Branch of the Royal Asiatic Society, that it is the custom in Central India for the finder of a stone axe or other stone implement to place it "under the village pipul tree," and sometimes to sanctify it with a daub of red paint, and thus to constitute it a Mahadeo. A somewhat similar practice exists, according to Chinese historians, in a country vaguely described as being to the west of the Yuh Pass in Chinese Turkestan, where "thunder stones" when found are deposited in the temples. May not this Indian practice have also been the custom of some of the aboriginal tribes of China? and may not the fact that in the two instances mentioned above the axes were found at the roots of riven trees be evidence of the antiquity of the custom, as in cases described by Mr. Rivett Carnac, in which the roots of the trees and the surrounding soil had in course of years so completely grown over the axes that they could only be cut and dug out with difficulty?

Stone arrow-heads do not seem to have come within Ch'ên's range of observation, although from historical references we know that they are to be met with in China. In the "Book of History," which is said to have been compiled by Confucius, mention is made of tribute, consisting of iron, silver, steel, and stone arrow heads, having been presented to the Chinese Court by the tribes on the Yellow River about the year 2200 B.C. The story is told also that on one occasion, as the Prince of Ch'ên (495 B.C.) was walking in the palace grounds, a bird fell dead at his feet, pierced through by a stone-headed arrow. As the kind of bird was unknown to the prince and his courtiers, Confucius was called in to give his opinion upon it. The bird he pronounced to be a species of sparrow-hawk from Northern Tartary, and he explained that the stone head which pointed the dart was similar to that which Wu Wang (B.C. 1122) presented to his prince. It appears also that stone arrow-heads were used in ancient times as emblems of authority, and that they have very commonly been presented to sovereigns as objects of curiosity and value.

The biographical dictionaries tell us that in course of his official duties Ch'ên was called upon to direct extensive irrigating works; and no doubt the excavations and cuttings which he then superintended led him to take an interest in the fossil remains with which the country abounds. On this subject he has many notes. In one he tells us that at a certain spot on the Yellow River, the banks having fallen away for a considerable distance, a fossil bamboo grove was disclosed, a fact which excited his surprise, as the district is not one in which bamboos grow at the present day, and he contrasts with this the fossil peach-stones, roots of rushes, snakes and crabs, which are found at the Kin-hwa Mountain, all of which things are still indigenous in the neighbourhood. At Tsêh-chow in Shansi, he states, a man, when digging a well, suddenly unearthed a "lizard resembling a dragon." At sight of the monster the man fled in terror, but observing from a distance that it remained motionless, he ventured to return, when, to his relief, he found that it was petrified. Philistine-like, his neighbours broke it to pieces, and only one bit of it was preserved. Another kind of fossil has long been a puzzle to the philosophers, from the great and wise emperor, K'ang-hi (1661-1720), downwards. Adventurous travellers who have braved the northern frosts have from time to time brought back accounts of the mammoths which are found in the frozen cliffs of Siberia. Deceived by a mistaken analogy, the Chinese wiseacres have arrived at the conclusion that these monsters must be huge ivory-producing rats, and, misinterpreting their continued preservation, have formed the opinion that darkness is necessary to their life, and that exposure to the outer air produces instant death. Their ivory is considered to be softer than elephant ivory, and in the hands of skilful chemists their flesh is said to make up into a highly invigorating tonic.

Speaking of the neighbourhood of the Loh River, Ch'ên mentions the discovery of ancient Troglodyte dwellings in which were found coins, and in one case a stone chest bearing on the outside fine tracings of flowers, birds, and other objects. On the lid were inscribed upwards of twenty characters, which were of such an archaic form that they were undecipherable. But the contents were easily understood, and were at once recognised as pieces of pure gold.

Constant mention is made by Ch'ên of meteoric stones, which in popular imagination are said to assume various strange and uncanny forms. Of the descent of one such stone which fell in the province of Kiang-su in the year 1064, he gives certain particulars on the authority of a Mrs. Heu. This lady, when in her garden one day, was startled by an explosion like a peal of thunder, and saw a large "star nearly as big as the moon" pass across the sky from south-east to south-west, and eventually fall within a few yards of the place where she was standing. On going to the spot she observed a deep hole, at the bottom of which was the "star shining brightly." By degrees the light died away, and eventually at a depth of three feet she dug up a round stone of the size of a man's fist, and of the weight and appearance of iron. Altogether Ch'ên's work is well worthy of the study of those who can read Chinese and who are interested in the palæontology of China.

ROBERT K. DOUGLAS

ON THE FORMATION OF STARCH IN LEAVES

IN a recent communication to the *Arbeiten des botanisches Institut* in Würzburg (Bd. iii.), Prof. Sachs gives the results of his work during the past summer in connection with the above subject. The investigations were made with the object of determining the formation and disappearance of starch in the leaves of plants growing in the open, and under normal conditions of vegetation, and were carried on chiefly during the months of June, July, and August on a large number of Dicotyledons from various families. Some twenty-two years ago Prof. Sachs showed that the presence of starch in chlorophyll grains can readily be detected by means of the now well-known iodine test, a modification of which was employed in these researches.

If fresh green leaves are plunged into boiling water for ten minutes or so, certain soluble substances are extracted, but the starch and colouring matter of the chlorophyll grains remain in the still unbroken cells of the mesophyll. A short immersion in alcohol now removes the green colouring-matter and certain bodies soluble in alcohol, leaving the starch behind in the colourless tissue. The presence of acids affects the degree of whiteness of the decolorised leaf; and the decolorisation proceeds more rapidly in sunlight or warm alcohol than in the dark and cold. Leaves of *Tropæolum* may be rendered completely white, like writing paper, in two or three minutes.

If the decolorised leaf be now placed in a strong solution of iodine in alcohol, the presence or absence of starch may be demonstrated in a few minutes. If no starch is present, the cellular tissue simply presents the well-known yellow colour; if a large quantity of starch exists in the cells, the tissue appears blue-black, the venation appearing as a pale network in the dark ground. Paler colours result if but little starch is present at the time of the experiment.

It will readily be seen how useful the above method is for the purpose of demonstrating the absence of starch from etiolated leaves, the white portions of variegated foliage, &c., and the sequel shows that the method affords means of obtaining far more delicate results, without the trouble of a microscopic examination.

In the first place, the same leaf may be found to contain very different quantities of starch at different periods of the day, or according to the weather; and secondly, the increase and decrease of the quantities of starch in a given leaf may be very rapid.

Sachs showed long ago that if a plant is placed in the dark, the starch disappears from the leaves; and it has also been known for some time that if a piece of tinfoil is placed on a leaf, the covered portion forms no starch, although the parts exposed to light may become filled with that substance. Moreover, Kraus showed how very rapidly starch can be formed in direct sunlight.

Sachs now demonstrates on a number of plants that the starch formed in the leaves during the day may disappear completely during the night, and that the leaves shown to be full of starch in the evening may be quite empty of starch next morning. This depends upon the temperature and health of the plant, but occurs normally during the summer in plants growing in the open. A large number of experiments are given in support of this, and showing how the rapidity and completion of the process depends upon the weather.

The experimental proof is very simple. A leaf is halved longitudinally at night, after a fine sunny day, and the excised half is shown to be filled with starch by the iodine test described; the remaining half is tested early next morning, and shows at once if any material diminution has occurred during the night. A simple and obvious modification of this experiment gives an idea of the quantity of starch formed between sunrise and sunset. The half leaf tested before sunrise shows no trace of starch: the other half, left on the plant during the day, is found to become more and more filled with starch towards the afternoon.

Some curious results were arrived at as to the effect of growing parts on the rapidity of the emptying of the leaves; some of these matters still require investigation.

Differences in the weight of leaves and in the intensity of the colour produced by the iodine test, as well as some other observations, lead to a better understanding of a fact already known generally, viz. that the starch disappears from the leaves in the form of glucoses, which travel by way of the vascular bundles into the stems, and thus pass to the places where they are used up in growth.

Some very telling observations were made in this connection, and the dependence of the processes on temperature again show forth clearly.

These results lead to the conclusion that the process of metamorphosis into glucoses and translocation of the products of assimilation are also going on during daylight, though they are less evident, because more starch is then being formed and accumulated than is abstracted at the time. Moll proved that such is the case by exposing leaves to the sunlight, but in an atmosphere devoid of carbon dioxide; the starch already in the leaves disappeared, and no more was formed to replace it. Sachs repeated Moll's experiments, and proved the correctness of his conclusions by means of the iodine test. Half leaves were shown to be full of starch; the companion halves were put into closed atmospheres, deprived of carbon dioxide by means of potassium hydrate, and exposed to sunlight. In an hour the latter halves were tested, and found to be nearly emptied of starch. Other experiments proved that depletion occurred in a few hours, the time depending on the temperature.

Further experiments demonstrate that the starch travels in the form of glucoses in all the above cases; but it is not proved whether the metamorphosis is effected by forces in the chlorophyll grains themselves, or by means of diastatic ferments in the cells of the leaf. A few hints are here given showing a field for further research.

Perhaps the most ingenious part of the paper is that which now follows. It is well known that Weber's patient and thorough researches on the energy of assimilation led to two important results, among *others*: (1) that the quantity of starch formed by a certain area of leaf-surface in a certain time may be relatively very large; and (2) that different plants probably differ specifically as to the quantities of starch formed in their leaves.

Sachs proposes to apply his method to the solution of this question, *i.e.* how much starch is produced in, say, one square metre of leaf-surface by assimilation during, say, ten hours' bright sunlight? The great difficulties in Weber's researches were connected with the enormous labour necessary to measure the leaf-surface accurately.

Sachs resolved the matter in a manner which we may summarise thus:—He cut off portions of large leaves found to be empty of starch, measured them rapidly by laying them on pieces of board cut to the size of one square metre, and killed, dried, and weighed the measured portions very rapidly. Certain precautions as to the area of fibro-vascular bundles, the possibilities of absorbing hygroscopic moisture, &c., may here be passed over. Supposing these portions of the leaves to be estimated in the morning, a quantity of the same leaves of equal area gathered in the evening was then compared, and the increase in weight gives the quantity of starch formed in the interval. By weighing large areas, and frequently, and by paying attention to the times and other circumstances, a large number of results were obtained, showing that the quantities given by Weber, for instance, are within the mark. Of course these results are not absolute. Starch is being changed into glucose, and passing away during the day, and some must be burnt off in respiration; moreover a certain minute quantity of mineral ash should be allowed for. Of course, it is an assumption that equal areas of mesophyll of the same leaves contain approximately the same amount of substance: nevertheless, if a large number of experiments are made, the error is probably small.

Experiments were made to show both the quantities of starch which disappear during the night and the quantities formed during the day. A few of the numbers may be given. In *Helianthus*, 9·64 grms. of starch disappeared in ten hours from one square metre of leaf-surface.

In the same plant 9·14 grms. were formed in the same time by the same area of leaf-surface.

In another case *Helianthus* was used, but the leaves were removed from the stem to prevent the passage back of the starch from the mesophyll into the stems.

A square metre was found to produce starch at the rate of 1·648 grms. per hour.

By combining his experimental results and taking note of all the circumstances, Sachs concludes that twenty to twenty-five grms. of starch per day may be produced by one square metre of leaf-surface as an ordinary occurrence; and these numbers are not only not excessive, but experiments show that there are plants which produce much more than those investigated here.

Some remarkably interesting and important results follow from the consideration of these experimental data.

They explain why plants are so vigorous during warm nights following upon hot bright days. The more readily the products of assimilation (formed in large quantities during the day) can pass into the growing organs, the better these are nourished, and so forth.

Leaves used for fodder, &c., must differ in nutritive value to a very great extent if their starchy contents vary so largely during the day and night: it thus becomes of primary importance whether such leaves are gathered in the morning or the evening, in cold or warm weather, &c. The same applies to *Tobacco* and *Tea*, &c. It must make a vast difference to the smoker whether his tobacco abounds in carbohydrates or is relatively richer in the alkaloids. It appears that tobacco is habitually cropped in the morning in some countries, a fact which suggests that experience has already shown that a difference in the quality exists; it will be interesting to inquire further into these matters.

Sachs's results will also materially affect the physiological value of the analyses of leaves. Some of us know how great are the variations met with in analyses of the ash contents of leaves of the same plant. It is clear that, in addition to the age of the leaf, the soil, manure, &c., it is important to know the amount of starch present. It cannot but happen that the mineral matters ebb and flow as well as the starch. The analyses of leaves will also be more valuable for the purposes of physiology if the numbers are stated, not in simple percentages, but in terms of one square metre of the leaf-surface.

The above brief summary of the results obtained by Prof. Sachs by no means does justice to the beauty of his methods, and the masterly way in which they were carried out: it must be admitted by all who understand the value and importance of this work that it is worthy of the great pioneer of vegetable physiology. Moreover, it suggests several matters which require further investigation, and would no doubt yield valuable results to those fortunate enough to have a botanical garden at hand.

H. Marshall Ward

Botanical Laboratory, Owens College

TELEPHONY AND TELEGRAPHY ON THE SAME WIRES SIMULTANEOUSLY

For the last eighteen months a system has been in active operation in Belgium whereby the ordinary telegraph wires are used to convey telephonic communications at the same time that they are being employed in their ordinary work of transmitting telegraphic messages. This system, the invention of M. Van Rysselberghe, whose previous devices for diminishing the evil effects of induction in the telephone service will be remembered, has lately been described in the *Journal Télégraphique* of Berne by M. J. Banneux of the Belgian Telegraph Department. Our information is derived from this article and from others by M. Hospitalier.

The method previously adopted by Van Rysselberghe, to prevent induction from taking place between the telegraph wires and those running parallel to them used for telephone work, was briefly as follows:—The system of sending the dots and dashes of the code—usually done by depressing and raising a key which suddenly turns on the current and then suddenly turns it off—was modified so that the current should rise gradually and fall gradually in its strength by the introduction of suitable resistances. These were introduced into the circuit at the moment of closing or opening by a simple automatic arrangement worked exactly as before by a key. The result of the gradual opening and gradual closing of the circuit was that the current attained its full strength gradually instead of suddenly, and died away also gradually. And as induction from one wire to another depends not on the strength of the current, but on the rate at which the strength changes, this very simple modification had the effect of suppressing induction. Later Van Rysselberghe changed these arrangements for the still simpler device of introducing permanently into the circuit either condensers or else electromagnets having a high coefficient of self-induction. These, as is well known to all telegraphic engineers, retard the rise or fall of an electric current; they fulfil the conditions required for the working of Van Rysselberghe's method better than any other device.

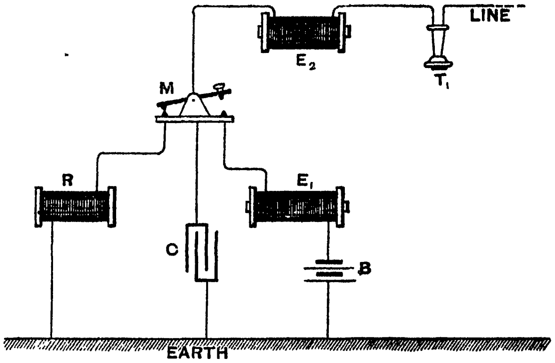

Fig. 1

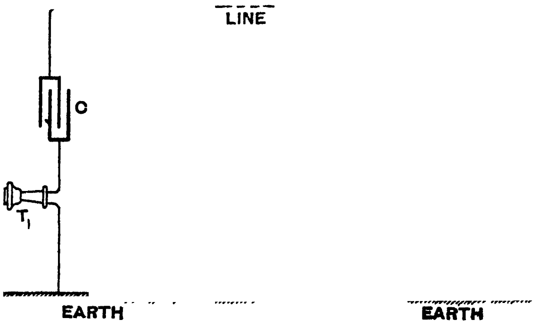

Fig. 2

Having got thus far in his devices for destroying induction from one line to another, Van Rysselberghe saw that, as an immediate consequence, it might be concluded that, if the telegraphic currents were thus modified and graduated so that they produced no induction in a neighbouring telephone line, they would produce no sound in the telephone if that instrument were itself joined up in the telegraph line. And such was found to be the case

Why this is so will be more readily comprehended if it be remembered that a telephone is sensitive to the changes in the strength of the current if those changes occur with a frequency of some hundreds or in some cases thousands of times *per second*. On the other hand, currents vibrating with such rapidity as this are utterly incompetent to affect the moving parts of telegraphic instruments, which cannot at the most be worked so as to give more than 200 to 800 separate signals *per minute*.

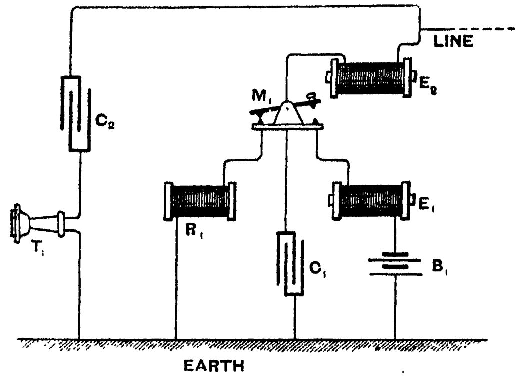

Fig. 3

The simplest arrangement for carrying out this method is shown in Fig. 1, which illustrates the arrangements at one end of a line. M is the Morse key for sending messages, and is shown as in its position of rest for receiving. The currents arriving from the line pass first through a "graduating" electromagnet, E_2, of about 500 ohms resistance, then through the key, thence through the electromagnet R of the receiving Morse instrument, and so to the earth. A condenser, C, of 2 microfarads capacity is also introduced between the key and earth. There is a second "graduating" electromagnet, E_1, of 500 ohms resistance introduced between the sending battery B and the key. When the key M is depressed in order to send a signal, the current from the battery must charge the condenser C, and must magnetise the cores of the two electromagnets E_1 and E_2, and is thereby retarded in rising to its full strength. Consequently no sound is heard in a telephone, T, inserted in the line-circuit. Neither the currents which start from one end nor those which start from the other will affect the telephones inserted in the line. And, if these currents do not affect telephones in the actual line, it is clear that they will not affect telephones in neighbouring lines. Also the telephones so inserted in the main line might be used for speaking to one another, though the arrangement of the telephones in the same actual line would be inconvenient. Accordingly M. Van Rysselberghe has devised a further modification in which a separate branch taken from the telegraph line is made available for the telephone service. To understand this matter one other fact must be explained. Telephonic conversation can be carried on even though the actual metallic communication be severed by the insertion of a condenser. Indeed, in quite the early days of the Bell telephone, an operator in the States used a condenser in the telegraph line to enable him to talk through the wire. If a telephonic set at T_1 (Fig. 2) communicate through the line to a distant station, T_2, through a condenser, C, of a capacity of half a microfarad, conversation is still perfectly audible provided the telephonic system is one that acts by induction currents. And since in this case the interposition of the condenser prevents any continuous flow of current through the line, no perceptible weakening will be felt if a shunt, S, of as high a resistance as 500 ohms and of great electro-magnetic rigidity, that is to say, having a high coefficient of self-induction, be placed across the circuit from line to earth. In this, as well as in the other figures, the telephones indicated are of the Bell pattern, and if set up as shown in Fig. 2, without any battery, would be used both as transmitter and receiver on Bell's original plan. But as a matter of fact any ordinary telephone might be used. In practice the Bell telephone is not advantageous as a transmitter, and has been abandoned except for receiving; the Blake, Ader, or some other modification of the microphone being used in conjunction with a separate battery. To avoid complication in the drawings, however, the simplest case is taken. And it must be understood that instead of the single instrument shown at T_1 or T_2 a complete set of telephonic instruments including transmitter, battery, induction-coil, and receiver or receivers, may be substituted. And if a shunt, S, of 500 ohms placed across the circuit makes no difference to the talking in the telephones because of the interposition of the separating condenser C, it will readily be understood that a telegraphic system properly "graduated," and having also a resistance of 500 ohms, will not affect the telephones if interposed in the place of S. This arrangement is shown in Fig. 3, where the "graduated" telegraph-set from Fig. 1 is intercalated into the telephonic system of Fig. 2, so that both work simultaneously, but independently, through a single line. The combined system at each end of the line will then consist of the telephone-set T_1, the telegraph instruments (comprising battery B_1, key M_1, and Morse receiver R_1), the "graduating" electromagnets E_1 and E_2, the "graduating" condenser C_1, and the "separating" condenser C_2. It was found by actual experiments that the same arrangement was good for lines varying from 28 to 200 miles in length. A single wire between Brussels, Ghent, and Ostend is now regularly employed for transmission by telegraph of the ordinary messages and of the telemeteorographic signals between the two observatories at those places, and by telephone of verbal simultaneous correspondence

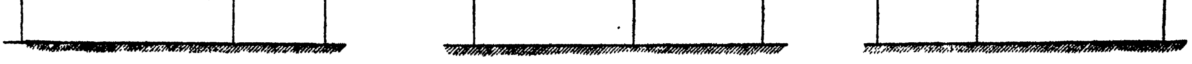

Fig. 4

for one of the Ghent newspapers. A still more interesting arrangement is possible, and is indicated in Fig. 4. Here a separating condenser is introduced at the intermediate station at Ghent between earth and the line, which is thereby cut into two independent sections for telephonic purposes, whilst remaining for telegraphic purposes a single undivided line between Brussels and Ostend. Brussels can telegraph to Ostend, or Ostend to Brussels, and at the same time the wire can be used to telephone between Ghent and Ostend, or between Ghent and Brussels, or both sections may be simultaneously used.

It would appear then that M. Van Rysselberghe has made an advance of very extraordinary merit in devising these combinations. We have seen in recent years how duplex telegraphy superseded single working, only to be in turn superseded by the quadruplex system. Multiplex telegraphy of various kinds has been actively pursued, but chiefly on the other side of the Atlantic rather than in this country, where our fast-speed automatic system has proved quite adequate hitherto. Whether we shall see the adoption in the United Kingdom of Van Rysselberghe's system is, however, by no means certain. The essence of it consists in retarding the telegraphic signals to a degree quite incompatible with the fast-speed automatic transmission of telegraphic messages in which our Post Office system excels. We are not likely to spoil our telegraphic system for the sake of simultaneous telephony, unless there is something to be gained of much greater advantage than as yet appears.

NOTES

WE are pleased to be able to announce that Prof. Flower's title is to be "Director" of the Natural History Museum, South Kensington, not "Superintendent," as Prof. Owen was styled. According to the Civil Service Estimates for the present financial year his staff consists of four keepers of departments (Botany, Geology, Mineralogy, and Zoology), two assistant keepers (Geology and Zoology), eleven first-class assistants, and fourteen second-class assistants. Large as this number may seem, it is notorious that in the Zoological Department at least a considerable reinforcement is required before the work can be expected to be efficiently performed.

WE regret to learn from the *Times* that M. Dumas, the venerable *Secrétaire perpétuel* of the Academy of Sciences, is lying in a critical state at Cannes.

POPE LEO XIII. has erected at his own expense at Carpineto-Romano, his native city, a meteorological observatory. It has been placed at the top of the castle of the Pecci family. The directorship of this establishment, which will be one of the most important in the whole Italian system, has been given to Count Lodovico.

WE are pleased to receive the first official publication issued from the Hong Kong Observatory by Dr. Doberck, giving the results of observations during the month of January. We are sure the establishment of this institution will be of the greatest service both to navigation and to science.

THE first International Ornithological Congress ever held was on Monday festively inaugurated at Vienna by its patron, the Crown Prince Rudolph—himself a noted ornithologist. In his opening speech, the Prince dwelt upon the great importance of those studies in natural history which characterise this century, a remark which was doubtless meant as a reply to the vehement attacks on modern science recently made by the Clerical Deputy Greuter in the Austrian Parliament. Germany and Austria have sent hither all their ornithological celebrities; but the Congress also includes delegates from the Russian and French Governments, and members from Switzerland, Holland, and Sweden. Even Siam and Japan are represented, while England is conspicuous by her absence. The Congress began its deliberations with the question of International Protective Legislation for Birds.

THE sixth Archæological Congress will be held at Odessa from August 27 to September 1.

A SOMEWHAT novel feature in connection with the International Health Exhibition this year will be the establishment of a library and reading-room, a home for which the executive council have assigned in a large double room in the Albert Hall, overlooking the conservatory. Steps have been taken to secure a representative collection of works on vital statistics; of reports and regulations relating to public health; of regulations with reference to injurious trades and of works thereon; and of reports, statistics, and other works on the science of education. Foreign powers have been invited to lend their cooperation in this effort to create an international library of works of reference bearing on the two divisions of the Exhibition, and several responses have already been received. India and the Colonies have also been asked to contribute towards the same end. Publishers and authors have likewise been invited to forward copies of their works. In addition to the library of reference, there will be a reading-room, to which the current numbers of periodical publications of a sanitary or educational character will be admitted. All books and periodicals sent to the library and reading-room will, under certain regulations, be arranged for the use of visitors, and not merely for exhibition. The books will be submitted to the jurors, and a full catalogue will be issued. All parcels for the library and reading-room should be addressed, carriage paid, to the Secretary of the Library Sub-Committee, Royal Albert Hall, London, S.W. The following handbooks are being written in connection with the Exhibition:—"Healthy Villages" (illustrated), by H. W. Acland, C.B., M.D., F.R.S.; "Healthy Bed-Rooms and Nurseries, including the Lying-in Room," by Mrs. Gladstone; "Healthy and Unhealthy Houses in Town and Country" (illustrated), by Mr. W. Eassie, C.E., with an appendix by Mr. Rogers Field, C.E.; "Healthy Furniture and Decoration" (illustrated), by Mr. R. W. Edis, F.S.A.; "Healthy Schools," by Mr. Charles Paget, M.R.C.S.; "Health in Workshops," by Mr. J. B. Lakeman; "Manual of Heating, Lighting, and Ventilation" (illustrated), by Capt. Douglas Galton, C.B., F.R.S.; "Food," by Mr. A. W. Blyth, M.R.C.S.; "Principles of Cookery," by Mr. Septimus Berdmore; "Food and Cookery for Infants and Invalids," by Miss Wood, with a preface by R. B. Cheadle, M.D., F.R.C.P.; "Drinks, Alcoholic," by John L. W. Thudichum, M.D., F.R.C.P.; "Drinks, Non-Alcoholic and Aërated," by John Attfield, Ph.D., F.R.S.; "Fruits of all Countries" (illustrated), by Mr. W. T. Thiselton Dyer, M.A., C.M.G.; "Condiments, including Salt," by the Rev. J. J. Manley, M.A.; "Legal Obligations in respect to Dwellings of the Poor," by Mr. Harry Duff, M.A., Barrister-at-Law, with a preface by Mr. Arthur Cohen, Q.C., M.P.; "Moral Obligations of the Householder, including the Sanitary Care of his House," by G. V. Poore, M.D., F.R.C.P.; "Laboratory Guide to Public Health Investigation" (illustrated), by W. W. Cheyne, F.R.C.S., and W. H. Corfield, M.D., F.R.C.P., M.A.; "Physiology of Digestion and the Digestive Organs," by Prof. Arthur Gamgee, F.R.S.; "Fermentation," by Dr. Duclaux, with a preface by M. Louis Pasteur, Membre de l'Institut; "Spread of Infection," by Mr. Shirley F. Murphy; "Fires and Fire Brigades" (illustrated), by Capt. Eyre M. Shaw, C.B.; "Scavengering and other such Work in Large Cities," by Mr. Booth Scott; "Athletics," Part I. (illustrated), by the Rev. E. Warre, M.A.; "Athletics," Part II., by the Hon. E. Lyttleton, M.A., and Mr. Gerard F. Cobb, M.A.; "Dress in relation to Health and Climate" (illustrated), by Mr. E. W. Godwin, F.S.A.; "The

Ambulance" (illustrated), by Surgeon-Major Evatt, M.D., A.M.D.; "The Influence of Schools of Art on Manufacturing Industry," by John Sparkes; "The Homes of the Poor," (author not yet settled).

LADY SIEMENS has placed at the disposal of the Council of the Society of Arts a sum of 20*l.*, to provide a prize, to be called the Siemens Prize, to be offered for the best application of gas to heating and cooking in dwellings (Class 24 in the International Health Exhibition). The prize will consist of a gold medal or 20*l.*, and will be awarded under the same conditions as the prizes announced in the *Journal of the Society of Arts* of the 14th inst.

THE Senkenberg Natural History Society at Frankfort has had a legacy of 40,000*l.* left to it by the late Countess Bose.

A HUMAN skull has just been discovered in a bed of clay near Podbaba in the neighbourhood of Prague. A few days previously a mammoth tusk was found in the same locality. The colour of the skull proves that it was lying in yellow diluvial loam. It is remarkable on account of its very flat forehead and the thickened eyebrow bones, thus closely approaching the well-known Neanderthal skull. Its facial angle seems to be even smaller than that of the latter, although an exact measurement is impossible on account of the absence of part of the jaw-bones. Further details on the subject will be published in the *Transactions of the Bohemian Academy of Sciences.*

THE first number has just been issued of a new Italian quarterly, entitled *La Nuova Scienza, Rivista dell' Istruzione Superiore*, edited by Prof. Enrico Caporali of Todi, Umbria. As implied by the title, the aim of this periodical is to popularise scientific subjects, and to chronicle the progress of discovery in Italy and abroad. The editor invites communications in the chief European languages, and declares that his efforts will be mainly directed to promoting the unification of the sciences with a view to the ultimate constitution of an exact philosophy. To the present number he contributes two spirited and learned papers on "Modern Thought in Italy," and on "The Pythagorical Formula of Cosmic Evolution." The appearance of such a publication in a small provincial town is itself a striking illustration of the general revival of serious studies since the establishment of political unity in Italy.

THE much discussed question as to the purification of water in rivers "by itself," that is, by the mere fact of its motion, seems to have entered into a new phase. Dr. Pehl, at St. Petersburg, has recently made a series of bacterioscopic measurements on the waters of the capital, which are summed up in the last issue of the *Journal of the Russian Chemical Society.* The water of the Neva itself appears to be very poor in bacteria, namely, 300 germs in a cubic centimetre. After heavy rains this number rises to 4500, and to 6500 during the thawing of the river. The canals of St. Petersburg, on the contrary, are infected with bacteria, their number reaching 110,000 in a cubic centimetre, even during good weather. The same is true with regard to the conduits of water for the supply of the city. While its chemical composition hardly differs from that of the Neva (by which they are supplied), the number of bacteria reaches 70,000, against 300 in the water freely taken from the river; and the worst water was found in the chief conduit, although all details of its construction are the same as in the secondary conduits. Dr. Pehl explains this anomaly by the rapidity of the motion of water, and he has made direct experiments in order to ascertain that. In fact, when water was brought into rapid motion for an hour, by means of a centrifugal machine, the number of developing germs was reduced by 90 per cent. Further experiments will show if this destruction of germs is due to the motion of the mass of water, or to molecular motion. The germs, among which Dr. Pehl distinguishes eight species, are not killed by immersion into snow. As the snow begins to fall it brings down a great number of germs, which number rapidly diminishes (from 312 to 52 after a three hours' fall of snow, on January 21, 1884), while their number on the surface of the snow increases, perhaps in consequence of the evaporation of snow or of the condensation of vapour on its surface.

IT is proposed, *Science* states, to establish a monthly *American Meteorological Journal.* It will begin with from twenty-four to thirty-two octavo pages, and will be enlarged as rapidly as is justified by the support given it. The first number will probably appear about May 1. It will be published in Detroit by Dr. W. H. Burr, and edited by Prof. M. W. Harrington of Ann Arbor.

IT is stated that the earthquakes of March 25 in Southern Hungary were also severely felt at Essegg, at Winkowze, and at Fünfkirchen. At Djakovar many houses were injured. Another earthquake was remarked at Ischia on March 28. The shock was but a slight one and of short duration.

FROM the Report for 1883 of the Glasgow Museum we see that it had 223,129 visitors during the year. There were large additions to the Natural History Department during the year.

WE have already noticed M. Erkert's anthropological measurements in the Caucasus. He publishes now in the *Isvestia* of the Tiflis Geographical Society (vol. viii.) his further measurements and conclusions. The different nationalities appear as follows with regard to their cephalic indexes:—Only the Aderbaijan Tartars are mesocephalic (79·4), all others being brachycephalic, the indexes being 80·9 with the Kalmucks, 81·4 with the Ossets, 81·9 with the Adighe and Chechenes, 83·2 with the Little-Russians, 83·7 with the Georgians, and 85·6 with the Armenians. A high index was found for the Lezghines, but the number of measurements was only three. As to the height of the skull the Aderbaijan Tartars have the highest and longest heads; the Armenians the shortest and highest (71·1); the Kalmucks the longest but lowest (62·0); while the Little-Russians, the Adighe, and the Georgians afford intermediate types, the heights of their skulls varying from 67·6 to 66·7. All the above nationalities have relatively low and broad or chamäprosopous faces, there being, however, a number of individuals with long or leptoprosopous faces, especially among the Tartars. In connection with the above it may be worth noticing the measurements of M. Chantre of Lyons, published in the *Bulletin de la Société d'Anthropologie de Lyon* for 1883. It results from his measurements made on 137 Kurd men and 21 women, that their cephalic index is 81·4; they are thus brachycephalous, and sometimes mesaticephalous. The index increases with those Kurds who live close by Armenians, and decreases with those who live close by Bedouins. Altogether the memoir of M. Chantre ("Aperçu sur les caractères ethniques des Anshariés et des Kourdes") is an important addition to our knowledge of Kurdistan, as well as his second memoir, published in the same serial, on the Stone and Bronze Ages in Western Asia, Syria, Mesopotamia, Kurdistan, and the Caucasus.

IT appears from the Caucasian *Isvestia* that the Russian Amu-daria Expedition has arrived at the following conclusions:—The I han branch of the delta of the Amu could be easily made navigable; as to the possibility of bringing the water of the Amu to the Caspian, General Glukhovsky's Commission does not yet give a definite answer, but it considers it most probable. The immense and deep depression of Sary-kamysh could be turned by the canal; the necessary inclination of level exists; and the immense desert west of Khiva could be irrigated without difficulty and without loss to the oasis of Khiva.

In the letter signed "O. S." (last week (p. 525), under the heading "Remarkable Sunsets," the French term should be *pelure d'oignon* and not *velure*.

The additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mrs. F. Mortimer; two Secretary Vultures (*Serpentarius reptilivorus*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Blue-and-Yellow Macaw (*Ara ararauna*) from South America, presented by Mr. H. W. Kingdom; two Common Peafowls (*Pavo crista'us* ♂ ♀) from India, presented by Mr. R. F. J. Cobbett Allen; a Common Viper (*Vipera berus*, black variety) from Hampshire, presented by Lord Londesborough, F.Z.S.; a Yaguarundi Cat (*Felis yaguarundi*) from South America, a Leuhdorf's Deer (*Cervus leuhdorfi* ♂) from Amoorland, two Jardine's Parrots (*Pæocephalus gulielmi*) from West Africa, three Rhinoceros Hornbills (*Buceros rhinoceros* ♂ ♀ ♀) from the Malay Peninsula, two Nepal Hornbills (*Aceros nepalensis* ♂ ♂), a Green Cochoa (*Cochoa viridis*), two Nepal Tree Pies (*Dendrocitta nepalensis*), a Gray-headed Thrush (*Turdus castanea*) from Nepal, three Bronze Fruit Pigeons (*Carpophaga ænea*), two White-breasted Gallinules (*Gallinula phœnicura*) from India, two White-backed Pigeons (*Columba leuconota*) from the Himalayas, seven Waxwings (*Ampelis garrulus*), two Proteus (*Proteus anguinus*), European, purchased; a Lucian's Parrakeet (*Palæornis luciani*) from China, a Geoffroy's Dove (*Peristera geoffroii* ♂) from Brazil, received in exchange.

OUR ASTRONOMICAL COLUMN

Comet 1884 *a*.—The comet notified by telegram from Mr. Ellery as having been discovered in the constellation Grus, appears to have been detected by Mr. Ross, a young amateur astronomer residing at Elsterwick, near Melbourne, on January 7. Observations were commenced at Melbourne on January 12, and were continued to February 4, when the comet had become very faint. The positions, as first communicated to the *Astronomische Nachrichten*, contained more than one obvious error, and generally (according to a comparison made by Dr. Kreutz with an orbit since received from Melbourne) appear to be strangely inaccurate, a circumstance that will probably have caused useless expenditure of time to computers. We subjoin the Melbourne orbit with one calculated by Mr. Hind from the observations on January 12 and 28 and February 4, as they are printed in *Astron. Nach.*, No. 2579:—

	Melbourne		Hind
Perihelion passage, 1883,	Dec. 25·7838 Melb. M.T.	...	Dec. 25·4998 G.M.T.
	° ′ ″		° ′
Longitude of perihelion	125 15 55	...	124 14·4
,, ,, ascending node	265 12 15	...	265 56·5
Inclination	64 53 16	...	64 59·7
Log. perihelion distance... ...	9·502384	...	9·51838

Motion—Retrograde.

It is to be remarked that Dr. Kreutz, calculating from the Melbourne orbit, does not reproduce the extreme positions stated to have been employed in its computation.

Variable Stars.—On comparing the late Prof. Julius Schmidt's determinations of the times of minima of *Algol* in 1883 with the formula given by Prof. Schönfeld in his second catalogue of variable stars, it will be found that, by a mean of the observations between August 14 and December 4, the formula gives the minimum too late by fifty-eight minutes. The mean annual errors for the period 1876-83 have shown irregularity, but the separate results within the same year differ considerably.

Mr. Baxendell has worked out new elements for R Arietis from his own observations 1859-81. He finds for—

Days
Maximum ... Epoch 1866, Sept. 1·3 + 186·71 E.
Minimum ... Epoch 1870, Jan. 2·3 + 186·63 E.

The mean interval from maximum to minimum is 99·0 days, and from minimum to maximum 87·7 days.

The Observatory, Cincinnati.—The seventh part of the publications of this Observatory has appeared. Parts 4, 5, and 6 were devoted by Mr. Ormond Stone to the double-star measures made with the 11-inch refractor in the years 1877-80. In the new part are given the observations of comets in the years 1880-82, including numerous physical observations as well as observations for position. There is a comparison with theory of the phenomena in the tail of the great comet of 1882. In a number of plates are illustrated the telescopic and naked-eye appearance of the great comets of 1881 and 1882 and of the first comet of the latter year.

Mr. H. C. Wilson is in temporary charge of the Cincinnati Observatory, Mr. Ormond Stone having been appointed Professor of Astronomy in the University of Virginia, and Director of the Leander McCormick Observatory.

The "Astronomische Gesellschaft."—The fourth part of the eighteenth volume of the *Transactions* of this Society is issued. It contains the proceedings at the meeting held in Vienna in September last and the usual critical notices of recent astronomical publications; also reports on the progress of the zone-observations from thirteen observatories. It was decided to hold the next meeting at Geneva in 1885; Prof. Auwers was chosen president for the second time, with Prof. Gyldén as vice-president, and Profs. Schönfeld and Seeliger (now at Munich) as secretaries.

PHYSICAL NOTES

The transition-resistance supposed by Poggendorff to exist in electrolytic cells between the surface of the electrode and that of the electrolyte in contact with it has lately been investigated with great care by Prof. J. Gordon Macgregor in solutions of very pure zinc sulphate, using electrodes of amalgamated zinc. The conclusion arrived at was that such a transition-resistance, if it exists at all, is less than 0·0125 of an ohm.

In another paper which appears in the *Transactions of the Royal Society of Canada* Prof. Macgregor describes an ingenious arrangement devised by him for measuring on Wheatstone's bridge the resistances of electrolytes. He employs alternate currents produced by a rotating commutator inserted in the circuit of two Daniell's cells; and in order to use with this arrangement an ordinary mirror-galvanometer, he recommutes the currents in the galvanometer circuit by means of a second commutator rotating on the same axle as the first.

The annual *conversazioni* of the Société de Physique, of Paris, will be held this year on April 15 and 17 respectively, the former being limited strictly to the members of the Society. These meetings will, by the invitation of Admiral Mouchez, be held in the Observatoire.

A note on Hall's effect was recently read at a meeting of the Physical Society of London by Prof. S. P. Thompson and Mr. C. C. Starling. They find that when a large sheet of foil is used, and placed symmetrically in a concentrated field between pointed magnetic poles, so that the junctions and connections are quite outside the influence of the field, Hall's effect is not produced. They find, however, an alteration in the equipotential lines of the current in the strip where it is magnetised, and have traced this effect to a change in the resistance. Strips of gold and tin show a decrease, strips of iron a slight increase of resistance when subjected to a strong magnetic field.

Another paper on Hall's effect appears in the current number of the *Journal de Physique* from the pen of M. Leduc. In this article M. Leduc draws a diagram of the equipotential lines, as, according to his ideas, they will be found to lie between the two "parasitical" electrodes. It does not appear whether he has verified his views by actual determinations of the position of the lines of equal potential.

Rowland's famous experiment demonstrating the magnetic action of electric convection has been called in question by Dr. E. Lecher of Vienna. In Rowland's original experiment the electrified rotating disk was horizontal, and the magnetic needle, protected from electrostatic influences by being inclosed in a metallic case, was held over the disk at a point near the circumference. Dr. Lecher, in attempting to repeat the experiment, placed the rotating disk in a vertical plane, its axis being horizontal; the magnet needle was placed parallel to the plane of the disk and in the axis of its rotation in fact relatively as the coil and needle of a Gaugain galvanometer. Disks of brass and of *papier-maché* covered with graphite were used, and charged from a Holtz machine to potentials of about 5000 volts as measured on an absolute electrometer. The velocity of rotation was about 200 revolutions per second. The astatised needle was protected within a metal case, and was observed in the usual way by a mirror. No deflection was observed either when the disk was still or when it rotated. Dr. Lecher intends to repeat Rowland's experiment with the original horizontal disposition of the disk.

DR. LECHER has also made another experiment of great interest. A ray of light was divided, as in many experiments on interference, into two parts, which, after passing through two parallel glass troughs, were caused to reunite, giving the usual interference-bands. The troughs contained strong solutions of nitrate of silver. By means of electrodes of silver an electric current of 6 amperes strength was carried in opposite directions along the troughs so that in one trough the current flowed *with* the light, and in the other against it. But in no case was any displacement of the fringes observed. Dr. Lecher concludes that the velocity of light is not influenced by a current flowing through the medium.

DR. LECHER has made a third and still more interesting experiment, attended, however, like the preceding, with a negative result. This was an attempt to prove whether Faraday's famous experiment of rotating the plane of polarisation by an electric current could be inverted. He has attempted to generate currents by rotating the plane of polarisation of light. The arrangement was as follows:—A ray of plane-polarised light was sent through the interior of two powerful helices of wire situated at some distance from one another. Through the first of these a powerful alternate current was sent, which impressed upon the ray a rapid oscillation of its plane of polarisation. The second helix was connected to a sensitive receiving telephone in the hope that sounds might therein be heard, as would be the case if the rapid rotations in the plane of polarisation of the ray were capable of setting up currents in the surrounding wire. Absolutely nothing was, however, heard.

BACTERIA

A VERY distinguished audience assembled at the Parkes Museum on Thursday evening, March 27, to witness Mr. Watson Cheyne's demonstration of pathogenic micro-organisms. The chair was taken by Sir Joseph Lister, Bart. After stating that the great group commonly called Bacteria might most conveniently be subdivided into four classes—(1) Micrococci (round bodies), (2) Bacteria (small oval or rod-shaped bodies), (3) Bacilli (large rod-shaped bodies), and (4) Spirochætæ and Spirilla (rods spirally twisted), and dwelling on the great variety as well as importance of the various parts played by this great group in the economy of nature, Mr. Watson Cheyne demonstrated numerous micro-photographs taken by Dr. Robert Koch, as well as some drawings by means of a limelight apparatus. He observed that great differences existed among the various bacteria in their behaviour towards the human body: some could be injected without causing any injury, others could not grow in the living body, but could develop in dead portions of tissue and the secretions of wounds, giving rise to poisonous products. The true pathogenic organisms were able to attack the living body and multiply in it; they included the organisms which found entrance through some wound, giving rise to the traumatic infective diseases, and others which could obtain entrance without observable wound. Further, certain organisms, such as the *B. anthracis*, were capable of growing outside the body in dead organic substance, while others, such as the *B. tuberculosis*, were apparently only capable of development in the living organism or under artificial conditions which reproduced to some degree those existing in the tissues of warm-blooded animals, though capable of long retaining their vitality in the dry state. With regard to the traumatic infective diseases, he thought that the most absolute proof had been furnished that the bacteria found in them, and nothing else, were the causes of these diseases. To establish such a proposition it was necessary that an organism of a definite form and with definite characteristics should always be found in the blood or in the affected part. The blood or the affected part when inoculated into another animal of the same species must produce the same disease. When the blood or the affected part was inoculated on a suitable soil outside the body, the micro-organisms grew, and must be indefinitely propagated on similar soil. When in this manner the organisms had been separated from the remains of the materials in which they were embedded, their inoculation in an animal must produce again the same disease, the same organisms being found in the diseased parts. These conditions had now been fulfilled with regard to anthrax, septicæmia of the mouse, erysipelas, tuberculosis, glanders, and acute pneumonia. With regard to typhoid fever, relapsing fever, cholera, and ague, the evidence was very strong, but not conclusive. Mr. Watson Cheyne concluded by dwelling on the importance of surrounding circumstances, chiefly those summed up in the phrase unhygienic conditions, as concomitant causes of disease by preparing the blood for the attacks of these micro-organisms.

The chairman, Sir Joseph Lister, dwelt upon the important fact that the organisms which produced particular diseases were only able to develop under very special conditions, instancing the bacillus which caused septicæmia in the house mouse, but which was unable to produce any deleterious effect on the field mouse. He thought this fact, which showed that the very slight difference in the blood of these two animals was sufficient to alter the conditions favourable to the development of the bacteria, might prove of very great interest, as it was possible to conceive that by the administration of some medicines, sufficient alteration might be produced in the blood of the human system to kill off or to prevent the development of any special bacteria on the first appearance of the symptoms of the disease in the patient. Sir Joseph Lister concluded by referring at some length to the importance of Pasteur's researches on modified virus.

Prof. Humphry paid an eloquent tribute to the great work which Sir Joseph Lister had already achieved, and looked forward with a large hope to the future of medicine.

THE STABILITY OF SHIPS

PROFESSOR ELGAR has recently made two important contributions to this important question; the first was read before the Royal Society on March 13 last. The main object of the paper was to exhibit the manner in which the stability of a ship varies with changes of load and draught of water such as merchant steamers are liable to. None of the properties possessed by a ship is more vital to her safety and efficiency than that of stability. At the same time none is dependent for its existence and amount upon so many or such diverse and variable circumstances as it. The stability of a ship, both as regards moment and range, is affected not only by the position of her centre of gravity, which largely depends upon stowage, but also by draught of water. If the centre of gravity be kept fixed in position at various draughts of water, the stability will still vary very considerably with the draught, and often in a manner that contains elements of danger.

The usual practice in investigating a ship's stability is to calculate a curve of metacentres, and one or more curves of stability at certain fixed draughts of water and with given positions of centre of gravity. The curve of metacentres gives the height at all draughts of water above which the centre of gravity cannot be raised without making the ship unstable when upright, and causing her to lie over more or less to one side. The ordinates of the curve of stability represent the lengths of the righting arms, which, multiplied by the weight of the ship, give the righting moments at all angles of inclination from the upright. The stability of numerous vessels, both of the Royal Navy and mercantile marine, have been investigated in this manner for certain draughts of water, and a great amount of information obtained respecting the variation of stability with inclination at such draughts, and the angle at which the stability vanishes in many classes of ships. The peculiar dangers attaching to low freeboard, especially when associated with a high centre of gravity, have been fully discussed and made known.

Curves of stability have been chiefly constructed for deep and moderate draughts; the character of the stability which is often to be found associated with very light draught, appears to have hitherto escaped attention. As a matter of fact, light draught is often as unfavourable to stability as low freeboard, and in some cases more so. The general opinions that have till recently prevailed upon the subject appear to have been based upon a vague impression that so long as a vessel has a high side out of water, and any metacentric height, she will have great righting moments at large angles of inclination and a large range of stability. It was shown at the *Daphne* inquiry, held by Sir E. J. Reed in

July last, that these opinions largely prevailed and were erroneous.

Prof. Elgar was called upon to make some investigations respecting the stability possessed by the *Daphne* at the time of the disaster which happened to her, and to give evidence respecting the same. He afterwards pointed out, in a letter to the *Times* of September 1 last, some of the considerations which obviously apply to light draught stability. The first, which it appears had never before been stated, is that any homogeneous floating body which is symmetrical about the three principal axes at the centre of gravity—such as a rectangular prism or an ellipsoid—will have the same moment of stability at equal angles of inclination, whether floating at a light draught with a small volume below water, or at a deep draught with a similar volume above water. For instance, if a homogeneous prism of symmetrical cross-section 5 feet high float at a draught of 1 foot, it will then have precisely the same moment of stability at equal angles of inclination, and consequently the same curve of stability throughout, as if it were loaded—without altering the position of the centre of gravity—till it had 4 feet draught of water, and 1 foot of free board. From this it follows that, in such elementary forms of floating bodies, lightness of draught has the same effect upon stability as lowness of freeboard; and if a low freeboard is unfavourable to stability, so also, and precisely to the same extent, is a correspondingly light draught of water. This proposition can be made still more general, as it applies to homogeneous bodies of any form of cross-section which revolve about an horizontal axis fixed only in direction. From this may be deduced the results given by Atwood in his papers read before the Royal Society in 1796 and 1798 respecting the positions of equilibrium and other peculiarities connected with the stability of floating bodies.

In considering the stability of a ship at various draughts of water, and comparing it with that of the class of figures above described, modifications require to be made for the departure from symmetry of form, and for the extent to which the vertical position of the centre of gravity differs from what it would be if the external surface inclosed a homogeneous volume. Prof. Elgar has done this with great fullness of detail in his paper, and shows, by means of curves, how the stability varies with draught of water at constant angles of inclination in various geometrical forms of floating bodies, and in a large passenger steamer of ordinary type. The curves thus dealt with are curves of righting moments, and not merely curves of lengths of righting arm. The ordinary curve of stability is usually made for lengths of righting arm, because the displacement is constant, and the same curve therefore gives upon different scales, either lengths of righting arm or righting moments. In the vertical or cross curves of stability, however, such as are now being dealt with, draught, and therefore displacement, is one of the variable quantities, and curves of righting moments are of a very different character from curves of righting arm. Complete cross curves for a ship, from which ordinary curves of stability can immediately be obtained for any draught of water and position of centre of gravity, can be constructed in a few days with the aid of Amsler's mechanical integrator.

Prof. Elgar shows conclusively the necessity in many cases of regarding the stability of a ship from the point of view of variation of righting moment with draught of water, the angle of inclination being constant, instead of from that of variation of righting moment with angle of inclination, the draught being constant, as is usually done; or rather of considering the subject from both points of view instead of almost exclusively from the latter. He also shows that it is necessary to investigate, more fully than has formerly been done, the moments and range of stability of ships and other structures that may be intended to float at very light draughts of water.

Prof. Elgar's second paper was read last week at the meeting of the Institute of Naval Architects; its title was "The Use of Stability Calculations in Regulating the Loading of Steamers."

The stability of ships, Prof. Elgar went on to say, is a subject that has received a considerable amount of theoretical investigation during recent years. The general character of the stability of certain classes of ships, and the circumstances which affect it, have been largely ascertained and made known; while the methods of performing the requisite calculations—especially when large angles of inclination are being dealt with—have been greatly improved. Curves of stability have been constructed and made public for numerous ships of various classes, both for war and mercantile purposes.

The results of the investigations that have thus been made are of great value to naval architects and men of science, and enable them to know much more respecting the actual stability often possessed by ships than was possible with the imperfect data available in former years. In the case of ships that are built for purely war and some other special purposes, the ordinary stability calculations enable instructions to be readily framed respecting the stability they possess under ordinary working conditions, or in such critical circumstances as may possibly occur during their career. Any risks of instability that may exist, or arise in certain contingencies, may be ascertained, and the precautionary measures necessary for counteracting them devised and pointed out.

The problem that has to be dealt with in advising those in charge of war ships how to effectually guard against instability, is well within the grasp of the naval architect. In such vessels the loading is mainly of a permanent character, while that part of it which is subject to variation, such as coals, stores, ammunition, &c., varies in a manner which can be readily taken into account in the calculations. Curves of stability that are constructed for war ships for three leading conditions, viz. (1) the fully-laden condition; (2) the same, but with all the coals consumed; and (3) the light condition with all coals, ammunition, and consumable stores expended, are usually sufficient to enable full instructions to be framed for the prevention of instability. In some war ships there are other critical conditions which may require consideration, such as the possible injury and laying open to the sea, of compartments not protected by armour; but in all these cases the conditions are comparatively fixed, and may be allowed for in the calculations. When curves of stability have once been constructed for a war ship to represent the various critical conditions to which she may be subjected, they are always applicable, and may be relied upon to furnish, at any time, a safe guide to her stability.

In the case of mercantile steamers, however, except such as carry no appreciable weight of cargo, the problem of how to apply the results of stability calculations to the guidance of those who have to work and stow them is of an entirely different character. The naval architect cannot control, or even estimate, the amounts and positions of centre of gravity of the various items of weight that make up the loading to anything like the same degree of certainty as in war ships. There are many steamers afloat in which the cargo is nearly or quite twice the total weight of the vessel, together with her machinery and equipment. In such cases the naval architect can only control in the design about one-third of the total weight of the vessel and her cargo, leaving the remaining two-thirds in the hands of the owner, master, or stevedore. It is obvious, therefore, that whatever may be the qualities of the empty vessel in respect of stability, these may be greatly modified or entirely altered by the manner in which she is loaded. It is the loading to which we must look in the large proportion of cargo-carrying steamers for the due preservation of such stability as is necessary for safety at sea.

It is in this direction also that we have to look for the cause of a great many of those losses which have occurred at sea during recent years, and to which attention was first prominently called by Mr. B. Martell, the Chief Surveyor of Lloyd's Register Society, in a paper read before this Institution in 1880 upon the causes of unseaworthiness in merchant steamers. Mr. Martell attributed, and quite rightly so, a great many of the losses of steamers to instability; and there can be no doubt that this cause of loss still continues to operate very largely. The evidence given at Board of Trade inquiries in cases of missing steamers is constantly pointing to instability as the cause of loss, although the full meaning and weight of the evidence may not always be fully and accurately appreciated at these inquiries. It often diverts attention from the main cause of loss to say that it occurred because the ship was unstable. The fact is, that the ship has frequently so little to do with the matter, and the stowage so much, that it is the latter which should be blamed for the instability, and not the ship herself. When a ship is built for a particular trade and for the purpose of carrying certain specific cargoes she may then, of course, be so designed as to be quite stable, in all conditions, while thus employed; but when vessels are built, as they often are, to dimensions fixed by owners, for general trading purposes, it is seldom possible for the designer to provide against instability arising in some possible or conceivable circumstances of loading. The due preservation of stability in such cases requires to be watched and provided for by those who control the loading.

It is erroneous to suppose, as appears to be sometimes done, that a cargo-carrying steamer should be so constructed and proportioned as to run no risk of becoming unstable, however she may be laden. If this idea were acted upon, such a mode of preventing instability, however easy and plausible it may at first sight appear to be, would only defeat the desired object of promoting safety at sea, because it would make many vessels dangerously stiff when laden with some classes of cargo. The true and reasonable mode of procedure is not to attempt to construct a ship so that she will be stable however she may be laden, but to see that any tendency she may have towards instability—if any such exist—is understood by those in charge of her, and that she is always laden with careful reference to it. There are no steamers afloat, whatever tendency they may have towards instability as sometimes laden, that they may not be kept perfectly safe if treated with full knowledge of what their stability is, and the stowage regulated accordingly. One great problem that the mercantile naval architect has just now to solve is, how any dangerous features of a ship's stability are to be made clearly known to those in charge of her, and in what manner they can be best taught to regulate the loading in cases where special care may be required.

It is sometimes supposed that owners and masters are not only negligent, but indifferent in this matter; and that they deliberately refrain from any consideration of it. It has been stated that there are no owners who avail themselves of the knowledge of stability now readily obtainable as a guide in the stowage and safe working of their ships. These are views which my experience does not enable me to indorse. I have found, on the contrary, that many of our leading owners of passenger and cargo steamers are extremely anxious about the matter; and not only anxious, but they adopt all means that lie within their power of dealing practically with it. The great stumbling-block they usually meet with, however, is the intrinsic difficulty of the subject.

Owners and masters have their own modes of thought and their own practical methods of ascertaining and regulating the stability of their ships, which are often quite sufficient for the purpose. They can very well comprehend whether a vessel will stand up when light without ballast, and, if not, how much it will require to make her do so. They can also understand if she is too stiff when laden with heavy dead-weight cargoes placed low down in the hold: or if she becomes unduly tender when laden with light cargoes of which more than a certain quantity is placed in the 'tween decks. They have not, however, had the technical training and experience which is requisite to enable them to understand and deal with metacentres, centres of gravity, and curves of stability; and to make all those allowances for constant variations in draught of water and position of centre of gravity which the different cargoes they carry render necessary. Some owners have recently obtained curves of metacentres and curves of stability for their ships, constructed for certain draughts of water and descriptions of cargo. These curves, as a rule, are put to no real practical use by them, as they find themselves unable to apply stability information in this highly specialised form to the accurate and reliable treatment of the various questions that arise in loading, or to compare it with the results of their own judgment and experience.

The above course has lately been taken in many cases because of the opinions which have been expressed that the way to prevent ships being lost through want of stability is to supply the masters with particulars of the metacentric height and a curve or curves of stability. The Wreck Commissioner advocates this course, and appears to entertain no doubt as to its desirability and practical efficacy. His object is a most praiseworthy one, but I do not believe it to be possible to carry it out in the way he suggests. The advice he gives is based upon the belief that shipmasters and others who have to do with the loading of ships can readily be made to understand what curves of stability represent, and to use them correctly in practice. I have during the last two or three years frequently tried to carry out this view, but have never yet met with a shipmaster—and I have had to do with some of the most capable and intelligent of the class—who could be got to understand curves of stability sufficiently well to be trusted to work with them in practice, or who would even profess that he could do so.

If mercantile steamers could always be loaded in a uniform manner, it might be possible to represent their stability in all conditions with sufficient accuracy and completeness for all working requirements by means of a curve or curves; but as regards the vast bulk of merchant shipping there are no curves of stability which could possibly be constructed, except that for the absolutely light condition, which would be likely to represent the actual stability of the ship except on a very few occasions during the whole of her career. The only use to which any curves of stability that might be furnished could, as a rule, be put is to furnish data for enabling the stability under different conditions from those for which they were constructed to be estimated. This is an operation which masters of ships cannot perform, and which would only be likely to confuse and mislead them if they were to attempt it.

The Wreck Commissioner laid great stress upon the use it would have been to the captain of the *Austral* at the time of the accident if he had been in possession of curves of stability and calculations which had been constructed for that condition, and laid before the Court. It does not appear to have been seen that, whatever particulars of calculations and curves of stability had been supplied to the captain, he could not by any possibility have had those which related to the condition of the ship at or somewhat prior to the time in question. Her stability on that occasion was determined by the amount of weight she happened to have in her, and the position of its centre of gravity; and this was the result of a chance state of things which only existed at that precise moment, and which may hardly occur again during the existence of the ship. If we assume that this information would have taught the captain more about her stiffness than he already knew through his previous experience of the vessel, still it could not have been supplied to him beforehand by any one. All that could have been done was to supply him with particulars of the stability at other draughts and with other positions of the centre of gravity, leaving it to him to estimate from these what it would be at the time in question if he thought it desirable to do so.

I need hardly say again that the operation of constructing curves of stability for a particular draught of water, and position of centre of gravity from the results of calculations made in the usual way for certain other draughts of water and positions of centre of gravity, is an operation which requires a well-trained naval architect to perform. No one knowing the subject can suppose that masters of vessels have had either the training or the experience to qualify them for performing such an operation, or can help fearing that the result of their attempting it might be misleading. As I have already said, I have never been able to discover a shipmaster who could be safely trusted to do it, or who cared for it to be supposed that he could. It is hopeless, at present, to expect either shipowners or shipmasters to use metacentric heights and curves of stability as a practical guide in stowage; and it is necessary to put stability information before them in a simpler form, and one which fits in better with their own ideas and modes of procedure, if it is to be utilised in furnishing any real guide towards safety in loading. It is quite unnecessary for us to require such persons to become specialists in the science of naval architecture before applying the results of scientific calculations to safeguarding the stability of their ships. I have myself been obliged to give up all attempts to deal satisfactorily with the question by supplying curves of stability and other information of that class.

The method which I have adopted is the following, and I now lay it before the Institution, chiefly for the purpose of eliciting opinions upon the subject, and as a suggestion to others who may be working in the same direction and have experienced similar difficulties with myself. In advising upon how a steamer should be treated and loaded so as to be kept safe in respect of stability, I state (1) the quantity of ballast, if any, that is required to enable her to stand up when quite empty, without water in boilers or tanks, coal in bunkers, and with a clean-swept hold, and to be stiff enough for all working requirements in dock or river; (2) if she is to be employed in carrying homogeneous cargoes, what proportion of the space in the 'tween decks it is safe to fill with such cargo, after the holds are full, and what weight of ballast is required in the bottom to enable the vessel to be loaded to her maximum draught with such cargo; (3) if required to carry two or more kinds of homogeneous cargo, such as grain and cotton, grain and wool, grain, meat, and wool, &c., the best mode of stowage, and whether or not the space in the 'tween decks can be filled with the lightest of the cargoes, and in what circumstances ballast, and how much of it, will be required; (4) if not intended for homogeneous cargoes, but for general cargoes, or partly homogeneous and partly general, the average densities of the general goods for various ports is arrived at after a little experience, and the same system adopted. The main point is, to state what space, if any, must be left unfilled in the 'tween deck cargo spaces, with the different descriptions of cargo, and what ballast, if any, is necessary if the vessel is to be loaded to her maximum draught; (5) if the consumption of the coal diminishes the stability materially, as is often the case in some classes of steamers, to call prominent attention to this fact, in order that the captain may not be misled by finding his ship appear to be rather stiff on commencing a voyage. The possible consumption of coal is, of course, taken into account in fixing upon the limits that should be imposed upon the stowage in all the conditions named; and (6) if there appear to be any circumstances in which a tendency towards instability may arise they are described, and suitable precautions suggested. I believe that Lloyd's Register Society, in fixing a load-line for vessels that may in some conditions be laden so as to have insufficient stability, describe the stowage that is requisite for safety in somewhat similar terms to the above.

General particulars, such as these, respecting the character of a ship's stability in different conditions, may be made to convey all the information that is necessary for the effective prevention of instability, and I find that they are appreciated by owners and masters, and actually used as a guide in the loading of ships. They may be made to fully define all the essential points upon which stability depends, and are expressed in a form and language that is understood by those who have to use them. This is shown by the fact that telegrams are sometimes received from foreign ports respecting ships which are to be laden with cargoes somewhat different from those to which the specific instructions apply, describing the cargoes that are to be carried, and asking whether any different arrangement of ballast or proportion of weight in the 'tween decks from what has been prescribed for some other cargo is necessary. Such inquiries show that intelligent use is being made of the information supplied, and that it is being utilised for practical guidance in loading.

One of the main reasons why it is better to give information in this simple form is that it obviously fits in with a shipmaster's own practical modes of thought and ideas respecting stability. It is a mistake to suppose, because owners and masters cannot express their views respecting the stability of ships in scientific language, that they therefore have no views that are worth anything. The fact is, that the masters of ships very often have quite correct ideas respecting the stability of their vessels and how to load them. If they see a vessel quite empty in dock, and observe the effect of moving weights in and out when light, they often acquire as much knowledge of her stability in the light condition as is requisite for all purposes of safety and efficient working. They also, by means of experience obtained in loading, frequently get to know as much about the stability of certain classes of vessels in the laden condition as is necessary for practical purposes, and certainly for all purposes of safety. Whether sufficient knowledge can be gained in this way or not for all possible requirements depends largely upon the type and peculiarities of a vessel. As a rule, it is all that is applied to the purpose, and there can be no doubt that in many cases it may be sufficient. It is in vessels which contain elements of danger that cannot be discovered in this practical manner that a different and more scientific mode of treatment becomes requisite.

The proper use of stability calculations is not to supersede or interfere with that knowledge of a vessel's qualities which may be gained by experience but to supplement and complete it in certain cases where it may be necessary. As an illustration I may refer to the small range of stability sometimes found to be possessed by deep vessels of low freeboard. The discovery of the dangers to which such ships are liable may perhaps be successfully made in some instances by simply observing their behaviour at sea; but probably it is more often made only when the ship capsizes. Then, again, many ships become unstable at sea through the consumption of their bunker coal, particularly when a large portion of such coal is carried, as it sometimes is, in a reserve bunker under the lower deck. There are cases in which the metacentric heights of cargo-carrying steamers are reduced by 1½ feet by the mere consumption of the bunker coal. In such cases instability may very readily arise at sea in a manner of which the captain is unable to form any accurate conception when merely judging by the results of his own experience. This is particularly likely to be the case when alterations are made in bunkers, or when portions of the hold are added as reserve bunkers for enabling voyages of longer duration to be made than have previously been contemplated. I certainly believe, as the result of an examination of the stability of many mercantile steamers, that a great number of vessels are lost at sea from each of these causes, viz. through capsizing on account of low freeboard and consequent small range of stability, and also through loss of stability by reason of the consumption of coal. In both of these classes of cases the danger is aggravated if the ships are flush-decked, without any or with but small water-tight erections above the upper deck.

It is very difficult to make a complete analysis of the various causes of loss at sea, and to show conclusively what is the relative mortality of vessels of various types and different descriptions of cargo. The difficulty is due to the fact that the Board of Trade returns are not compiled in a manner which enables all the necessary information to be extracted from them. So far as it is possible to judge, however, by the particulars available, it appears that the types of steamers that are least subject to mysterious losses at sea are those which have long ranges of water-tight erections on deck, and are therefore least liable to become unstable. I believe that the comparative immunity against loss which appears to be possessed by many efficiently built and protected "well-deck" steamers, is largely due not only to their comparatively low centre of gravity of cargo, but to the righting power furnished at large angles of inclination by their extensive deck erections. This is undoubtedly the case, notwithstanding the fact that seas may break into the well, and often fill it with water. It may be somewhat startling to persons familiar with the loading of flush-decked steamers, to find many well-decked vessels making voyages across the Atlantic with portions of their decks so near to the water as they sometimes carry them; but a little examination suffices to show that the fact of the water entering a properly constructed and fitted and moderately sized well cannot do much to endanger the safety of the ship. Any effect it may have upon the stability is only at small angles of inclination.

In order to show how small is the effect of water in the well of an ordinary first-class steamer of this type upon her stability, I have given two curves of stability in Fig. 1 for such a vessel. That marked P is for the condition of no water being in the well till the vessel is inclined sufficiently for the edge of the deck to become immersed, and that marked Q for the condition of the well being filled with water before the inclination commences. Mr. Martell was good enough to have these curves calculated for me, in order that I might have them in time for the reading of this paper. They are for a raised quarter-deck vessel 257 feet by 35 feet 6 inches by 18 feet 6 inches, with a well 60 feet in length, and bulwarks over 5 feet high; the freeboard amidships to the main deck being 2 feet 2 inches. Prior to the water entering the well the vessel is assumed to be at her usual trim of about a foot by the stern, and a correction is made for the change of trim caused by the filling of the well. No allowance is made for the quantity of water that would be thrown out of the well by the movements of the ship, but it is assumed to be possible to completely fill it with water to the height of the rail at the fore end of the bridge, and for no other way of escape to exist for the water but that of pouring over the rail as the vessel inclines. The freeing ports and scuppers are not assumed to have any effect in clearing the deck of water. The weight of water which the well will hold when the vessel is upright is 186 tons, but when she is inclined to 10° it will only hold 98 tons, and when inclined to 20° it becomes reduced to 28 tons. These figures and the curves in Fig. 1 show that water in the well of such a vessel cannot materially affect her stability after a small angle of inclination has been reached, and that so far as stability is concerned the well cannot be regarded as a serious element of danger.

A practical point of great importance in determining the amount of stability a ship should possess at sea is the minimum metacentric height that may be regarded as sufficient for safety. Different types of vessels have quite different characteristics in respect of stability. War ships, and some classes of merchant steamers, require large metacentric heights in order to insure sufficient righting moments at moderate angles of inclination, and a safe range of stability. The curves of stability given in Fig. 2 apply to such a case. Those curves belong to a typical three-decked steamer, without any water-tight deck erections, 280 feet by 34 feet 6 inches, by 24 feet 6 inches. The mean load draught is 22 feet 6 inches, and displacement 4400 tons; the freeboard being 5 feet 4 inches. The metacentric height is 6 inches for the curve A, and 1 foot for the curve B. It is obvious that, in judging of the safety of small metacentric height for such a vessel, the range of stability is an important factor to be considered. The range necessary for seaworthiness largely determines and often fixes the limit below which the metacentric height should not be reduced in such a type of vessel and in many others.

But there are very large numbers of steamers, such as passenger liners and cargo steamers, of the spar and awning-deck classes, which generally have very large ranges of stability, and large righting moments at great angles of inclination, whatever the metacentric height may be; and in many cases, even with no metacentric height at all. In such cases the minimum metacentric height which is essential to safety and efficiency has to be determined by entirely different considerations from those which apply to war ships, and those classes of mercantile steamers whose stability is of the character shown by the curves in Fig. 2. When we have to deal with vessels which even with no metacentric height will return to the upright, provided water does not get into the ship, and no large weights shift, whatever angle of inclination may be reached, the conditions of the problem are entirely changed. The principal object which then has to be considered is to prevent too easy an inclination from the upright by the action of the wind and other forces which may operate upon her; and the question mainly turns upon what may fairly be considered sufficient for this purpose.

Fig. 1.

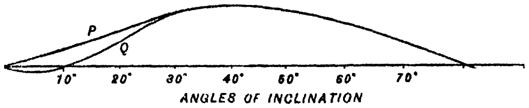

Fig. 2.

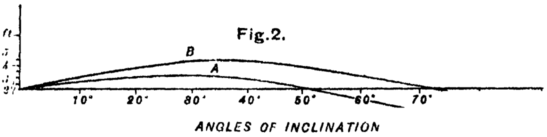

Fig. 3.

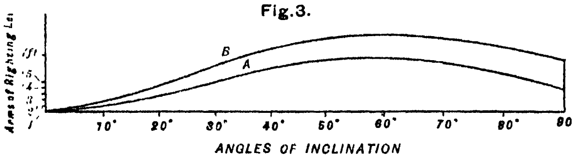

Fig. 4.

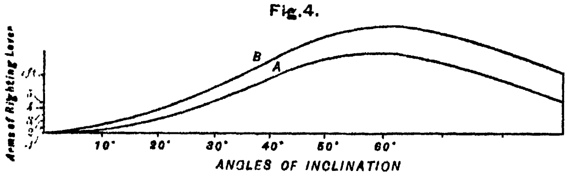

Many persons have been surprised on first learning how little metacentric height many high-sided mercantile steamers are in the habit of working with in safety. There are many steamers of the spar and awning-deck classes employed in carrying homogeneous cargoes, which have been performing their work for years, not only with perfect safety but without showing any signs of what nautical men call tenderness, the metacentric heights of which, during certain periods of their voyages, are frequently not more than 8 inches or even 6 inches. The latter figure may probably be regarded as about the minimum which such vessels approach without indicating to those on board that they are becoming unduly tender: but it is quite certain that many never show any such signs, and appear to be perfectly safe with 8 inches of metacentric height.

Vessels of this class have curves of stability of which those shown in Figs. 3 and 4 are types. The curves in Fig. 3 are for a spar-decked steamer 318 feet by 40 feet by 22 feet. The load draught is 23 feet 6 inches, and displacement 5760 tons; the freeboard being 8 feet 6 inches. Those in Fig. 4 are also for a spar-decked steamer 220 feet by 30 feet by 23 feet. The load draught is 16 feet, and displacement 2000 tons; the freeboard being 8 feet 6 inches. The curves marked A in each of these figures are constructed for 6 inches of metacentric height, and those marked B for 1 foot, in order that they may be compared with the corresponding curves in Fig. 2. The metacentric height of 6 inches is about what each of these vessels would have if laden to the draughts named with homogeneous cargoes, such as they frequently carry; and the metacentric heights of 1 foot are obtained by leaving a portion of such cargo out of the 'tween decks, and replacing it by an equal weight of ballast in the bottom.

It will be seen that the increase of righting moment in Figs. 3 and 4 continues up to a very large angle of inclination. This increase of righting moment tends to prevent dangerous inclinations being reached, while the smallness of the metacentric height causes such vessels to be very easy and comfortable in a seaway. Some steamers whose stability is of this character are vessels which carry cargoes liable to shift, such as grain or coals, and it may be thought that with cargoes of this class a small metacentric height is particularly unsafe, and that considerable initial stiffness is necessary to prevent any danger arising through shifting of cargo. Any opinions that may be formed upon this point are necessarily more or less speculative, as we have but little exact information to go by; but it should be borne in mind, in considering the question of initial stiffness in connection with shifting cargoes, that, although such stiffness increases the resistance to inclination, it increases at the same time the tendency to roll, and to displace or shift the cargo.

The question of the minimum metacentric height which may be regarded as consistent with safety in those types of ships where it is not governed in any degree by the necessity of providing range of stability, as shown by Figs. 3 and 4, is a subject which has never been much discussed, and which, on account of its important and immediate bearing upon the safety of many vessels at sea, is, in my opinion, deserving of the consideration of this Institution. If any of the remarks contained in this paper should serve to elicit opinions, information, or facts bearing upon the subject, my purpose in making them will be answered.

I may add, in conclusion, that the following are the main points which I have desired to lay before the Institution in this paper:—(1) The form in which the results of stability calculations can be put before owners and masters of mercantile steamers, so as to be of the greatest practical use in loading such steamers, and regulating their stability in accordance with the requirements that may arise; (2) the fundamental difference which exists between the relation of righting moments at large angles of inclination and range of stability to metacentric height in the various types of steamers, as shown by Figs. 2, 3, and 4, such relation making it necessary to fix the minimum metacentric height that should be allowed with due regard to the righting moments at large angles of inclination in some cases and unnecessary to do so in others; and (3) the minimum metacentric height that may be regarded as consistent with safety in cases where range of stability and the righting moments at large angles of inclination are so ample as not to call for consideration. The two latter points are so intimately connected with the first that they naturally require to be considered along with it.

THE INSTITUTION OF NAVAL ARCHITECTS

THE Institution of Naval Architects held its twenty-fifth Session at the Rooms of the Society of Arts on April 2, 3, and 4, Lord Ravensworth in the chair. Whilst the papers read were of course mainly on technical questions of naval construction, equipment, &c., some of them possessed points of general scientific interest, of which a brief account may be given. The President's address dealt mainly with what may be called the economic side of the shipping industry, dwelling on such points as the Merchant Shipping Bill, the length of time occupied in building ships of war, the depression of the carrying trade, &c. Passing on to the papers contributed, the first read was by Mr. J. D. Samuda on the *Riachuelo*, a steel armour-clad twin screw turret-ship of 6000 tons displacement, and 6000 horse-power, lately built by his firm for the Brazilian Government.

The second paper, by Mr. A. F. Yarrow, was on an Electrical Launch tried last year both on the Thames and on the Danube, and already mentioned in these columns. It dealt with the question from a practical and not an electrical point of view, and is so far valuable as presenting a fresh aspect of the question. On the whole the author's conclusions are satisfactory. He considers that there is even now a field for electrical launches in cases where the conditions are favourable, such as having a supply of cheap motive power for recharging the batteries; and that they are pre-eminently adapted for torpedo boats, owing to their being always ready for action, and their complete noiselessness when in motion. On the whole the advantages and disadvantages as compared with the steam-launch are summed up by Mr. Yarrow as follows, beginning with the former :—

1. Entire absence of noise.
2. Great cleanliness.
3. The whole of the boat is available for passenger accommodation, the midship or best part of it not being occupied by machinery.
4. When once charged it is ready for use at a moment's notice.

The points against it are :—

1. Difficulty and delay from frequent charging.
2. Greater first cost.
3. Greater cost of working in those cases where an engine has specially to be laid down for the purpose of charging.

The third paper read was on the Vibration of Steam-vessels, by Mr. Otto Schlick, which dealt with the shaking so well known to passengers on screw steamers from the practical and theoretical point of view. It is shown clearly that the phenomenon is merely due to the fact that the ship, considered as an iron girder, has one or more fixed periods of vibration depending on her length, her width, and other dimensions. With regard to the practical means of overcoming such vibrations, it is pointed out that anything which causes the engine to run at a different speed, for instance, the putting in of a new propeller, will probably have a favourable effect. The shifting of the screw to a different angle with regard to the cranks is recommended as often giving a good result, inasmuch as two of the forces causing the vibration may be balanced one against the other. An ingenious apparatus for measuring such vibrations is described by the author.

The morning of April 3 was occupied during the whole period of five hours by the reading and discussion of three papers on the burning question of Stability. One of these, on the Use of Stability Calculations in Regulating the Loading of Steamers, by Prof. Elgar, we print at length. Another, on Cross Curves of Stability, was read by Mr. W. Denny, the well-known shipbuilder of Dumbarton. He observes that stability curves are required for at least four draughts of any steamer, viz. the launching condition, the condition completely finished, but without any cargo, coals, &c., on board, the fully loaded condition, and the condition with the coals consumed. If the stability curve be also calculated for an intermediate draught between the second and third of these, five points will be obtained at each angle, by means of which a cross curve of stability can be produced. It is therefore of great importance to work out such cross curves and to find a method by which they can be readily constructed from the ordinary curves of stability. A method for doing this with the assistance of Amsler's Integrator has been devised, and when drawn the curves are also represented by means of a solid model. These cross curves are each for a given angle, and have the length of the righting arm varying with the draught or displacement. With such cross curves in number sufficient to cover angles at intervals of 10°, 15°, and 20°, and each ranging through all the draughts from the launched to the loaded condition, ordinary curves at any draught and with any height of centre of gravity can be easily obtained, and with great rapidity. The method employed is fully described, as is also another method due to Mr. Couwenberg. Tables are also given showing the results obtained for the same steamer by the two methods, which, though worked out separately, were found to agree very closely.

The third paper was on a New Method for Calculating the Stability of Ships, by M. Daymond. This is an elaborate paper of a theoretical character, illustrated with numerous diagrams. It gives the history of the means adopted for calculating stability, especially the method invented by M. Ferranti. The author's own method is an improvement on this. Having made for various ships numerous drawings which showed on the vertical section of the ship, in length and in direction, the arms of the righting levers, for various draughts and inclinations, he conceived the idea of joining by continuous lines the extremities of these arms corresponding to the same angle of inclination. Taking such angles at intervals of 10°, he thus obtains a curve which he calls the "pantocarène isocline," and from these curves he obtains at once with complete accuracy and for all possible cases the usual curves of statical stability. The paper gives the principal properties of these curves, together with the mode of their calculation and various examples of working. The paper had been translated by Sir E. J. Reed, who may therefore be considered to have lent his authority to the value of the method proposed. The discussion on these papers turned mainly on unimportant and to some extent personal questions, and, though animated, does not need production here.

On Thursday evening, April 3, the most important paper was one by Mr. James Howden on Combustion of Fuel in Furnaces and Steam Boilers by Natural Draught and by Supply of Air under Pressure. The object of it was to describe a new boiler on which the author was experimenting, and which, if his account be correct, is likely to realise very important advantages in the way of economy of fuel. The experiments are not concluded, but the author considers them to justify him in claiming a most extraordinary economy as compared with ordinary marine boilers. Taking the instance of the Oregon, the latest-built of the swift Atlantic liners, he professes that the coal consumption might be reduced from 31,000 to 19,000 lbs. per hour, with an equal supply of steam and with a diminution in the fire-grate surface from 1512 to only 641 square feet. In the discussion which ensued very grave doubts were expressed as to the reality of such a saving, and it would probably have been more wise if the author had completed his experiments before claiming so very large a step in advance.

The next paper, by Mr. A. B. Broun, on the Application of Hydraulic Machinery to the Loading, &c., of Steamships, gave an interesting account of a complete hydraulic system applied to all the work required in an ordinary vessel, but did not raise any theoretical questions. A paper was then read by Mr. J. F. Hall, on Cast Steel as a Material for Crank Shafts. The author, who belongs to the well known firm of Messrs. Jessop of Sheffield, advocated the making of these important parts of a ship by the ordinary method of casting steel, without any subsequent hammering or working. His view is that such hammering can never reach the centre of a large mass of steel, such as an ingot; and that even if it did it would not completely weld up and remove the cavities which are not infrequently found in that region. In fact his view was that forging actually did harm by consolidating the outer layers and preventing them from contracting subsequently, as the hotter interior shrank in its cooling. By using ordinary methods of casting, and taking care to have a sufficient head or column of metal standing up above the casting itself, he considered that all fear of cavities within the latter was removed. Any unsoundness would be found only within the column, which would of course be cut off when the casting was cool.

The remaining papers, read on Friday, will not require any extended notice. That of Mr. P. Jenkins, on the Construction of Metacentric Diagrams, was a theoretical paper, dealing with the problem of stability, and chiefly devoted to establishing the following theorem:—"For any position of the centre of gravity the initial righting moment is either a maximum or a minimum when the water plane is so placed that the centre of curvature of the curve of flotation is at the same height in the vessel as the centre of gravity." Another contribution to the same problem, that of stability, was read by Mr. S. Benjamin, and described a model or apparatus enabling a shipowner to determine the position of the centre of gravity of his vessel for any loading before she is loaded, and also the alteration of its position due to any subsequent change in the loading. Yet another paper, by Dr. A. Amsler, described the application of the integrating apparatus which bears that name to such calculations as those of the curves already mentioned in Mr. Denny's paper. Mr. J. E. Spence described a form of diagram exhibiting in a simple shape all the data depending on the form of a ship which are required for determining her stability, and also a simple and direct method of graphic calculation for attaining these data. Mr. Thomas Phillips read a paper on the comparative safety of the particular class of vessels known as "well-decked" steamers. These were formerly treated with some suspicion by underwriters, but great improvements have lately been made, some of which were described in the paper, and with these the vessel appears to be even safer than what are called "flush" ships. Lastly, Mr. A. Taylor described a special instrument invented by him, and called a Stability Indicator, for determining the initial stability and stowage of ships at any displacement.

Mr. H. H. West read a paper on the Riveting of Iron Ships, giving tables for calculating the plate and rivet area for double-riveting, treble-riveting, and quadruple-riveting. He referred to the researches of Sir Edward Reed, the Institution of Mechanical Engineers, and others, but did not mention the modification of treble-riveting proposed some years ago, and lately carried into effect by a firm in Holland. On this system, in the middle row of the three rows of rivets, the rivets are spaced only half the distance apart of the two outer rows, the result being to increase very largely the proportion of strength. Capt. Heathorn described an arrangement called by him a Water-brake, for stopping the way of a ship in cases of collision or otherwise; and finally, Mr. J. E. Liardet described an apparatus for indicating the position of a ship's helm.

On the whole the Institution is to be congratulated on the interest and importance of the papers provided for it, and still more on the vigour and ability with which they were discussed by the very eminent engineers and shipbuilders who thronged the rooms of the Society of Arts for the purpose.

SCIENTIFIC SERIALS

Bulletin de l'Académie R. de Belgique, January 5.—On the existence of a fourth species (*B. borealis*) of the genus Balænoptera in the North Atlantic and Arctic Oceans, by M. Guldberg.—On the action of chlorine on combinations of sulphur, and on organic oxysulphurets, third communication, by M. W. Spring.—Researches on spermatogenesis in the Selacians (*Scyllium catulus*, *Sc. canicula*, *Raja clavata*), the salamander and mammals, by Prof. A. Swaen.—Essays on the political history of the last three centuries, by M. Van Praet.—Biographical notice of the painter Michael Van Cocxyen of Mechlin, by M. Castan.

Atti della R. Accademia dei Lincei, January 20.—Letter from King Humbert announcing an additional annual grant of 400*l*. for the promotion of biological studies, to be distributed in prizes in any way the Academy may think fit.—Some philological remarks on the 104th Psalm, by Guidi Ignazio.—Notice of an unpublished work of Prince Federico Cesi, entitled "De Laserpiteo et Laserpitii pluvia," in the library of the Botanic Institute at Padua, by Prof. A. Favaro.—Note on the antiquities discovered at Ventimiglia, Montefiascone, Naples, Pompeii, and other parts of Italy during the month of December 1883, by S. Fiorelli.

February 3 and 4.—Notice of some unpublished writings of Galileo Galilei in the National Library of Florence, by Prof. Favaro.—Report on Prof. Bellonci's work "On the Segmentation of the Egg of the Axolotl," by S. Trinchese.—Report on Dr. G. Frattini's work "On Some Propositions in the Theory of Substitutions," by S. Battaglini.—Report on Dr. L. Macchiati's work on the chemical nature of chlorophyll, by S. Cannizzaro.—Observations of the solar spots and faculæ made at the Observatory of the Collegio Romano during the year 1883, by Pietro Tacchini.—On the temperature corresponding to the Glacial period, third note, by Pietro Blaserna.—On the extraordinary crepuscular phenomena observed during the last few months, by Lorenzo Respighi.—Contributions to the study of the carbopyrolic acid α, by G. L. Ciamician and Paolo Silber.—Remarks on the Veronese Chelonian (*Protosphargis veronensis*) discovered in 1852 in the Upper Chalk near St. Anna di Alfaedo in Valpolicella, by Giovanni Capellini.—Geological observations on the islands of the Tuscan Archipelago, by B. Lotti.—Reports on the competition for the Royal Prizes for Physics, History, and Geography for the year 1882, by Signors Cantoni and Villari.—Reports on the Ministerial prizes for the Philosophical, Social, and Natural Sciences for the year 1883, by Signors Bonatelli and Trinchese.

February 17.—Obituary notices of the late Pietro Canal and Edoardo Laboulaye, Members of the Academy, by the President.—On the practice of burying human bones stripped of the flesh in Neolithic times, by Luigi Pigorini.—Note on the antiquities discovered at Felonica, Este, Imola, and in other parts of Italy during the month of January 1884.—Remarks on some codices in the Angelica Library connected with patristic theology, by Enrico Narducci.—Note on the parabolic orbit of the comet (*e*) discovered by Hartwig at Strasburg on August 24, 1879, by E. Millosevich.—On a remarkable disposition of the isogonic lines of terrestrial magnetism observed in the eastern districts of the Valley of the Po (two illustrations), by Ciro Chistoni.

Rivista Scientifico-Industriale, February 15 and 29.—Description of a new apparatus for the measurement of electro-motor forces (four illustrations), by E. Reynier.—Mathematical demonstration and value of the angle of least deviation described by a ray of light in its passage through a prism (one illustration), by Giuseppe Vanni.—Practical determination of the metallic resistance and chemical reaction of an electrolytic circuit, by Eugenio Marchese.—On the causes of the remarkable after-glows witnessed in Italy and elsewhere in 1883-84, by Prof. Carlo Marangoni. The author compares these phenomena with others of an analogous character observed in various parts of Europe in the year 1869. On several grounds he infers that the pink and red glows could not have been produced by moisture disseminated in the atmosphere in the solid, liquid, or gaseous state. He concludes that they are due to the presence of dust or minute particles of sand, which absorb the coloured rays in the central region of the solar spectrum while transmitting the extreme colours—that is, red and violet. The paper, which is to be continued, offers no suggestion as to the possible origin of the particles of dust to which the phenomena are attributed.—Note on the extinct and living mollusks of the Gardone district, by Prof. Strobel.—On the fossil insects of the Carboniferous schists of Commentry, by S. Brongniart.—Note on the limits of diatomaceous vegetation in marine basins, by Count A. F. Castracane.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 27.—"On the Electro-chemical Equivalent of Silver, and on the Absolute Electromotive Force of Clark Cells." By Lord Rayleigh, D.C.L., F.R.S.

The investigations upon this subject which have been carried on by Mrs. Sidgwick and myself during the last year and a half, though not yet quite finished, are so far advanced that no doubt remains as to the general character of the results; and as these results have application in the daily work of practical electricians, it is thought desirable to communicate them without further delay.

The currents are measured by balancing the attraction and repulsion of coaxal coils against known weights, as described before the British Association in 1882, a method which has fully answered the favourable expectations then expressed. To what was said on that occasion it will be sufficient for the present to add that the readings are taken by *reversal* of the current in the fixed coils, and the difference of weights thus found (about 1 grm.) represents the double force of attraction free from errors depending upon the connections of the suspended coil, and other sources of disturbance.

The difficulties which have been experienced, and which have been the cause of so much delay, have related entirely to the behaviour of the silver voltameters, of which never less than two, and sometimes as many as five, have been included in the circuit of the measured current. In order to render the deposit more compact, and thus to diminish the danger of loss in the subsequent manipulations, *acetate* of silver was added in the earlier experiments to the standard solution of nitrate. Experience, however, has shown that the principal risk is not in the loss of metal, but in the obstinate retention of salt within the fine pores of the deposit, leading to an over-estimate of the amount. When the texture is very compact, this danger increases, and deposits from a solution containing acetate are often decidedly too heavy, even after the most careful and protracted washings. On heating to low redness a portion, at any rate, of the retained salt is decomposed NO_2 is driven off, and a loss of weight ensues. With pure nitrate, to which we finally recurred, the risk is much less.

The actual weights of deposited silver were usually from 2 to 3 grms., and, so far as the mere weighings are concerned, should have been correct to 1/10,000. Discrepancies three or four times as great as this are, however, actually met with, whether due to retention of salt or to loss of metal it is difficult to say. The final number, expressing in C.G.S. measure the electro-chemical equivalent of silver, is a little lower than that (1·119 × 10^{-2}) given on a previous occasion (*Cambridge Proceedings* for November 26, 1883). It approximates closely to 1·118 × 10^{-2}, and is thus in precise agreement with the number announced within the last few weeks by Kohlrausch, viz. 1·1183 × 10^{-2}. Its substantial correctness can therefore hardly be doubted, more especially as it does not differ very much from the number (1·124) obtained by Mascart. In terms of practical units, we may say that the ampere current deposits per hour 4·025 grms. of silver.

When we are provided with means for the absolute measurement of currents, the determination of electromotive force is a very simple matter if we assume a knowledge of absolute resistance. A galvanic cell is balanced against the known difference of potentials generated by a known current in traversing a known resistance. The difficulty relates entirely to the preparation and definition of the standard cells. A considerable number of Clark cells have been set up and tested at intervals during the last six months, and their behaviour has been satisfactory, the extreme range after the first ten days) not much exceeding 1/1000. A modified form of cell, in which the solid zinc is replaced by an amalgam, is at present under trial.

In Mr. Latimer Clark's own determination the B.A. unit is assumed to be correct, and the E.M.F. of the cell at 15° C. was found to be 1·457 volt. *On the same assumption* we obtain the not greatly differing value 1·453 volt. If we take the true value of the B.A. unit as ·9867 ohm, 1·453 will be replaced by 1·434.

Experiments are also in progress to determine in absolute measure the rotation of the plane of polarisation of light in bisulphide of carbon under the action of magnetic force. Of the results obtained by Gordon and Becquerel, differing by about 9 per cent., our preliminary measurements tend rather to confirm the former.

Mathematical Society, April 3.—Prof. Henrici, F.R.S., president, in the chair.—The Rev. A. C. E. Blomfield was admitted into the Society.—The following communications were made:—On double algebra, by Prof. Cayley, F.R.S.—On the homogeneous and other forms of equation of a plane section of a surface, by J. J. Walker, F.R.S.—A direct investigation of the complete primitive of the equation $F(x, y, z, p, q) = 0$, with a way of remembering the auxiliary system, by J. W. Russell.—On electrical oscillations and the effects produced by the motion of an electrified sphere, by J. J. Thomson.

Chemical Society, March 31.—Anniversary Meeting.—Dr. W. H. Perkin, F.R.S., president, in the chair.—The President read his annual address. The number of Fellows is at present 1324. During the past twelve months the Society has lost by death nineteen Fellows, including Sir C. W. Siemens, Messrs. W. Spottiswoode, J. T. Way, and J. Young. After briefly alluding to the more important advances in chemical science, the president drew attention to the fact that the number of original papers read before the Society had steadily decreased since 1881, notwithstanding the steady increase in the number of Fellows, and the greater facilities for the study of chemistry now offered by the numerous laboratories recently opened. The Longstaff Medal was awarded to Mr. O'Sullivan. The following Officers and Council were elected:—President: Dr. W. H. Perkin, Ph.D., F.R.S.; Vice-Presidents: Sir F. A. Abel, Warren De La Rue, E. Frankland, J. H. Gilbert, J. H. Gladstone, A. W. Hofmann, W. Odling, Sir Lyon Playfair, H. E. Roscoe, A. W. Williamson, P. Griess, G. D. Liveing, E. Schunck, T. E. Thorpe, A. Voelcker, W. Weldon; Secretaries: H. E. Armstrong, J. Millar Thomson; Foreign Secretary: H. Müller; Treasurer: W. J. Russell; Members of Council: E. Atkinson, H. T. Brown, T. Carnelly, M. Carteighe, R. J. Friswell, W. R. E. Hodgkinson, D. Howard, F. R. Japp, R. Meldola, R. Messel, C. O'Sullivan, C. Schorlemmer.

Geological Society, March 22.—Prof. T. G. Bonney, F.R.S., president, in the chair.—The Rev. Frank Ballard, M.A., was proposed as a Fellow of the Society.—The following communications were read:—On *Rhytidosteus capensis*, Owen, a Labyrinthodont Amphibian from the Trias of the Cape of Good Hope, by Sir Richard Owen, K.C.B., F.R.S. The author first noticed the discovery of certain forms of Amphibia belonging to the genera *Labyrinthodon*, *Brachyops*, *Petrophryne*, and *Rhinosaurus*, and called attention to certain typical peculiarities in the structure of the teeth, the form of the bony palate, and the double occipital condyle. An imperfect cranium of the species now described as *Rhytidosteus capensis* was procured by Mr. Heer in the Orange Free State from the Trias of Swanopol, Beersheba, and deposited by him in the Bloemfontein Museum. This specimen, which was brought to England and submitted to the author by Dr. Exton, consists of the anterior portion of the skull with part of the mandible attached. The general form is batrachoid, and one of the hinder palato-vomerine teeth, on being examined microscopically, exhibited the characteristic labyrinthodont structure. The surface of the skull, and the characters of the premaxillary, nasal, frontal, and prefrontal bones were described. The parietals and postfrontals are imperfect, the hinder part being lost. The rami of the mandible are also imperfect behind, but a broken fragment shows the articular surface. The vomerine bones were also described, with the posterior nostril and the teeth before and behind this opening. The breadth of the bony palate at its hinder fractured border is 5 inches; the length of the part preserved 4¼ inches; the mandible, when perfect, was probably from 11 inches to a foot in length. The author also gave an account of the dentition wielded by the premaxillary, maxillary, vomerine, palatine, and mandibular bones. The author pointed out that the type of air-breathing vertebrates to which the present genus belongs reached its highest development in the Triassic period in Britain, Russia, North America, Hindostan, and South Africa. The only known antecedent form from which the labyrinthodont structure of tooth might have been derived is a genus of fishes named *Dendrodus*, in the Old Red Sandstone. The Liassic Ichthyosaurs also show some similarity in tooth-structure; but in them there is far greater simplicity.—On the occurrence of antelope-remains in Newer Pliocene beds in Britain, with the description of a new species, *Gazella anglica*, by E. Tulley Newton, F.G.S.—A comparative and critical revision of the Madreporaria of the White Lias of the Middle and Western Counties of England, and of those of the Conglomerate at the base of the South-Wales Lias, by Robert F. Tomes, F.G.S.

Zoological Society, April 1.—Prof. W. H. Flower, LL.D., F.R.S., president, in the chair.—Prof. Flower exhibited and made remarks on a series of skulls of the Bottle-nosed Whale (*Hyperoodon rostratus*), illustrating the various stages presented by this animal as regards the conformation of its skull in the different ages of both sexes. Prof. Flower also exhibited, on behalf of Messrs. Langton and Bicknell, a specimen of spermaceti obtained from the head of the *Hyperoodon*.—Mr. Sclater exhibited and made remarks on specimens of the eggs of two species of Testudinata (*Testudo elephantopus*, and *Chelys matamata*) recently laid by animals living in the Society's Gardens.—Mr. R. Bowdler Sharpe exhibited and made remarks on a Red-throated Pipit (*Anthus cervinus*) caught near Brighton in March last. Mr. Sharpe exhibited at the same time an example of the true Water-Pipit (*Anthus spinoletta*) captured at Lancing, in Sussex, in March 1877.—Prof. E. Ray Lankester, F.R.S., exhibited and made remarks on a large living Scorpion (*Buphus cyaneus*) from Ceylon.—A communication was read from Prof. T. Jeffrey Parker, being the first of a series of studies in New Zealand Ichthyology. The present paper gave a description of the skeleton of *Regalecus argenteus*. The species was founded on a specimen cast ashore at Moeraki, Otago, in June 1883.—A communication was read from Viscount Powerscourt, F.Z.S., containing an account of the origin and progress of the herd of Japanese Deer at Powerscourt.—A communication was read from Mr. G. A. Boulenger, giving the diagnoses of some new Reptiles and Batrachians from the Solomon Islands, collected and presented to the British Museum by Mr. H. B. Guppy, of H.M.S. *Lark*.—A communication was read from Mr. C. O. Waterhouse, containing an account of the coleopterous insects collected by Mr. H. O. Forbes in the Timor-Laut Islands.—Mr. F. D. Godman, F.R.S., read a paper containing an account of the Lepidoptera collected by the late Mr. W. A. Forbes on the banks of the Lower Niger, the Rhopalocera being described by Messrs. F. D. Godman and O. Salvin, and the Heterocera by Mr. H. Druce. The species of butterflies were fifty in number, and comprised representatives of all the families of Rhopalocera hitherto known from Tropical Africa, except the Erycinidæ, a

STOKES ON LIGHT

Burnett Lectures. On Light. First Course, On the Nature of Light. By G. G. Stokes. (London: Macmillan, 1884.)

BYRON once wrote about a work of art:—

> "What nature could, but would not, do,
> And beauty and Canova can."

A dozen, or more, years ago, the scientific world was excited by the announcement that a treatise on *Light* was to be published by Prof. Stokes, as a companion volume to Clerk-Maxwell's remarkable *Theory of Heat*. The announcement was, however, ultimately withdrawn. Nature could, but would not, do it.

But Beauty and Canova, in the form of a Conservative Government and its *Endowed Institutions* (*Scotland*) *Act* of six years ago, did it:—and we now have, as a result, the first of a series of three volumes by Prof. Stokes!

The Burnett foundation, now about a century old, was essentially of a Teleological character. It had been applied, in accordance with the Founder's will, at intervals of 40 years, to the award of prizes for Essays:—the competition being perfectly open. Those who know what Teleology was, half-a-century ago or more:—even at its very best, as in the once-celebrated *Bridgewater Treatises*:—will probably be of opinion that the Commissioners, under the Act referred to, did real good by their modification of the terms of the Burnett Endowment.

True:—it is still possible that the Trustees may some day appoint to the Burnett Lectureship a rabid Teleologist of the old school. Even this might be defended on the ground of even-handed justice; though an ill-informed, but zealous, champion of such a cause is probably more dangerous to it than is a declared enemy. But the appointment of Prof. Stokes, as the first holder of the new office, augurs well for the future. Beside his scientific qualifications, he is possessed of that calm, judicial, mind which is absolutely required in so delicate a position:—where, indeed, to say too little might involve the charge of luke-warmness, if not of positive unbelief; while to say too much would display that presumption which is usually characteristic of ignorance.

As the title of the work implies, the subject is the nature and extent of the present evidence in favour of the Undulatory Theory of Light. The reader is supposed to have an elementary acquaintance with the simpler facts of geometrical optics, nothing further. Hence the work is, in the true sense, a popular one; suited to any reader of average intelligence and information. The language is simple and, as far as possible, devoid of technicalities:—while it "goes without saying" that the author does not condescendingly patronise the assumed weakness of his reader, nor does he anywhere attempt to escape from a difficulty by the use of mysterious or indefinite expressions.

As the book will, undoubtedly, find its way into the hands of every one who desires to see an important and difficult subject brought by a Master to the level of the understanding of any ordinary reader, we will content ourselves with a few selections. These have been made on a very catholic principle, some to exhibit novelties of matter or treatment, some for their historical bearing, and one to show how the special difficulty of the Lecturer's position has, so far, been met.

First, we have the two rival theories of Light compared, with the chief arguments for and against each:—

"*Primâ facie* there is much to be said in favour of the theory of emission. It lends itself at once to the explanation of the rectilinear propagation of light, and the existence of rays and shadows. It falls in at once with the law of aberration. The laws of reflection and refraction admit of an easy explanation in accordance with it; at least if we accept the existence of both reflection and refraction; for according to this theory we should rather have expected beforehand that light would have been *either* reflected or refracted, according to circumstances, not that incident light should have been *divided* into a portion reflected and a portion refracted.

"The theory of undulations on the other hand presents at the outset considerable difficulties. In the first place it requires us to suppose that the interplanetary and interstellar spaces are not, strictly speaking, a vacuum but a plenum; that though destitute of *ponderable* matter they are filled with a substance of some kind, constituting what we call a *medium*, or vehicle of transmission of the supposed undulations. When I speak of this medium as a substance, or as material, I mean that it must possess that distinctive property of matter, inertia; that is to say, a finite time must be required to generate in a finite portion of it a finite velocity."

Then the special difficulty which made Newton abandon the wave-theory:—

"The necessity of assuming the existence of some kind of substance in what we commonly speak of as a vacuum, does not appear to have been a serious preliminary difficulty in the way of the reception of the theory of undulations. A far more formidable difficulty appeared at first to be presented by the existence of rays and shadows. It was this that led Newton to adopt the theory of emission, though even he was led in the course of his researches on light to suppose that there was some sort of medium through which the particles of light moved, and in which they were capable in certain cases of exciting a sort of undulation. But the supposition of particles darted forth seemed to him necessary to account for shadows."

How, mainly by the marvellous insight of Young, this difficulty has been, not merely got over but, converted into one of the strongest arguments in favour of the Undulatory Theory:—

"There is no difference of explanation as regards light and as regards sound, save what depends on the difference of scale entailed by the difference of wave-length. Take as regards light the case of a small circular hole, say the tenth of an inch in diameter, and of distances from the luminous point to the screen in which the hole is pierced, and from that again to the screen on which the light is received, of say 8 feet 4 inches, or 100 inches, each. In this case, regarding the luminous patch on the screen as a whole, there would be no great diffusion of light, but the phenomena of diffraction would nevertheless be fairly pronounced. There ought to be a corresponding case of diffraction for sound; but on what scale? Take 50 inches as the length of a wave of sound, which would correspond to a musical note of moderate pitch. Taking as before the 1/50000 part of an inch as the wave-length for light, the length of the wave of sound will be two-and-a-half million times as great as the wave-length of light. Consequently to obtain the corresponding case of diffraction for sound, our 'small' circular hole would be obliged to have a diameter of rather more than four miles, say four miles, and the distances from the source of sound to the hole through which it passes, and from that again to the place where the sound is listened to, would have to be 4000 miles each.

"It is remarkable that the existence of rays, which formed the great stumbling-block in the way of the early reception of the theory of undulations, is now shown to belong to a class of phenomena, those of diffraction, the complete and marvellously simple explanation of which afforded by the theory of undulations now forms one of the great strongholds of that theory."

In connection with the Lecture on the *Senses*, by Sir W. Thomson, which has recently appeared in NATURE (vol. xxix. pp. 438, 462) we may take the following passage. [At the same time it may be well to remark, in passing, that Sir W. Thomson omits altogether the Sense of *Rotation*, which seems to be fully established by the researches of Crum Brown, De Cyon, Flourens, Mach, &c. He also distinguishes between the Senses of Touch and of Heat, making the so-called Muscular Sense a case of the former; while it seems more probable that Touch and Heat are the same sense, and the Muscular sense an independent one.]

"As regards the mode of perception, while there are analogies between sound and light there are at the same time notable differences. In sound, the tympanum of the ear is thrown mechanically into vibration, and the nerves of hearing are mechanically affected, as a mechanical disturbance of a point on the surface of the body is made known by the sense of touch. But in light, just as we have seen reason to believe that it is the disturbance of the ultimate molecules, or of their constituent parts, by which the vibratory motion which constitutes light is in the first instance communicated from ponderable matter to the ether, so we have reason to think that when light is absorbed what takes place is that the disturbance of the ether is communicated, not to portions of matter regarded as forming portions of a continuous elastic body, but to the ultimate molecules of which matter consists, or to their constituent parts. It may be that temporary chemical changes are thereby produced in the ultimate filaments of the nerves of the retina, in which case the sense of sight would be more analogous to the sense of taste than to that of touch."

As a specimen of the firm, yet cautious, way in which the Lecturer meets the grand difficulty of his position, take the following :—

"In studying this subject, one can hardly fail to be struck with the combination of these two things :—the importance of the ends, the simplicity of the means. When I say the importance of the ends, I use a form of expression which is commonly employed as expressing design. And yet on that very account we must be on our guard against too narrow a view. When we consider the subject of vision in its entirety, the construction of the recipient organ as well as the properties of the external agent which affects it, the evidence of design is such, it seems to me, as must to most minds be irresistible. Yet if I may judge of other men's minds by my own, it is rather in the construction of the recipient organ than in the properties of the agent that affects it that the evidence of design is so strongly perceived. And the reason of this may be that we are here dealing with what more nearly resembles design as we know it in ourselves. Man takes the laws of matter as he finds them; the laws of cohesion, of the conversion of liquid into vapour, of the elasticity of gases and vapours, and so forth ; and in subserviency to those laws he constructs a machine, a steam-engine for instance, or whatever it may be ; but over the laws themselves he has absolutely no control. Now when we contemplate the structure of the eye we think of it as an organ performing its functions in subserviency to laws definitely laid down, relating to the agent that acts upon it, laws which are not to be interfered with. We can, it is true, go but a little way towards explaining how it is that through the intervention of the eye the external agent acts upon the mind. Still, there are *some* steps of the process which we *are* able to follow, and these are sufficient to impress us strongly with the idea of design. The eye is a highly specialised organ, admirably adapted for the important function which it fulfils, but, so far as we can see, of no other use ; and this very specialisation tends to make the evidence of design simpler and more apparent. But when we come to the properties of the external agent which affects the eye, we begin to get out of our depth. These more nearly resemble those ultimate laws of matter over which man has no control ; and to say that they were designed for certain important objects which we perceive to be accomplished in subserviency to them, seems to savour of presumption. It is but a limited insight that we can get into the system of nature ; and to take the very case of the luminiferous ether, while as its name implies it is all-important as regards vision, the present state of science enables us to say that it serves for one object of still more vital importance ; we seem to touch upon another ; and there may be others again of which we have no idea."

At the end of the work we are told that the two volumes, which are to follow this, are to deal with

II. *Researches in which Light has been used as a means of investigation*, and

III. *Light, considered in relation to its beneficial effects.*

The former of these we may hope to have in a year from the present time ; for the final volume we must wait a year longer. But in the meantime let us be thankful for the first instalment, which is a masterpiece of simplicity and strength ; and be grateful to the Commission, and the Trustees, to whom we are so very directly indebted for it. And, above all, let us lay to heart the valuable lesson which the Author has drawn from the story of the two rival theories of Light, and of their chief supporters, a lesson good for all time :—

"It may be said, If the former theory is nowadays exploded, why dwell on it at all ? Yet surely the subject is of more than purely historical interest. It teaches lessons for our future guidance in the pursuit of truth. It shows that we are not to expect to evolve the system of nature out of the depths of our inner consciousness, but to follow the painstaking inductive method of studying the phenomena presented to us, and be content gradually to learn new laws and properties of natural objects. It shows that we are not to be disheartened by some preliminary difficulties from giving a patient hearing to a hypothesis of fair promise, assuming of course that those difficulties are not of the nature of contradictions between the results of observation or experiment and conclusions certainly deducible from the hypothesis on trial. It shows that we are not to attach undue importance to great names, but to investigate in an unbiased manner the facts which lie open to our examination."

On this it would be impertinent to make any farther comment.

SAMOA

Samoa. A Hundred Years ago and long before. By George Turner, LL.D. With Preface by E. B. Tylor, F.R.S. (London : Macmillan and Co., 1884.)

FOR the purposes of comparative ethnology Dr. Turner's new work on Samoa, that group of ten islands in the Pacific which the Frenchman Bougainville named the Navigators' Islands in 1768, is entitled to stand in the same rank with such books as Williams's account of Fiji or Mariner's "Tongan Islands." The careful study of Samoan beliefs and customs for a period of more than forty years confers unusual authority on the writer's statements, whilst his description of their heathen condition derives more than ordinary value from the fact of his having been among the earliest missionaries who visited the islands. Mr. Tylor, in the short preface he has prefixed to the book, speaks with justice of the peculiar interest which attaches to a work that describes Polynesian life as seen in its almost unaltered state before contact with European races had inaugurated a period of rapid change and made what was original and native indistinguishable from what was of foreign importation.

Complete as is the account given by Dr. Turner of Samoan life generally, of the government, social condition, and laws, of the people's food, their houses, or their canoes, the main interest and value of the work lies in the chapters which deal with the religious and mythological ideas of the Samoans. The book in this respect is not only a storehouse of curious myths and legends, but it helps to throw light on the vexed question of the origin of mythology as known in other parts of the world. The whole of Samoan mythology is based on the conception of the male and female nature of all things, such as we still find traces of in the genders of European languages. Thus, according to their cosmogony, from the marriage of the high rocks and the earth rocks sprang the earth, from the marriage of the earth and the high winds sprang the solid clouds, and so on till they come to the gods and chiefs down to the individual who was proclaimed king in the year 1878.

Stories betraying the same rude conception of nature abound. A girl turns into a mountain without difficulty (p. 117); a certain stone is a coward who fled in battle (p. 45); certain trees are transformed men (pp. 119, 219). The important thing is that these and similar stories are spoken of as "seriously believed" by many. "In all these stories the Samoans are rigid literalists and believe in the very words of the tradition" (p. 214).

Samoan ingenuity has its explanation for the origin of most things : of man himself ; of the name Samoa as well as of that of all the islands and their chief places ; of springs (p. 10) ; of the sea (p. 12) ; of pigs (p. 111); and, strangest of all, the story of the origin of cocoa nuts (p. 244).

Dr. Turner reckons the number of Samoan deities that had come to his knowledge at 120, yet there was a time when the Samoans were said to have no religion of any kind. Each individual, each household, each village, had his or its peculiar god, incarnate generally in some creature, but sometimes in a stone, a shell, or even a star. The rules and ceremonies of this fetichistic religion resembled very much those in vogue in America or Africa. A man, while considering it death to cut or injure the incarnation of his own god, would owe no respect to the incarnation of his neighbour's. Illnesses and death were the result of some offence against the gods, and prayers and offerings played in consequence a large part in the daily life of the Samoans.

An ill-defined supremacy among the gods belonged to Tangaloa. He made the heavens and the earth. He was specially prayed to before war, before fishing, or before planting, and thunder was the sign that the prayer was heard (p. 53). Like Zeus, he sometimes was attracted by mortal women, and to obtain the lady who ultimately became his wife he sent down first thunder and storm, then lightning and darkness and deluging rain, and, last of all, a net in which he succeeded in catching her (p. 232).

The souls of dead Samoans started for Pulotu, the spirit-world, through two circular holes near the beach, the larger hole being for the souls of chiefs, and the lesser for those of commoners. They went under the sea till they came to a land where all things were very much as they had been on earth. Chiefs looked forward with pride to the use of their bodies as pillars in the house of the Samoan Pluto (p. 260).

In the Tongan Islands there was the same belief in Boluto as the future world; and Dr. Turner's work is suggestive at every turn of comparisons with the beliefs or customs of remote parts of the world. The Samoan story of the origin of tattooing, turning on a mistake in the delivery of a message (p. 55), recalls the Kaffir and Hottentot account of the origin of human mortality. The story of the turtle and the fowl (p. 218) points the same moral as the classical fable of the tortoise and the hare. The story of the woman and her child who were taken up to the moon, where they may still be seen (p. 203), is precisely similar to the moon myths of European folklore. The custom of artificially flattening the heads of children (p. 80) connects the Samoans in habit with the American tribe who, for doing the same thing, were called the Flathead Indians.

With regard to Samoan customs generally the most interesting allusions in Dr. Turner's work are to the mock burnt-offerings, when for some offence against the gods a man would undergo a counterfeit process of baking in a cold oven (pp. 32, 69) ; to the ordeals for the detection of theft (pp. 19, 184) ; to imprecations by taboo, as when the fear of a shark was instilled into a thief by the plaited figure of one (p. 186) ; to the confession of crimes for the purpose of obtaining divine pardon (pp. 34, 40, 141) ; to purification before battle by sprinkling (p. 64). It is perhaps to be regretted that in reference to the rules of marriage the information vouchsafed by Dr. Turner is not so full as on the preceding points : we are not told whether the Samoans were endogamous or exogamous, nor to what extent purchase entered into matrimony.

A modified system of communism prevails with regard to property, every man having claims on the general possessions of the clan, so that in building a house or a canoe he can always draw on his relations. Dr. Turner says that this system is a sad hindrance to the industrious; but he also points out that it obviates the necessity of poor laws by making poverty unknown and inconceivable (p. 160).

We miss in Dr. Turner's book any estimate of the progress made by the Samoans since or in consequence of the arrival of the missionaries in 1830; though he makes it clear that before that time they had made some independent advance in the ways of civilisation. Thus he notices the previous mitigation of their penal code (p. 178); and points to tradition as attesting in former times the custom both of cannibalism (pp. 236, 240) and of human sacrifices (p. 201). One would gladly know whether their numbers are increasing or the reverse; whether their wars have stopped; and whether it can still be said of them, as Dr. Turner says of them as heathens, that "few drank to excess."

The last chapter deals with twenty-three islands away from the Samoan group, such as the Gilbert group and the New Hebrides, but in reference to these the writer speaks more on the authority of native teachers than on a prolonged personal residence among them. The most noticeable thing is the frequency of the custom of making infanticide compulsory by law; and the generality of the belief in the original resting of the sky upon the earth and in the necessity of pushing it upwards. Perhaps the most curious custom on these islands is that quoted of the isle Peru, by which a married woman for years after her marriage was prohibited from looking at or speaking to any one but her husband. When she went out she was covered in a mat with only a small hole in it by which she might see her way, and any man who saw her coming was obliged to hide himself till she had passed (p. 298).

Having touched on the chief points of interest in Dr. Turner's work, we cannot do more than commend it earnestly to the attention of all who take interest in the customs of unadulterated heathenism. We may fairly describe it as one of the most important contributions to the science of anthropology that has been published for many years. In matter and arrangement it is a great improvement on the "Nineteen Years in Polynesia" in which Dr. Turner first gave to the world his experiences of Samoa. There is an entire absence, perhaps too much, of personal missionary narrative; nor will any one regret in the present work the long chapter which in the former drew attention to a quantity of more or less trifling resemblances between the customs of the Samoans and the Jews. The similarity is doubtless a real one, but it only shows, as wherever else it appears, not that the people in question had any connection whatever with the Jews, but that the Jews in their evolution from savagery passed through the same stages of thought and custom which still characterise barbarism wherever it exists. The more the customs of remote parts of the world are brought into comparison, the more wonderful in its almost mechanical regularity must appear the history of human development.

J. A. FARRER

VOICE, SONG, AND SPEECH

Voice, Song, and Speech. A Practical Guide for Singers and Speakers, from the Combined View of Vocal Surgeon and Voice Trainer. By Lennox Browne, F.R.C.S. Edin., &c., and Emil Behnke, &c. 8vo, pp. 322. (London: Sampson Low, Marston, Searle, and Rivington, 1883.)

THIS bulky handsome volume of 322 pages seems at first sight to present considerable difficulties to a reviewer, which begin with the very title-page, wherein its contents are said to be derived "from the combined view of vocal surgeon and voice trainer." The latter occupation is fairly definite; but what exactly is the former? It might indeed be thought that the striking photograph, with wide-opened mouth and glaring eyeballs, which faces the title, represents the vocal surgeon in question, seen in the very act of giving tongue. But this explanation turns out to be incorrect; as it is an excellent though not a "combined" view of Mr. Emil Behnke's larynx, taken from nature and untouched by hand. This feature, if indeed the larynx can be correctly called a feature, of the work, is, it may be at once said, the best it contains. The gentleman just named has exhibited remarkable energy and perseverance in obtaining, for the first time, a series of autolaryngoscopic views of the vocal chords in the process of phonation, and in different registers of the voice. Four of these, given on an enlarged scale in the body of the volume, go some way towards settling the long debated question as to the different mechanism of the natural and the artificial or "falsetto" voice. In all other respects the book is very unequal, and contains little that cannot be as well or better obtained elsewhere. It has two prefaces: one of the usual kind, and in the usual place; the other at the opposite extremity of the work, quaintly termed a Preface to Advertisements, in which it is stated that "the authors have stipulated with the publishers that no advertisement whatever should be admitted without their express sanction." The opening chapter is entitled "A Plea for Vocal Physiology," and is followed by others on the laws of sound, the anatomy and physiology of the vocal organ, and on the larynx, which need no special notice except to remark that the nomenclature adopted in the description of the last-named organ, like that employed in another of Mr. Behnke's works, is somewhat un-English and clumsy. The old Greek names thyroid, cricoid, arytenoid, and the like are at least as graceful, and perhaps as easy to retain in the memory as the "ring-shield aperture," the "shield-pyramid muscles," and the "buffer cartilages." In the chapter on vocal hygiene some characteristics, fortunately uncommon, begin to show themselves. We are told that "Better than a respirator is the veil invented by Mr. Lennox Browne, and sold by Messrs. Marshall and Snelgrove." On turning to the selected and expurgated advertisements, we find one from the latter firm, adorned with a fascinating picture of a lady wearing the said invention, of which the price is "5*s*., or by post 5*s*. 2*d*." On pp. 110 and 111 we meet two old friends, again ladies, one with a natural, another with a deformed waist; and to our delight they reappear with farther internal detail on pp. 112 and 113. Four pages having been thus pleasantly got over, we learn with relief on p. 117, that "hygienic corsets, exactly of the kind we describe, can be obtained from Mr. Pratt (surgical mechanist of Oxford Street)." On turning to the advertisements, we, singularly enough, find Mr. Pratt also among the elect. Hutchinson's well-known spirometric experiments are then largely drawn upon, and freely quoted, by which means we reach p. 132, where we find four pages of illustrative cases, including those of the "Rev. Canon G.," who "broke down in voice"; "A. B., Esq., M.P.," who "suffered from impediment in speech"; "C. W. P., Esq., Mus. Bac.," who "spoke in a child's treble"; and "Miss D. M.," who "was rapidly losing the upper and middle notes of her voice from faulty production." All these, and others, to the number of eight, even a Scotch precentor among them, were happily cured.

We next pass to the oft-told history of the laryngoscope and its teachings, to find on pp. 163-169 some really good woodcuts of the five registers of the voice, named, according to Mr. Curwen's system, the lower thick, the upper thick, the lower thin, the upper thin, and the small respectively. Farther on two of these, and the falsetto, are reproduced by photography as above stated.

The chapters on voice cultivation, on breathing, on "attack," and on resonance go rather beyond the scope of a scientific paper. As an exercise, the pupil is recommended to repeat the syllable *koo* four times rapidly, once long; following with *oo*, *oh*, *ah*. The effect, with a large class, would be highly pastoral and pleasing. Indeed, it is a comfort to know that this "will be published very shortly by Messrs. Chappell and Co., of 50, New Bond Street" (*vide* advertisement). The most original chapter of all is, however, that on "The Daily Life of the Voice-User." He or she is instructed as to residence, "ablutions," "face and neck powders" (see advertisement), dress, and especially as to a "special woven and shaped combination, reaching from neck to ankles and wrists." On turning with feverish haste once more to the advertisements, we find that this boon to human nature can be obtained of E. Ward and Co. of Ilkley, and that the cost is only 12*s*. 6*d*. On the other hand, while treating of diet, the authors, no doubt from a "combined view," say (p. 256), "We decline to give an opinion on cucumber."

The above extracts will show the general tone and style of the work. The writer of these lines wishes to speak with the greatest respect of Mr. Behnke's really valuable photographs, which he exhibited at the Royal Institution about a year ago. He cannot help regretting that that gentleman in bringing his new conception into the world should have called in the obstetrical aid of any surgeon, however "vocal." W. H. STONE

OUR BOOK SHELF

A Sequel to the First Six Books of the Elements of Euclid. By John Casey, LL.D., F.R.S. (Dublin: Hodges, 1884.)

WE have noticed (NATURE, vol. xxiv. p. 52, vol. xxvi. p. 219) two previous editions of this book, and are glad to find that our favourable opinion of it has been so convincingly indorsed by teachers and students in general. The novelty of this edition is a supplement of "Additional Propositions and Exercises" (pp. 159-174). This contains an elegant mode of obtaining the circle tangential to three given circles by the method of false positions, constructions for a quadrilateral, and a full account, for the first time in a text-book, of the Brocard, triplicate-ratio, and (what the author proposes to call) the cosine circles. Dr. Casey has collected together very many properties of these circles, and, as usual with him, has added several beautiful results of his own. He is not so thoroughly well up in the literature of the subject as he might be, but he has done excellent service in introducing the circles to the notice of English students. Again, Question 31, p. 174, to one unacquainted with geometrical results, would appear to make its *début* here, whereas it figures as a question in the "Reprint from the *Educational Times*" (vol. iii. p. 58),[1] and is discussed there in connection with an envelope which forms the subject of a paper by Steiner (see also pp. 97, &c., and vol. iv. p. 94).

Many of the trifling errors we previously pointed out have been corrected, but some are still left, as on p. 39, line 15, "*A B*" should be "*A C*"; p. 110, reference should be to the "*Reprints from the Educational Times*"; p. 74, line 8 up, should be "*B D*," not "*P D*"; Question 103, p. 157, is incorrectly printed; p. 172, the Brocard angle, in all the papers we have seen, is denoted by ω and not by α. We think a better place for the "Observation" on p. 172 would be after Question 3 on p. 171. The figure on p. 134 is inverted. In the "Index," Pascal's Theorem should be referred to p. 129 and not to p. 139. We only need say we hope that this edition may meet with as much acceptance as its predecessors: it deserves greater acceptance.

The Ores of Leadville, and their Mode of Occurrence, &c. By Louis D. Ricketts. 4to. (Princeton, New Jersey, 1883.)

THE author, in accordance with the requirements of the Ward Fellowship in Economic Geology in Princeton University, spent upwards of four months at Leadville in the study of the ores and their mode of occurrence, and more particularly in the Morning and Evening Star Mines. The result of his investigations are presented in a very useful memoir dealing with the minuter phenomena of the two mines investigated, which are admirably placed for this purpose, as, although small, they have yielded an enormous quantity of carbonate of lead associated with silver ore in the form of chloride and bromide, the whole deposit being probably a pseudomorph or substitution-product of a blue limestone of Carboniferous age, by infiltration of metallic minerals from an overlying sheet of gray porphyry. This class of substitution is not unknown in other parts of the world, the famous calamine deposit of Vielle Montagne being one of the most familiar examples, but nowhere else is it illustrated on the great scale observed around Leadville, which now produces nearly one-half of the total quantity of lead raised in the United States. The ore itself varies very considerably in character, consisting of mixtures in every conceivable proportion of hard granular and soft carbonate of lead, often exceedingly pure, with quartzose brown iron ore and silver chloride and chlorobromide, the latter sometimes in lumps of a few ounces or even a pound weight; more generally, however, it is diffused through the mass, which is enriched to from 50 to 100 ounces in the ton of ore. A point of great interest, we believe first noticed by the author, is the occurrence of beds of basic ferric sulphate underlying the lead carbonate, and also containing some silver as chloride and lead as sulphate. This the author considers to be due to the oxidation *in situ* of a belt of iron pyrites more or less mixed with galena, the change being so complete that no trace of pyrites is ever seen in it. In a second section the author gives much interesting detail as to the working of the mines and their produce, the whole forming a monograph of considerable value. H. B.

[1] It was proposed in the *Educational Times* for February 1865.

Elemente der Organographie, Systematik, und Biologie der Pflanzen. Von Dr. Julius Wiesner. (Wien: Alfred Hölder, 1884.)

THIS is the second volume of a more extensive work entitled "Elemente der wissenschaftlichen Botanik," the first volume of which dealt with the anatomy and physiology of plants. The first part of this the second volume is occupied with organography: the author recognises five fundamental types of vegetative organs, viz. "phyllom, caulom, rhizicom, trichom, thallom," and thus ignores the conclusion of Sachs, that stem, leaf, and root are not coordinate categories, but that the root should rather be coordinated with the shoot, a structure composed jointly of stem and leaf. Further, he cites the sporangia of Ferns as examples of trichomes (p. 5), and thus does not adopt the view of Goebel, that the sporangium is an independent organ, and is not referable to the categories of vegetative organs. These two points are sufficient to show that the book is not abreast of current morphological opinion.

The second part is devoted to the systematic study of plants. The arrangement adopted is that of Eichler's "Syllabus," in which the classification of Angiosperms is different from that in current use in England. This section appears to consist chiefly of an enumeration of facts, and the student is left to draw his own comparisons between the plants described.

Then follows a part on "Biology," a very readable treatise on the life of the individual, reproduction, and the origin of species. As an appendix a short history of the development of botany is given, and in a few pages of notes, references are given to the most important works on various branches of the subject. It is surprising under the head of classification of Phanerogams (p. 424) to find no mention of the "Genera Plantarum" of Bentham and Hooker, the most important publication of the sort in recent years. The book is illustrated by numerous woodcuts, many of which are taken from older books, for example Schleiden's "Grundzüge." Looking at the book as a whole, there is nothing sufficiently new either in the material or in the treatment to recommend it above others already before the public.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

On the Motion of Projectiles

I HAVE read with great interest Mr. Bashforth's article on a new method of estimating the steadiness of elongated shot when fired from large guns, and I have no doubt that we should have a much better knowledge of every new gun to be brought into service if we could try it, using the Bashforth chronograph, which is the most perfect for measuring the times occupied by a shot in passing over a succession of equal distances. That would give us at once the coefficient of resistance of the air to the projectiles used in that special gun, and then by very simple formulæ and tables the calculation of trajectories (which is one of the main points in artillery) would be a very easy task.

Instead, with the present system, viz. knowing only the muzzle velocity, we must rely for these calculations on the coefficients determined with only one sort of projectiles; and of course such coefficients must vary very much (more, perhaps, than is generally thought) with different projectiles, with different shapes of the head, and especially with the different methods of giving rotation.

Lately many improvements have been made in the form of the projectiles: many ogival-headed shots of two diameters have been introduced, and the use of breechloaders instead of muzzle loaders has allowed the use of better means of giving rotation.

Of course the present coefficients still hold good for comparatively short ranges, and for heavy projectiles, because then the loss of velocity is little on account of the small $\frac{d^2}{w}$. But when the $\frac{a^{\cdot}}{w}$ is rather large, as in the case of small guns or rifles, then the coefficients K_v are less reliable.

I have had great experience in calculating with the Bashforth method, and I have been able to calculate trajectories for heavy guns, which were not far out from the actual practice; I had still better results using Prof. Niven's method and table; but when I had to calculate trajectories for small guns, both these methods failed to give me reliable results.

For instance, in calculating the trajectories for the Nordenfeldt one-inch gun, I had with Bashforth's method for an angle of elevation of 9° a range of 2282 yards, and for 12° of elevation a range of 2539 yards: instead by actual practice the elevations required were found to be—

For 2200 yards	7° 12′
,, 2400 ,, ...	8° 20′
,, 2600 ,, ...	9° 36′

The bullets have an ogival head struck with a radius of one diameter and a half, therefore they are not different in shape from the shots used by Mr. Bashforth in his experiments. Besides I divided the trajectory into many small arcs, and I was very careful in applying the correction for the different density of the air, viz. using always the formula $\frac{d^2}{w}\left(1 \pm \frac{\Delta}{534 \cdot 22}\right)K_v$, instead of simply $\frac{d^2}{w}K_v$. I was even rather afraid of overdoing this correction, taking a lighter weight of the air than was necessary; and I was very much astonished when I saw that the trajectories calculated were much too short.

It seems to me also that the correction to be applied when the bullet rises to a great height, requires a little more consideration, and a thorough mathematical investigation.

I think that the problem of a body moving in a medium which becomes less and less resistant as the body advances through it is more complicated than we would think at first, and cannot be dealt with by only considering the density of the medium equal to the mean of the densities at the two terminal points.

E. RISTORI

Christian Conrad Sprengel

THE interest in my note on Sprengel (NATURE, vol. xxix. p. 29) may excuse some additional facts. In the Life of Dr. E. L. Heim (by G. W. Kessler, Leipzig, 1835, 8vo) the following is reprinted from Heim's diary, vol. ii. p. 72:—

"I read Rector Sprengel's work with indescribable satisfaction. Since the time when I read Hedwig's system of the fructification of the mosses, fourteen years ago, I never had such a great and thorough pleasure as to-day. I cannot admire enough the power of observation, the untiring assiduity, the acuteness, and the correct and clear exposition of the facts which he had observed. His work is a masterpiece, an original, which gives him honour and of which Germany can be proud."

Dr. Heim, who afterwards became a distinguished physician in Berlin, Prussia, was an enthusiastic mycologist, who had made the acquaintance of Sir J. Banks and Solander, had studied carefully Dillenius's Herbarium in Oxford, had later visited Gærtner and Koelreuter. He speaks rather enthusiastically about this naturalist, who showed and explained to him his experiments. Dr. Heim gave also the first instructions in botany to Alexander von Humboldt.

Mr. Kessler, the editor of Heim's Life, says (vol. i. p. 286):—"Heim found in Rector Sprengel, to whom he gave the first instructions in botany, a remarkable student. Sprengel repaid largely all pains which Heim had spent on him by the fruit of his careful studies."

The editor wrote this in 1835, and the fact that he selected out of the diary the above-quoted note proves well how much Sprengel's work was appreciated and admired even by non-scientists.

In Kœnigsberg, Prussia, Prof. C. F. Burdach, in his yearly lectures on physiology, taught and appreciated highly Sprengel's discoveries. In his large "Physiology," published in 1826 with the assistance of C. E. von Baer and H. Rathke, and in the second edition, 1835, with the same assistance, and, besides them, with E. Meyer and J. Valentin, and in a French translation of the same work, § 237 gives an account of Sprengel's discoveries. "If he should have gone a little too far in some cases it would be without importance; the same occurs with every scientist who makes a great discovery, and becomes with it enthusiastically excited." I know personally that Burdach's well-reputed assistants were thoroughly acquainted with Sprengel's observations.

Prof. H. Burmeister had studied in Greifswald and in Halle, and published his "Handbuch der Entomologie," 1832; an English translation by F. Shuckard. He speaks (vol. i. p. 303) about Sprengel's and Koelreuter's observations at some length, also as well known and of the highest importance. Prof. Burmeister will be indeed best able to state if he became acquainted with the facts in Prof. Hornschuck's lecture on the physiology of the plants, "naturæ mysterias nobis aperire expertus est" ("vita" in Prof. Burmeister's dissertation), or in Halle by Prof. Carl Sprengel, the nephew of Rector Sprengel, or somewhere else. I know personally that in Berlin, Link, Lichtenstein, Klug, Erichson were entirely acquainted with Sprengel's discoveries. Prof. Kunth was a very old friend of Heim (Life, ii. p. 9), and beyond doubt acquainted with the facts, though he has not brought it forward in his lectures after Dr. F. Müller's statement. I was assured by scientific friends that Treviranus in Bonn and Nees von Esenbeck in Breslau were well acquainted with Sprengel. I confess that I am entirely at a loss to understand how it happened that Sprengel was unknown to scientists in England, where Kirby and Spence's "Introduction," &c., had seven editions from 1815 to 1867, the last of 13,000 copies. There would be no difficulty to find in German libraries more publications to corroborate my views, but I believe those quoted are sufficient to prove what I intended to state in my former note. H. A. HAGEN

Cambridge, Mass., March 24

Salt-water Fish-Types in Fresh Water

MR. HARDMAN'S observations on the occurrence of "sea-fish in fresh-water rivers" (NATURE, vol. xxix. pp. 452-53) are not by any means unique, as he has supposed. On the contrary, cases similar to those he has recorded are so frequent as to justify him in believing that "some caution must be observed in the classification of strata as fresh-water or marine on the evidence of fish alone." The incursion and confinement of the two types specially mentioned—the "sunfish" and "shark"—in fresh water have many parallels. For instance, in NATURE, vol. xiii. p. 107, Messrs. W. W. Wood and A. B. Meyer have recorded that "near Manila is the Lacuna de Baij, a large sheet of water" whose "water is quite fresh, and, after settling, perfectly potable," but in which live a sunfish (*Pristis perotellii*) and a small shark. Further, in Lake Nicaragua, whose mean height above mean tide in the Pacific and Atlantic Oceans is 107·63 feet, are likewise found a sunfish—apparently *Pristis antiquorum*—and a peculiar shark—*Eulamia* (or *Carcharias*) *nicaraguensis*. The last have been especially noticed in a "Synopsis of the Fishes of Lake Nicaragua, by Theodore Gill, M.D., and J. F. Bransford, M.D., U.S.N.," in 1877 (*Proc. Acad. Nat. Sci. Phila.*, pp. 175-91). Therein it is also urged that "these instances, supplemented as they are by many others, are sufficient to convey a caution against too extensive generalisation of the physiographical conditions hinted at by fossil remains of aquatic types." THEO. GILL

Washington, April 1

"The Axioms of Geometry"

MR. ROBT. B. HAYWARD has written to me that some of the statements in my article, "The Axioms of Geometry," in NATURE, March 13 (p. 453), are too sweeping, and that in particular Euclid I. 16 does not necessarily hold for the geometry of the eye-being, or, to use the more familiar language of spherical geometry, that this theorem does not hold unless the median line of the triangle on the side on which the exterior angle lies is less than a quadrant.

Mr. Hayward has also pointed out that the error lies in the assumption that a terminated straight line "may be produced to any length."

All this is clear enough, and I was conscious of it when I wrote the article. In fact I meant to add, but somehow omitted to do so, that every figure considered has to be limited to less than a hemisphere, or to less than half the space round the eye-being. If this is done, and if by the whole figure is understood the given figure together with any addition required for the proof, then my statements will hold, but with one exception. I was wrong in saying that Legendre's proof, given by Mr. Casey, can be treated in the same manner as Sir Wm. Hamilton's. For in this proof a series of triangles is constructed with sides which increase till they become infinite. The reasoning is therefore not applicable to the sphere. But neither is it to the plane. We have no right to reason about infinite figures as we do about finite ones. O. HENRICI

Wild Duck laying in Rook's Nest

A WEEK ago to-day six wild duck's eggs were taken out of a rook's nest about four miles from here. The rookery is situated on the banks of the River Test. The nest from which these eggs were taken (the bird flew off as the nest was approached) was in a horse-chestnut tree, and was about thirty feet from the ground; the tree was about twenty-five yards from the river, and was surrounded by others, mostly elm. An instance of so unusual a situation for wild duck's eggs might, I thought, interest some of your readers. JOHN H. WILLMORE

Queenwood College, near Stockbridge, Hants, April 3

[Our correspondent has sent us one of the eggs referred to, which we have submitted to a well-known oologist, who is of opinion that the egg is most likely a wild duck's.—ED.]

The Remarkable Sunsets

I LEARN from Mr. Frank Atwater, a teacher in the Native College here, that he observed the "glow" at 5 a.m. on September 5, when landing from the steamer at Maalaea, thirteen miles south-east of this. He had arrived in the islands only two days before, and marvelled much if such were the sunrises here. He is the only person I have met who observed it prior to the evening of that day. Mr. Atwater's date is verifiable by the regular movements of the steam-packet.

Lahaiua, Hawaiian Islands, March 14 S. E. BISHOP

Cats on the District Railway

WITH reference to Mr. Vicar's letter last week (p. 551) about the cats at Victoria Station, I beg to state that there are cats all over the District Railway both in and out of the tunnels, and many of them—familiarly called "Stumpy" by the men on the line—can testify by the shortness of their tails to the hairbreadth escapes they have had from passing trains. Those I have seen are mostly full-grown cats, and only once have I seen a kitten walking on the rails, and that was at night after the traffic had ceased. At one signal-box which is built on a platform over the line, and the only access to which is by a steep iron ladder, down which no cat could climb, there are two full-grown tabbies—toms I believe—and I have often seen them asleep behind the signal bells or even on the handrail of the platform, utterly callous to the trains rushing by underneath. As a rule the men are very kind to them, and give them milk, &c.

I would add that until quite recently there was a small fountain and circular basin near one of the pumping-engine houses wherein were two fish which had been there for about twelve years. One died last year, and now I see the basin has been converted into a flower-bed by the man in charge. E. DE M. MALAN

Victoria Station, District Railway, April 14

THE GEODETIC SURVEY OF THE UNITED STATES[1]

WE would congratulate Prof. J. E. Hilgard, the Superintendent of the Survey, on his first general Report on the work of his department, which gives an account of the Survey for the fiscal year ending June 1882. We are unable to gather why its issue has been deferred until now, but its arrival at the present time is not the less opportune, particularly as the programme of

---

[1] "Report of the Superintendent of the Survey," Washington, 1883, 556 pp., 4to.

the approaching International Geodetic Conference at Washington is beginning to claim decision.

The Report describes the nature and general procedure of the coast and topographical surveys, with a description of the instruments employed; full details of the observations and their methods of reduction being given.

Whilst the original leading aim of the Survey, the security of navigation, has been kept in view, other objects incidental to the work of trigonometrical survey, and of the highest scientific interest, have not been lost sight of.

Hydrographic surveys have been prosecuted in the waters and off the coasts of seventeen States and Territories, and topographic surveys for the exact definition and delineation of shore line have been carried on in eleven States and Territories. The triangulations for this work have been advanced in twenty-two States and Territories, and included the measurement of the base-line in California; and also, as is well known, the extension of the trans-continental triangulations urged by the late Prof. Peirce, for connecting the surveys of the Atlantic and Pacific coasts. In the interior States the work has included the continuation of the triangulations of Kentucky, Tennessee, and other States.

The incidental work has comprised the carrying of lines of precise "leveling" between points far distant (1125 miles); the exchange by telegraphic signal of the longitudes of important cities; the usual observations for latitude and azimuth, and of the magnetic elements; the determination of the force of gravity by pendulum experiment; and the study of ocean currents, particularly of the Gulf Stream.

For the year ending June 1884 the cost for carrying on the work of the U.S. Coast and Geodetic Survey, by which designation this department has been known since 1878, was estimated at $573,000, and it is gratifying to note that on the other side of the Atlantic the value of active scientific inquiry continues to be recognised by the State, provision having been made for further tidal, magnetic, gravity, and other scientific observations.

In a geodetic survey extending over an area so large as that of the United States the question of the size and figure of the earth becomes of great importance. Although, as Prof. Hilgard points out, different opinions are held as to the mode of prosecuting gravity experiments, all geodists agree that widely-distributed pendulum observations will give results valuable to geodesy and geology. It is undoubtedly desirable that opportunity should not be lost of combining the results of pendulum observations taken in different parts of the globe, and we trust that the valuable pendulum work done in India ("Great Trigonometrical Survey," vol. v.), and the discussion at the informal conference on gravity determinations between Col. J. Herschel, R.E., Prof. S. Newcomb, and the officers of the Survey Department, which was held at Washington in May 1882, may stimulate the recognition in this country of the necessity of further experiment and inquiry in this direction. Although the conclusions proposed by Prof. Newcomb, as amended and adopted by the conference, have been elsewhere discussed, it appears desirable at the present time again to invite attention to them. Generally they are as follows:—

1. The main object of pendulum research is the determination of the figure of the earth.
2. A complete geodetic survey should include determinations of the intensity of gravity.
3. A minute gravimetric survey of some limited region is at present of such interest as to justify its execution.
4. Extended gravimetric linear exploration is desirable.
5. Each series of such determinations should be made with the same apparatus.
6. Such determinations ought commonly to be accurate to the 1/200,000th part.
7. All pendulums should be compared at some central station.
8. Determinations of absolute gravity will probably prove useful in comparing the yard and the metre, and they should at any rate be made in order to test the constancy of gravity against the constancy of length of a metallic bar.
9. In the present state of our experience, unchanged pendulums are decidedly to be preferred for ordinary explorations.

In an appendix (No. 21) is given the reduction, with the employment of modern constants, made by the late Dr. C. R. Powalky at the charge of the Bache Fund of the National Academy of Sciences, of the places of 150 stars observed by La Caille at the Cape of Good Hope and at Paris, between 1749 and 1757. Since all these stars have been re-observed in recent years at Melbourne and at the Cape, the comparisons of La Caille's places with these determinations and with those of Dr. B. A. Gould at Cordoba became of scientific value.

An account is also given of the measurement of the primary base-line in Yolo county, Sacramento Valley, begun in 1879 with the new compensating base apparatus designed by Assistant C. A. Schott. The measurement was made under the directions of Assistant George Davidson, but the discussion of its results does not appear in the present Report

The measuring bar of the compensating apparatus is of a construction different from other compensating bars, but involves no new mechanical principle. It is composed of two metals, zinc and steel, so proportioned as to be compensatory for change of temperature, the expansion or contraction of a zinc bar five metres in length being counteracted by the expansion or contraction of the two steel bars between which it is placed.

The determination of the rate of expansion of the subsidiary steel and zinc bars by which the five-metre standard was verified was done by means of two micrometer microscropes securely fixed to stone piers placed a metre apart, the metre bar whose rate of expansion was to be determined being compared when at different temperatures with the distance between the two microscopes as determined at a constant temperature by reference to a second standard metre bar. The distance between the microscopes thus becomes a function of the temperature, and in this respect we cannot but think that the method attributed to General Wrede, by which the variable distance between the microscopes becomes unimportant, has a decided advantage.

The active investigations since 1871 as to the distribution of terrestrial magnetism in North America have beome generally known from the reports of Prof. Hilgard, as well as by the publication of Mr. Schott's paper on the magnetic variation of secular declination. Mr. Schott also now gives an important appendix to the Report on the distribution of the magnetic declination in the United States at the epoch January 1885, together with three isogonic charts in continuation of those issued by the Survey up to the year 1876. The results are also given of the magnetic observations made by Lieut. Very on the north-eastern coast of America, particularly at Labrador, in the remote settlement of Nain (lat. = 56° 33′ N., long. 61° 44′ W.).

In the exploration of the Gulf Stream, the facts brought out by the deep-sea soundings of Commander J. R. Bartlett during 1881, with Siemens's admirable electrical deep-sea thermometer, are also referred to; and the account of the deep-sea soundings taken off the Atlantic coast between 1879 and 1883 by Lieut. J. E. Pillsbury, in connection with the exploration of the Gulf Stream, and the discussion by Prof. Ferrel on the tides of the Pacific coast are now published. The inquiries of Dr. Thos. Craig as to fluid motion, particularly as to the motion of vessels and of bodies such as pendulums, when totally immersed in fluid, are also adverted to.

Twenty-five useful maps and charts are attached showing the general progress of the survey, particularly on the coasts of Florida, California, Oregon, and Carolina; together with illustrations of the apparatus used. As compared for instance with the precise drawings given by General Ibanez in his Reports in 1860 and 1865 on the Madrid base-line, there may perhaps be room for improvement in the finish of the illustrations given in this Report.

In the Report of the Superintendent for 1883 we shall look forward with interest to the results of the experimental researches on the force of gravity, by Assistant C. S. Peirce, who is now visiting Europe for the purpose of his inquiries.

In the success with which the Superintendent has been able to deal with the different branches of his department, much is due, as he indicates, to the forethought and systematic treatment of his eminent predecessors, particularly to Carlile P. Patterson, to whose memory a graceful tribute is rendered in the Report; as well as to the able assistance which the Government have placed at the Superintendent's disposal.

AGRICULTURE IN SUSSEX[1]

THIS Report bears evidence of a considerable amount of careful research bearing upon the agricultural practice of Sussex. The honorary secretary, Major Warden Sergison, must be congratulated upon his zealous administration of the finances, whereby an annual income of about 770*l.* has been secured for the three successive years of active operations. This Report deals with the results of the third year's work, which completed the period over which it was originally calculated that the work should be extended. We are therefore in a position to form some opinion as to the practical value of the results which have been gained. It appears from this Report that it is intended to extend this inquiry.

These experimental researches have been conducted by Mr. Thomas Jamieson, the Fordyce Lecturer on Agriculture in the University of Aberdeen, and it will be interesting to notice the improvements and economics which are claimed in his Report as resulting from this rather costly investigation. He says:—"The results are too numerous to give, . . ." but "an attempt will be made to give in a general way the lessons they seem to teach." He then proceeds to indicate these, placing them in the form of question and answer. We will take the first of these.

"*What food do plants need?* Prior to the experiments now recorded, the answer to this question would have been 'Nitrogen, phosphorus, potassium, sulphur, calcium, magnesium, iron.' The results of the experiments warrant us in saying that the latter four substances may be disregarded by farmers. We thus realise the value of experiments. If the farmer of 100 acres will lay his manure bill before a chemist, and ask him to calculate how much he has paid for those useless—or hurtful—ingredients, he will recognise the direct benefit of such experiments."

Those who have watched the good work which Mr. Jamieson has done in connection with the Aberdeenshire Agricultural Association, and who have recognised the opposition with which he had to contend, cannot but regret the hasty conclusion at which he has arrived. It is a very bold assertion to make that sulphur, calcium, magnesium, and iron are not needed as plant-food. He cautions his friends "not to be led away by opposed statements, however plausible, if unaccompanied by proof." In this case Mr. Jamieson shall supply his own proof, for which purpose we refer to the Report of the Aberdeenshire Agricultural Association, 1875-76, p. 29. Here Mr. Jamieson reports a very valuable series of experiments which he made. White sand was supplied with all the ingredients found in turnips—except one—and turnip seeds were then sown. He says:—"Precisely the same sand, precisely the same seed, precisely the same watering, precisely the same ingredients added, except one—which was purposely omitted—*calcium*. In consequence of this omission, although all the other ingredients were present in abundance, the healthy seed produced healthy young plants, but speedily *the whole of them died.* Just as in an ordinary chemical experiment *the desired substance cannot be formed if one of the essential ingredients is absent.*" The lesson derived from this experiment is perfectly consistent with agricultural science, and it is a source of profound surprise to find that this substance—*calcium*—is one of the four bodies named in the Sussex Report as being unnecessary, and that it should be stated that "farmers will not hurt their crops by omitting these four elements." This is *a dangerous lesson* to deduce from this valuable series of experiments, and we regard it with the greater regret because the facts do not justify such a conclusion.

Other examples might be selected from this Report, which conflict with other experimental trials conducted with, at least, equal care, which also tend to show the necessity for taking more *practical* views of the results gained. The opinions expressed upon permanent pasture are also open to severe criticism. If the general series of Sussex experiments be placed in comparison with the investigations carried out for the Aberdeenshire Agricultural Association, they will be found devoid of those great national advantages which must long attach to the Scotch experiments. The value of the Aberdeen Association work has never been as fully appreciated as it deserves, and the agricultural public would have been highly gratified if the Sussex Association experiments had been equally definite and satisfactory.

SOCOTRA[1]

FOUR years have elapsed since an expedition was sent out from this country by the British Association and the Royal Society to explore the Island of Socotra. With the exception of diplomatic visits by the resident at Aden in the two or three preceding years, and of a short exploration in 1847 by the French naturalist Boivin, there is no record of any European having sojourned on the island since the date, forty years ago, of its abandonment by the Indian troops which had occupied it for this country during four years, and Wellsted's account of his survey of the island (in *Journ. Roy. Geog. Soc.* v. 1835) made in 1834, has been up till now the most recent and most satisfactory. It is remarkable that an island so long neglected and forgotten should be visited in two successive years by exploring expeditions; yet this has happened. In 1881 a party of German explorers followed the British Expedition. This German Expedition to Socotra formed part of a scheme of scientific exploration of many unknown or but little-known regions of the globe set on foot by Dr. Emil Riebeck, and for which his liberality provided the means, and the results of this portion of his undertaking, some account of which now lies before us, must be gratifying to him as they are valuable to and welcomed by science. Dr. Riebeck was accompanied to Socotra by the well-known traveller Dr. Schweinfurth and two other companions, Drs. Mantay and Rosset—a quartet of observers well qualified to take advantage of every opportunity of extending our knowledge of nature. Many difficulties and dangers beset their progress to the island, and their leave-taking appears to have been no less troubled; but eventually it has been their good fortune to bring to Europe a magnificent collection of specimens illustrative of its structure, its products, and the character of its inhabitants.

---

[1] "The Annual Report of the Proceedings of the Sussex Association for the Improvement of Agriculture in Sussex. Season 1883."

[1] "Ein Besuch auf Socotra mit der Riebeck'schen Expedition." Vortrag von Professor Dr. Schweinfurth. (Freiburg, 1884.)

"Allgemeine Betractungen über die Flora von Socotra," von G. Schweinfurth. Sep. Abd. aus *Engler's botanischen Jahrbüchern*, v. (1883).

"Land-Schn[illegible]en von Sokotra," von E. von Martens, aus *Nachrichtsbl. d. deutsch. Ma*[illegible], No. 10 (1881).

Most of the collections have now been worked out either in this country or on the Continent—Schweinfurth's large herbarium having been, with rare generosity, sent by him to this country to be examined along with that of the British Expedition—and the details regarding them are published in various periodicals. Herr von Martens' paper above mentioned is a supplement to the first part of Godwin-Austen's account (*Proc. Zool. Soc.* 1881, p. 251) of the shells brought home by the British Expedition, and deals with some new forms collected by the German explorers not mentioned in that account. It appeared, however, when the second part of Godwin-Austen's paper was in the press, and this overlapping of the papers has unfortunately led to some forms being described by both authors and under different specific names.

In the other pamphlets before us Schweinfurth gives us in his usual lucid and vigorous language a general *résumé* of results so far as they have been at present determined. It is satisfactory to find that his conclusions, drawn from considerations of the physical features and the fauna and flora, are almost entirely in consonance with those deduced by the British observers (see Bayley Balfour in *Rep. Brit. Ass.* 1881, and *Proc. Roy. Instit.* for April 1883). The antiquity of the island, the strong affinities of the animals and plants with those of the adjacent African and Arabian coasts, the presence in the flora of Mediterranean and general tropical types, as well as of forms related to those found on the highlands of Abyssinia, South Africa, and West Tropical Africa, are features insisted on by both. There is, however, a divergence of opinion regarding the Madagascar affinities. Godwin-Austen supposes these point to the conclusion that in Socotra and Madagascar we have remnants of an ancient and more advanced coast-line on the western side of the Indian Ocean, which was probably continuous through Arabia towards the north. Martens questions the identifications upon which this supposition rests, and does not agree with it, and Schweinfurth, though without advancing any cogent reasons, concurs with him.

The question, who are the Socotrans, and whence have they sprung? is one to which the German Expedition gave special attention, and Schweinfurth devotes a considerable portion of his address to its discussion. At the present time he estimates the population at ten to twelve thousand inhabitants. Of these about one-tenth are Arabs, colonists from the adjacent mainland, who live in the coast-villages, and are the merchants of the islands. Along with these are found many negroes, most of them runaway slaves. But the dwellers on the hills are the true Socotrans, and speak a language quite peculiar. Amongst them Schweinfurth recognises, as did Vicenzo in the seventeenth century, two races—a darker with curly hair, and a lighter one with straight hair. In addition he finds an apparently Semitic type, characterised by small head, with long nose and thick lips, straight hair, and lean limbs. The Socotran generally is of average height and size, with a quick, intelligent eye. The type of the true Socotran is quite different from that of the Somali, Galla, Abyssinian, South Arabian, and Coast Indian. From the little known of the Mahra and Qara tribes which inhabit the hill regions of middle South Arabia opposite, Schweinfurth is inclined to consider the Socotran resembles them most nearly. Many skulls were obtained from the grave caverns, and these are now in the hands of Prof. Welcker, whose report upon them may be looked forward to with interest.

From a study of the peculiar Socotran language the Germans anticipated much aid in elucidating the problem of the origin of the people. Unfortunately difficulties with interpreters prevented their achieving much success in this line. Schweinfurth notes, however, regarding the language two marked features. Firstly, its resemblance with the Mahra dialect, which is quite different from the old and the new Arabic, and is a peculiar element amongst the South Arabian dialects. This is opposed to the statement of Capt. Hunter, who says it in no way resembles Mahra. But Schweinfurth in support of his statement quotes the report of Wellsted, that the Mahras and Qaras could understand the Socotrans whilst coast Arabs could not do so; and further, a comparison of the vocabularies made by Wellsted and by his own expedition with the results of von Maltzhahn's studies on the Mahra dialect show many similarities between them. Secondly, it contains many foreign elements, and this is especially noticeable in the names of plants and animals, many of them having a thoroughly Greek sound.

Turning to history for a clue to the origin of the Socotrans of to-day, we find many references to their island in the older writers, and to these Schweinfurth refers. The author of the "Periplus" speaks of the people as a mixture of Arabs, Indians, and Greek merchants; and the presence of the Greeks is explained by subsequent writers by the story that Alexander the Great on the advice of Aristotle sent a colony of Greeks—some say Syrians—to cultivate the aloe. Cosmas relates that under the Ptolemies many colonists were settled on the island, and Jakut in the thirteenth century tells of the Greeks who had become Christians dying out and thus making room for an incursion of Mahra Arabs from the opposite coast. In these old narratives there is, as Schweinfurth points out, much that is contradictory and conflicting, and unfortunately there is at the present day but little internal evidence confirmatory of the existence in earlier times of a cultured race on the island. The visit of the Wahabees in 1800, as Wellsted says, may probably account for the disappearance of monuments and temples. Schweinfurth speaks of certain small heaps of ruins as perhaps representing old altars—but the only definite relic of this character now known is a series of hieroglyphics upon a wide limestone slab at Eriosch near Kadhab. These have attracted the attention of all who have visited the island in recent times, and Dr. Riebeck has paid especial attention to them. His interpretation has not yet been made public, but Schweinfurth states that in them some rows of Greek cipher are to be recognised. It may be hoped that their explanation may afford some clue which will help the solution of the interesting problem of the derivation of the Socotrans. The evidence existing at present is of so imperfect a character that it is impossible to determine with certainty their stock. Schweinfurth conjectures that in the Semitic element he observed may be traced a Greek type, and that the Mahra Arabs have most probably had a great share in forming the features of the present people. Future exploration must settle the question.

Altogether these papers by Schweinfurth are of the greatest interest, and his long experience amongst the native tribes of Africa gives to his observations regarding the people of Socotra great value. The material obtained by the two expeditions—British and German—has enabled us now to obtain a fair idea of the general character of the people, the natural history and physical features of Socotra; but the short time for work possible to the members of the expeditions—little more than six weeks in each case—naturally renders their results somewhat fragmentary. What has been done as yet is but preliminary, and from it we learn that there is still a vast field for future explorers—not only in Socotra itself but on the adjacent mainlands of Africa and Arabia. Until such further investigation takes place many most interesting problems—ethnological as well as concerning the distribution of plants and animals—must remain unsolved.

THE THREE HUNDREDTH ANNIVERSARY OF THE UNIVERSITY OF EDINBURGH

THIS week the University of Edinburgh is holding its Tercentenary Festival. An elaborate programme of festivities is being gone through by a collection of guests of literary, scientific, and social eminence such as rarely graces a British or even any foreign University seat. A mere recital of the list of those who are to be present to receive honorary degrees would be interesting, as showing the scope and catholicity of modern University culture. We see Hermite, Helmholtz, Pasteur, Haeckel, Virchow, Browning, Renan, Bishop Lightfoot, and Principals Tulloch and Rainy, capped by the same academic hand.

It may not be without interest to our readers to dwell for a moment on certain parts of the history of an organism whose appreciatory functions are so varied and at first sight even contradictory.

Three hundred years, though not an infant's age, is after all no great age for a University. Any uncertainty therefore that surrounds the early history of the University of Edinburgh is more the result of initial obscurity than the glamour of remote antiquity. She is, as some one has said, hopelessly modern. Nevertheless, her history is in some respects a very remarkable one. What has now developed into one of the largest of the Universities of Europe, numbering its students by thousands, began as a college for the "town's bairns," under the patronage of the Town Council, who in fact remained its rulers until 1859. There can be little doubt that the comparatively modern date of the foundation of the college, and the peculiar[1] nature of the governing body favoured its growth and development into what has claims to be the most liberally constituted of the Scottish Universities.

A glance at the chronology of science will show that the opening of the new Town's College in Edinburgh in 1583 falls at the time when the tide of progress in physical and mathematical science was just beginning to rise over Europe.

Napier of Merchiston was living hard by; Gilbert was probably collecting material for his great work on the magnet; and Galileo and Kepler were doing great things for physical science.

Nevertheless, the progress of the young institution was not at the outset very remarkable. This arose partly from the miserable poverty of its early endowment and of Scotland itself, partly from the plan of "regenting" on which it was organised, which compelled each of four regents to carry his students in four years through the whole course of the seven liberal arts of the mediæval curriculum. This plan, so fatal to special excellence in teaching or learning, continued until 1708, when it was finally abolished, and professors of the separate subjects established. During this first century, however, the patrons had already engrafted the germs of the modern University by appointing professors of separate subjects, which were sometimes outside the curriculum of the regents altogether, sometimes auxiliary to it. In this way arose some of the present chairs of the faculty of arts, and in this way originated many of the chairs that now form the separate faculties of theology, law, and medicine.

The powers of the Town Council left them absolutely unfettered in the founding of new chairs, and they proceeded in this work guided by their own views as to the necessities of the times, and aided by the best advice they could obtain inside, or more frequently outside, the University. They were not always quite judicious or wholly unbiased in their procedure, and many of their reforms were carried out in the face of bitter hostility from within the University. Yet it cannot be denied that, on the whole, their action as patrons and founders of chairs was for the good of the University. The sectarian feuds which occasioned the Disruption of the Established Church ultimately led, in 1859, to the severance of the close tie between the Town Council and the Town's College, long ere then grown into a full-blown University. There is no need here to dwell on the dark side of the picture of the management of the University by the Town Council. Their misdeeds are, we may hope, not likely to be imitated by modern patrons, and their enlightened policy in the foundation of chair after chair as the wants of the institution grew is, after all, the more important part of the story, and well worthy to be read in this day of infant Universities and of experiments on the large scale in the remodelling of older Universities of the kind.

As most of our readers probably know, the strength or weakness of a Scottish University depends wholly on the professoriate, with whom lie the whole of the teaching and disciplinary duties. Within certain limits set him by the Ordinances, and with some restrictions owing to the presence of colleagues in allied departments, a Scottish professor within his own classroom is absolutely free, and may develop into a great success, a mediocrity, or a great failure, according to circumstances; and with him rises or falls the department intrusted to his care. The system has its drawbacks sufficiently obvious; but it has this to say for itself, that it is an economical arrangement, and that it has produced a large body of citizens sufficiently well educated to take rather more than their own share of the higher employments in the British Empire. It will thus be seen that the interest of the educational history of a Scottish University centres mainly in the record of the occupants of its various chairs. We offer a few desultory remarks on this subject, chiefly from the scientific point of view, referring those who are interested in the matter generally to the recently published "Story of the University of Edinburgh," by Principal Sir Alexander Grant.

The earliest foundation of a special scientific chair was that of mathematics, to which the Town Council called James Gregory in 1674. This distinguished mathematician and physicist, the author of various theorems in pure mathematics and of several great ideas in optics (represented to the mind of the ordinary student by Gregory's "Series" and the Gregorian telescope), came of an Aberdeenshire family (related, by the way, to the notorious Rob Roy Macgregor), which, during the last three hundred years, has furnished something like a score of distinguished professors and men of science to the Scottish and English Universities. Gregory was not the first nominal Professor of Mathematics, but he was the first professor who had more than the name. After his brief but brilliant tenure, the office, with but little intermission, was filled by a line of distinguished followers, among whom we must content ourselves with naming David Gregory, who became Savilian Professor of Astronomy at Oxford, who was appointed on the urgent recommendation of Newton himself, who was in fact the friend and interpreter of Newton, and was by him reckoned worthy, along with Halley, to continue the great work of the co-ordination of celestial phenomena begun in the "Principia." He has the credit of introducing the Newtonian philosophy into the curriculum of Edinburgh thirty years before it obtained a similar place in the University of its author. Colin Maclaurin is the greatest perhaps of all the men of science that Edinburgh has produced; of his wide culture and extended activity we may give some idea when we say that he was a worthy successor to Newton in pure and applied mathematics, that he was a great teacher of mathematics and physics, a great popular lecturer in his day (one of the first of the scientific tribe of such, perhaps), that he was an authority on life assurance, on surveying, on geographical exploration, that he was an excellent classical scholar, a man of great social qualities, and lastly, that he tried to organise a defence of the town of Edinburgh against the Pretender in 1745, and caught thereby the malady that ended his life. Other occupants of the chair were Matthew Stewart, still remembered for his "Propositiones Geometricæ"; John Playfair, distinguished as a critic and historian of science, introducer of the Continental methods into the mathematical studies of Edinburgh; John Leslie, an excellent geometer, but now better remembered for his contributions to the science of heat; and William Wallace, inventor of the eidograph.

---

[1] Peculiar from a University point of view, for the older Universities as a rule were privileged corporations independent of, nay, often antagonistic to, the municipalities where they were situated.

At first, natural philosophy, in so far as it was distinct from Aristotelian physics, seems to have been in the province of the Professor of Mathematics. It was so in Maclaurin's time, although a separate professorship for it had been founded in 1708. The first professor that need be mentioned here is John Robinson, whose articles in the third edition of the *Encyclopædia Britannica* are still worth consulting, and whose "Elements of Mechanical Philosophy" was for a time a standard work on the subject. The original close connection between mathematics and natural philosophy probably led to what at first sight seems a curious succession of professors. It more than once happened—notably in the cases of Playfair and Leslie—that the holder of the Chair of Mathematics was transferred to that of Natural Philosophy; in fact, it was in the latter subject that both these professors attained their greatest distinction, the former by his account of the Huttonian Theory of the Earth, the latter by his well-known researches on heat. But the greatest of all the past Professors of Natural Philosophy was undoubtedly James David Forbes; he, along with David Brewster, at first his patron, and for a long time his rival, are to be reckoned among the greatest ornaments of the University of Edinburgh during the generation that has passed away. Both were students of the University and both were candidates for the Natural Philosophy Chair; Brewster, failing probably for political reasons, was reserved for the higher honour of the principalship. The works of these two great men are so fresh in the recollection of our readers that no words need be wasted here in emphasising them. It is worthy of mention, however, that the late James Clerk Maxwell and Prof. Balfour Stewart, whose fame sheds undying lustre on their Scottish *alma mater*, were trained in practical physics under Forbes.

The Chair of Chemistry, founded in 1713, was at first essentially a medical chair; its first occupant, James Crawford, was a remarkable man in every way, a pupil of Boerhaave, and well versed in what little chemical knowledge then existed. It is noteworthy, as showing the small extent of medical and chemical knowledge at that time, that he was also Professor of Hebrew! His immediate successors call for no remark until we reach Cullen (1755), who, though better known as a great physician, was also distinguished as a great teacher of chemistry; he was, in fact, the first to establish that science as a study separate and distinct from medicine. His two immediate successors, Black and Hope, followed his lead, and were very successful teachers; in fact, in Hope's time the class reached the astonishing number of 500. Besides being a good teacher, Black was a man of genius. His results regarding carbonic acid, embodied in his graduation thesis "De humore acido a cibis orto, et magnesia alba," and his discovery of latent heat form cornerstones in the structure of modern chemical and physical science. Perhaps the greatest praise is, that Lavoisier regarded him as his master. Hope will be remembered for his experiments on the maximum density point of water, and for his discovery of strontia as a separate alkaline earth. In 1844 the chair became a chair of pure chemistry. Among the past professors since then we may mention Sir Lyon Playfair, whose scientific reputation is now overshadowed by his fame as an educational organiser, and an able political champion of the interests of science.

The Chair of Natural History was a later foundation (1770?), and at first was a sinecure. Since the beginning of the century, however, it has not wanted for distinguished occupants. Jameson (1804) was an excellent mineralogist; he founded the splendid museum now absorbed in the Museum of Science and Art, and must have been a great teacher to judge by the number of distinguished pupils that he trained, among whom were Edward Forbes, John and Harry Goodsir, Macgillivray, Nicol, and Darwin. The first of these succeeded him, but was cut off after a brief but brilliant career too well known to need description. The last of the past occupants of this chair, Wyville Thomson, has done the University of Edinburgh enduring honour by connecting it with that most fascinating of all the walks of modern natural science—the exploration of the deep sea.

The history of the Chair of Astronomy has been little but a record of misfortune, as far as the University is concerned. The first professor, Robert Blair, was endowed with a fair salary, but no Observatory was given him, and he never lectured or took any part in the work of the University. He is remembered chiefly for his researches on achromatic telescopes, which he brought to great perfection by means of fluid lenses of his own invention. The second professor, Thomas Henderson, was invested with the dignity and duties of Astronomer Royal for Scotland, and was provided with the present Observatory on the Calton Hill. He devoted himself ardently to his duties as an observer, and will be remembered as the first to determine the parallax of a fixed star (α Centauri). He never lectured. Where the blame of the unsatisfactory position of the Astronomy Chair and of the Edinburgh Observatory rests, and how the matter is to be remedied, is one of the vexed questions to be settled by the coming University Commission for Scotland.

The Chair of Technology was inaugurated with great promise of success by George Wilson, whose brilliant lectures and important services in connection with what is now the Museum of Science and Art showed how important such a chair might under favourable circumstances become. The chair was, however, abolished in 1859, under circumstances that do not appear to reflect much credit either on those who then acted for the Senatus, or on the Government department which was concerned in the transaction. It may be hoped that, now the importance of technical education is being recognised, the mistake then committed will be remedied. This is all the more to be desired because Edinburgh already possesses the rudiments of a technical faculty in the Chairs of Engineering and Agriculture.

There remains but one more Chair of Natural Science to be mentioned, viz. Geology. It numbers but one past professor, Archibald Geikie, concerning whom we need only express the wish that his followers may be worthy of him.

Although the subject scarcely belongs to these pages, yet no notice of the scientific side of the University of Edinburgh would be complete without at least an allusion to the glories of its medical school, which have attracted the admiration, if not occasionally the envy, of similar institutions. It may seem curious, but it began by the institution of a botanical, or, as it was properly then called, a physic garden. The keeper of this garden (originally, it is believed a member of the characteristically Scotch Guild of Gardeners), was after a time constituted (1676) the first Professor of Botany, and in fact the first medical professor.

If it were needful to insist farther upon the important place which the University of Edinburgh occupies among the educational bodies of Great Britain, we might point to the number of her students that now hold professorial chairs all over the United Kingdom, and indeed throughout the British Empire; and to the work which her *alumni* have done, and are doing, in science both pure and applied.

It might be profitable also to dwell on her defects, which she has in plenty, like other institutions guided by human brains, and endued with her own share of human inertia. But, as she has no want of candid critics, and is by and by to be put into the refining crucible, along with the other Scottish Universities, to emerge, let us hope, purified and strengthened, we may content ourselves with offering her, and asking of readers to join us therein, a hearty wish that she may prosper during the next hundred years as she has done during the present century.

G. CHRYSTAL

THE CONGO[1]

ALTHOUGH claiming to be little more than the record of a passing visit paid to the Lower Congo Basin towards the end of the year 1882, this is really a work of permanent interest to the naturalist and ethnologist. The author, a young and ardent student of biology in its widest sense, here conveys his impressions of West African life and scenery in a series of graphic pictures, which owe much of their freshness and vigour to the circumstance that they are always drawn at first hand from nature, and are often an exact reproduction of jottings made with pen and brush in the midst of the scenes described. His skill as a draughtsman he turns to good account by illustrating the text with numerous drawings of plants, animals, and human types, many of which are absolute fac-similes executed by the Typographic Etching Company.

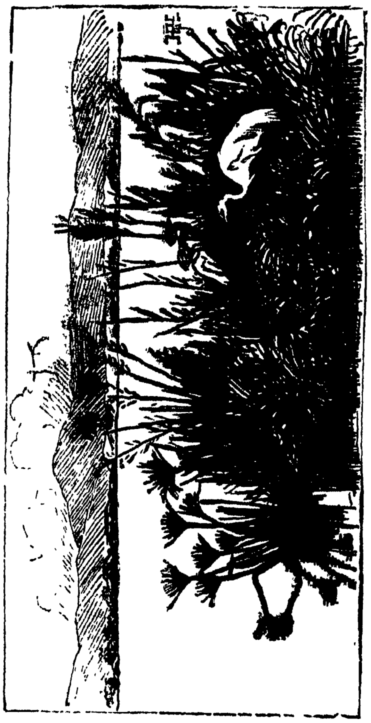

Fig. 1.—Floating Reed Island on Stanley Pool.

But Mr. Johnston does much more than merely describe in striking language the varied aspects of tropical nature revealed to his wondering gaze as he ascended from the low-lying marshy coastlands along the great artery from terrace to terrace to the grassy steppes and park-like uplands of the interior. Informed by the quickening influences of the new philosophy now accepted by all intelligent students of nature, he compares as he describes, carefully observes, and in apparently trifling incidents endlessly recurring throughout long ages he discovers the causes of mighty revolutions in the organic world. In Stanley Pool and elsewhere on the Congo he meets with numerous floating islands, tangled masses of aquatic vegetation, firmly matted together by their roots and fibres, and strong enough to bear the weight of a man (see Fig. 1). These, like the huge snags and trunks of trees borne along by the swift current, are thickly peopled with all forms of animal and vegetable life, which are thus carried a long way from their original homes. Hence the inference that "on many rivers these floating trees must serve as a great means for the diffusion of species" (p. 283). So also in his recent work on the "Indians of British Guiana," Mr. Im Thurn notices the presence of turtles on the logs and stems swept down the rivers of that region.

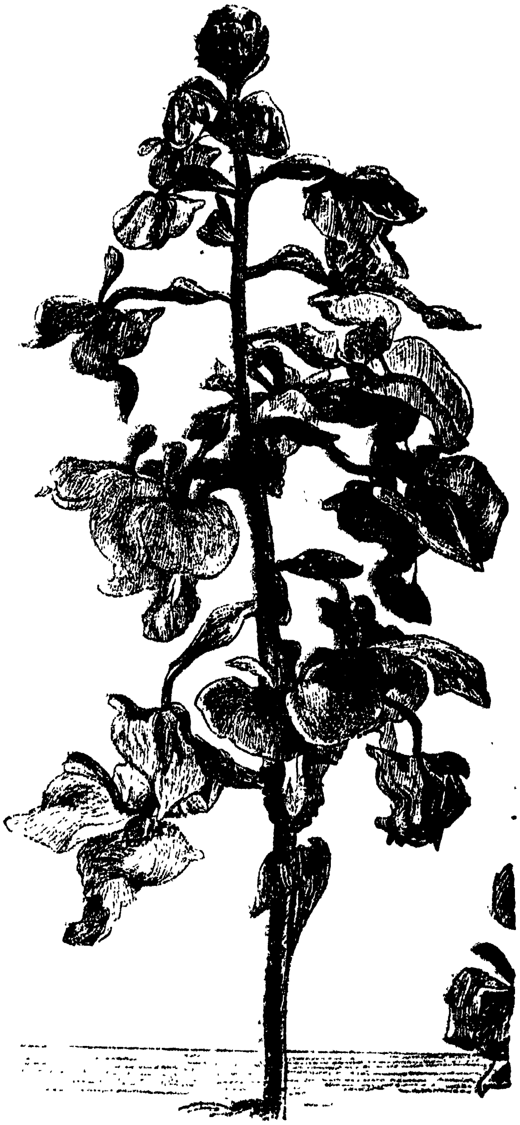

FIG. 2.—*Lissochilus giganteus.*

---

[1] "The River Congo, from its Mouth to Bólóbó," by H. H. Johnston, F.Z.S. (Sampson Low, 1884.)

Another inference is that the Congo cannot possibly form a true parting-line or natural boundary in the distribution of the West African flora and fauna. "I have read in many works on Africa that the Congo was the southern boundary of the habitat of the gray parrot, the anthropoid apes, and the oil-palm (*Elaïs guineënsis*). Now the gray parrot reaches, perhaps, its great development in Malanje, a district of Angola nearly 300 miles south of the Congo, and, together with the oil palm, continues to be found as far as the tenth degree south of the equator, while the anthropoid apes can hardly be said to be limited southward in their distribution by the lower course of the Congo, for they do not reach even to its northern bank, or approach it nearer than Landana, 100 miles away. . . . There are, besides, many West African plants which stretch right away from the Gambia, across the Congo, into Angola on the south. In short, I have never seen any difference between the fauna and flora of the northern and southern banks of this great river; nor do I believe that it acts in any way as a limitation in the range of species" (p. 318).

On another point also our explorer differs from some distinguished botanists, who hold that tropical vegetation is inferior in brightness and fragrance to that of the temperate zone. "Although the Congo offers nothing, as we yet know, that is unique as genus or family, yet probably nowhere in Africa are there such magnificent displays of colour formed by the conspicuous flowering trees and plants. Here, at any rate, no one can maintain that the temperate zone can offer anything equal in the way of flower-shows. Many of the blossoms also exhale strong odours, sometimes very offensive, but also in many cases fragrant and delicious. Few perfumes are more pleasing than the clove-like smell of the *Camoensia* or the balmy scent of the *Baphias*" (p. 324).

His botanical descriptions and sketches are generally admirable, as, for instance, of the *Lissochilus giganteus* (see Fig 2), "a splendid orchid that shoots up often to the height of six feet from the ground, bearing such a head of red-mauve, golden-centred blossoms as scarcely any flower in the world can equal for beauty and delicacy of form. These orchids, with their light-green, spear-like leaves, and their tall swaying flower-stalks, grow in groups of forty or fifty together, often reflected in the shallow pools of stagnant water round their bases, and filling up the foreground of the high purple-green forest with a blaze of tender peach-like colour, upon which no European could gaze unmoved'" (p. 35).

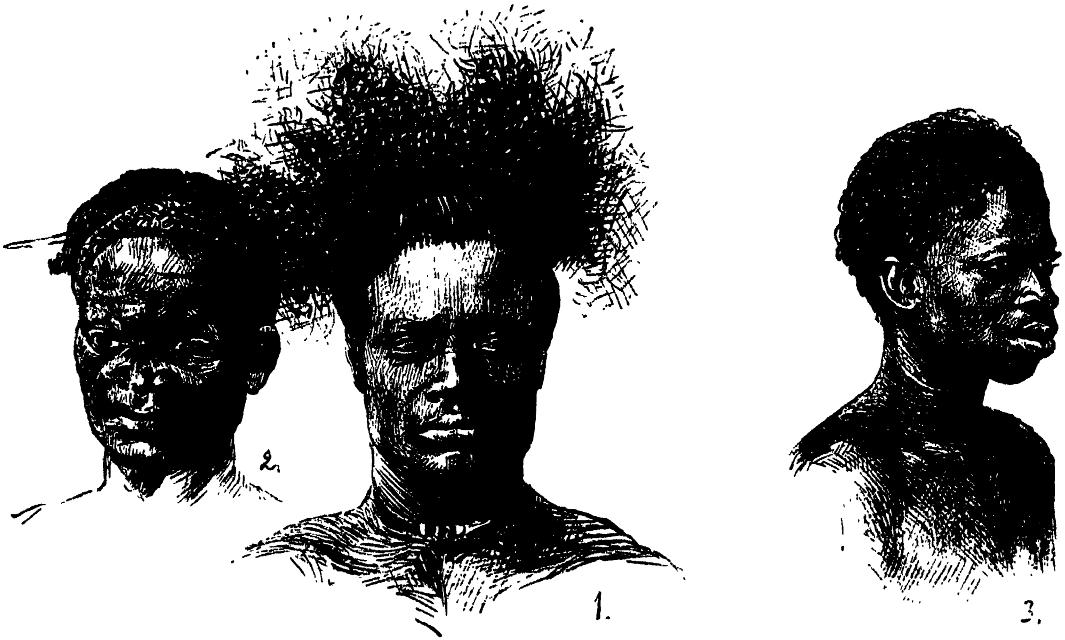

FIG. 3.—1, Mu-yansi; 2, Mu-téké; 3, Mu-shi-Kongo.

There is a deeply interesting chapter on the "People of the Congo," who, with the doubtful exception of some dwarfish or Bushman tribes, are all grouped in "that great Bantu family which, when seen in its purest exemplars, the Ova-héréro and Ova-mpo of the south-west, the tribes of the Zambesi, the people of the great lakes of Tanganyika and Nyassa, and the western shores of Victoria Nyanza, and finally of the Upper Congo, is so distinct, physically and linguistically, from the divers Negro, Negroid, and Hamitic populations to the north of it, and from the Hottentot-Bushman group to the south" (p. 396). Here we find the Bantus as a race distinguished by a good observer, not only from the Hottentots, Hamites, and Negroes proper, but even from the surrounding Negroid populations Further on the Bantus themselves are said to vary considerably in physical appearance, a statement fully borne out by the accompanying typical heads of a Mu-yansi, a Mu-téké, and a Mu-shi-Kongo (see Fig. 3). "The Congo tribes," we are told, "on nearing the coast, begin to lose their distinctive Bantu character, either through the degradation the coast climate seems to entail, or because on their migration westward from the north-east Bantu focus, they originally met and mixed with, in the low-lying coast-lands, an earlier Negro population. This latter supposition sometimes strikes me as being the true one, for the reason that, in such a littoral tribe as the Kabinda or Loango people, there are distinctly two types of race. One—the Bantu—a fine, tall, upright man, with delicately small hands, and well-shaped feet, a fine face, high thin nose, beard, moustache, and a plentiful crop of hair; the other an ill-shaped loosely-made figure, with splay feet, high calves, a retreating chin, blubber lips, no hair about the face, and the wool on his head close and crisply curled. The farther you go into the interior the finer the type becomes, and two points about them contrast very favourably with most of the coast races, namely, their lighter colour—generally a warm chocolate—and their freedom from that offensive smell which is supposed, wrongly, to characterise most Africans" (p. 397).

In this instructive passage all the facts are stated with tolerable accuracy. Yet the general inference cannot be accepted. There is, strictly speaking, no Bantu type at all, and the expression, correct in a linguistic sense, has no definite anthropological meaning. But for the fact that most of the peoples occupying the southern half of the continent speak dialects of a common mother-tongue, no ethnologist would ever have thought of grouping them together as forming a separate branch of mankind. Physically they must be regarded as distinctly Negroid, that is, an essentially mixed race presenting every possible shade of transition from the true Negro of Sudan and the West Coast to the true Hamite of the north-east coast. Between these two extremes they oscillate in endless variety, presenting nowhere any stable type distinct from either, and bound together only by the single element of their common Bantu speech. On the other hand, this Bantu speech itself is not Hamitic, but Negro, as clearly shown by the absence of grammatical gender. There appears to be also present a more or less distinct substratum of Negro blood in all the Bantu-speaking tribes, from the Mpongwés of the Gaboon to the Ama-Khosas of the extreme south-east, and from the Wa-Swahili on the East to the Ba-Congo on the West Coast. Hence these peoples should apparently be regarded rather as Negroes affected by Hamitic than as Hamites affected by Negro elements. In other words they are Negroid rather than Hamitoid.

The spread of a single organic speech of an extremely delicate structure over such a vast area, unaided by the prestige of letters, or by far-reaching political influences, is certainly a surprising phenomenon. But it is not without its analogues in other quarters of the globe, where we find an equal and even wider diffusion, for instance, of the Malayo-Polynesian, Ural-Altaïc, Aryan, Athabascan, and Guarani-Tupi forms of speech, also before the rise of literatures and great empires. And as no sound anthropologist regards the Aryan or the Malayo-Polynesian-speaking peoples as belonging to one physical type, neither can they regard the Bantu-speaking tribes as constituting a single ethnical group. All these terms, Aryan, Malayo-Polynesian, Bantu, are essentially linguistic, and as such have a definite meaning. Ethnologically they have little or no scientific value. It is noteworthy that, when not advocating theories, Mr. Johnston himself speaks of the Bantus of the Congo Basin as Negroes. Thus at p. 298, where he contrasts them unfavourably with the half-caste Wa-Swahili of Zanzibar, he writes :—"The mixture of Arab blood and Arab culture gives a stability and manliness to the Wa-Swahili which is lacking even in the finest race of pure Negro origin. The Congo peoples, for instance, are usually amiable and soft-mannered, but at heart they are seldom to be depended on. There is something so eminently childish in the Negro's character. . . . All these traits are found in the black races of Africa *that are of purely Negro or Bantu stock;* but in the Semiticised people of Zanzibar you find men of thought and reflection, whom you may use as counsellors and confidants; men who are really capable of zealous service, of disinterested affection, and to whom gratitude is a concept neither foreign to their intelligence nor their tongue." This is true and well put, and is the common experience of all travellers who have had dealings with the natives of South Central Africa. It shows at the same time that "even the finest" Bantu peoples must ultimately be affiliated to the Negro stock.

Besides the numerous illustrations, two useful maps and a copious index, this handsome volume is furnished with comparative linguistic tables of the chief Bantu languages current in the Congo basin, as well as full lists of the plants, birds, and mammals occurring in the same region.

A. H. KEANE

NOTES

EUROPEAN science has sustained a terrible loss during the past week. Monsieur Dumas, the venerable Perpetual Secretary of the French Academy of Sciences, died at Cannes on the 11th inst. at exactly the age of the century. Old as the great chemist was, his death will be felt as a real and serious loss to French science, for up to the last he took an active interest in all its doings. We gave in vol. xxi. so full a biography from the masterly pen of Prof. Hofmann of Berlin, that it is unnecessary to go over the ground again. We may, however, attempt in a future number to appreciate to some extent the position of Dumas in the chemistry of the past sixty years. The funeral took place at Mont Parnasse Cemetery on Tuesday, when MM. Bertrand, D'Haussonville, and others delivered addresses at the grave. The sitting of the French Academy of Sciences on Monday was postponed after the reading of an address by M. Rolland, the president, who praised M. Dumas for the talent and impartiality he exhibited as Perpetual Secretary of the Academy.

THE Museums of Economic Botany at Kew are second in importance to none in the world, and, except perhaps as to the size and splendour of the buildings, they are in every way worthy of a nation which has trade relations with every part of the globe. The foundation of these museums was laid by Sir W. J. Hooker in 1847, when he obtained leave to fit up an old fruit store with cases suitable for the exhibition of important vegetable products. Ten years later the house now known as Museum No. 1 was opened to the public, and in 1881 this was added to and the approaches greatly improved. It will be remembered that these buildings were not originally designed for museum purposes, and yet such is the arrangement of the cases and so well are the objects displayed and illuminated that we know of no museum built for the purpose that we would prefer to No. 1 Museum at Kew. The collections are contained in Museum No. 1, which is directly opposite the Palm House, on the other side of the Ornamental Water, in Museum No. 2, which is close to No. 1, at the northern end of the Herbaceous Garden, while Museum No. 3 occupies the old Orangery. At the north end of the Broad Walk the last Museum contains specimens of large timber, while the monocotyledons and flowerless plants are arranged in No. 2, and the dicotyledons in No. 1 Museum. An official guide to the contents of the latter Museum has just been published. As nearly every object exhibited is fully labelled, this guide-book does not enumerate a tithe of these, but a certain number of important objects are marked with a conspicuous number, and these numbers are referred to in the catalogue. In the 130 pages of this guide there is compressed a vast amount of information, a great deal of which is easily understood, even apart from the interesting collection on which it is founded; and if the student, as he walks through the Gardens, is struck at the beauty of the vegetable kingdom, he will, as he studies the products of that kingdom within these museum walls, be more struck at the extreme indebtedness of mankind to this kingdom for the necessaries and luxuries of life.

WE regret to learn that Sir Sidney Smith Saunders, C.M.G., for many years British Consul in various Mediterranean ports, and a distinguished entomologist, died suddenly on Tuesday evening (15th) at an advanced age. He was one of the original members of the Entomological Society of London, and was a vice-president of the Society at the time of his death. He devoted special attention to the singular bee-parasites known as *Stylopidæ*.

THE following are the arrangements for the lectures at the Royal Institution after Easter:—Dr. Klein, two lectures on the Anatomy of Nerve and Muscle, on Tuesdays, April 22 and 29; Prof. Gamgee, five lectures on the Physiology of Nerve and Muscle, on Tuesdays, May 6 to June 3; Prof. Dewar, seven lectures on Flame and Oxidation, on Thursdays, April 24 to June 5; Mr. Hodder M. Westropp, three lectures on Recent Discoveries in Roman Archæology, on Saturdays, April 26 to May 10; and Prof. T. G. Bonney, four lectures on the Bearing of Microscopical Research upon some Large Geological Problems, on Saturdays, May 17 to June 7. The following is a list of the Friday evening lectures:—April 25, the Art of Fiction, by Walter Besant; May 2, Krakatoa, by Prof. Judd; May 9, Mohammedan Mahdis, by Prof. Robertson Smith; May 16, the Dissolved Oxygen of Water, by Prof. W. Odling; May 23, Sidereal Astronomy, by Dr. David Gill; May 30, Sur les Couleurs (in French), by Prof. E. Mascart; June 6, Prof. Dewar.

BESIDES subjects of general anthropological interest, the following specially American topics, as to several of which Canada affords important evidence, are suggested for papers to be read in the Anthropological Section at the Montreal meeting of the British Association. The papers on each subject will, as far as possible, be grouped for reading on the same day, so as to insure a general discussion. (1) The native races of America: their physical characters and origin; (2) Civilisation of America before the time of Columbus, with particular reference to earlier intercourse with the Old World; (3) Archæology of North America, ancient mounds and earth-works, cliff-dwellings and village-houses, stone architecture of Mexico and Central America, &c.; (4) Native languages of America; (5) European colonisation and its effects on the native tribes of America. It is requested that all papers may be sent to the office of the Association, 22, Albemarle Street, London, W., on or before July 1.

THE International Ornithological Congress at Vienna was brought to a conclusion on Friday last by an appropriate speech from its patron, the Crown Prince Rudolph, who, among other things, warmly thanked the scientific men from abroad for their appearance in Vienna. The next Congress will not take place till three years hence, and will be held in Switzerland. The Crown Prince has accepted the honorary office of Patron of the Permanent International Committee for the Establishment of Ornithological Observatories, or stations for the observation of the habits of birds, especially those of the migratory species. Prof. Blasius, the president of the third section, to whose sphere the subject belongs, explained the nature, object, and importance of such ornithological stations of observation. M. Rodde proposed that the meteorological stations should be used as ornithological ones. Dr. Schier of Prague afterwards gave an account of his efforts to secure a regular system of observation. He had received from some hundreds of correspondents many valuable notices in regard to the line of passage of migratory birds.

THE Academy of the Lincei have elected Prof. Francesco Brioschi, a senator, to fill their presidential chair recently left vacant by the death of Signor Quintino Sella, electing at the same time Commendatore Fiorelli, who so long directed the excavations at Pompeii, to fill the office of vice-president. The new president, Signor Brioschi, is a distinguished mathematician.

AN interesting little volume appears this week in Edinburgh containing an annotated list of the illustrious dead who have been in any way connected with Edinburgh University. The names are classified according to the departments with which they are connected, "Zoologists and Botanists," for example, beginning with Erasmus Darwin and ending with Charles Darwin. The brief notes attached to the names have, we believe, been compiled by various specialists.

THE Anthropological Institute will hold its first meeting in its new premises, No. 3, Hanover Square, on the 22nd instant.

THE next Ordinary General Meeting of the Institution of Mechanical Engineers will be held on Thursday, May 1, and Friday, May 2, at 15, Great George Street, Westminster. The Chair will be taken by the President, Mr. I. Lowthian Bell, F.R.S., at half-past seven p.m. on each evening. The following papers will be read and discussed as far as time will admit:—On Thursday, May 1, on the consumption of fuel in locomotives, by M. Georges Marié, of Paris; on portable railways, by M. Paul Decauville, of Petit-Bourg, Paris; on the Moscrop engine recorder, and the Knowles supplementary governor, by Mr. Michael Longridge, of Manchester. On Friday, May 2, description of the automatic and exhaust-steam injector, by Mr. A. Slater Savill, of Manchester; description of the apparatus used for testing current-meters, at the Admiralty Works at Torquay for experimenting on models of ships, by Mr Robert Gordon, of Burmah; description of the Francke "Tina" or vat process for the amalgamation of silver ores, by Mr. Edgar P. Rathbone, of London.

THE Report of the U.S. Solar Eclipse Expedition, *Science* states, has just been ordered to be printed by Congress. Among its contents are:—Meteorology of Caroline Island, by Mr Winslow Upton. Botany of Caroline Island, collections by Dr. W. S. Dixon, U.S.N., and identifications by Prof. W. Trelease; Notes on the zoology of Caroline Island, by Dr. W. S. Dixon, U.S.N.; Memorandum on the butterflies, &c., of Caroline Island, collections by Dr. J. Palisa, identifications by Messrs. Herman Strecker and Arthur G. Butler; Chemical constituents of the sea-water of the lagoon of Caroline Island, determined by Messrs. Stillwell and Gladding; Observations of twenty-three new double stars, by Prof. E. S. Holden and Prof. C. S. Hastings; Plans for work on the day of the eclipse, by Prof. E. S. Holden.

FROM *Science* we learn that at the request of the Navy Department, the Fish Commission steamer *Albatross*, Capt. Tanner commanding, was fitted out during the winter for the purpose of carrying on a series of deep-sea soundings and dredgings in the Caribbean Sea, a region very little known in respect to its depths. The vessel left Washington on January 1, and reached St. Thomas on the 17th, and, after coaling, proceeded on her voyage, making the following ports:—Curaçoa, Trinidad, the Island of Oruba, Alta Vela, Jacmel, Gonaives, Santiago de Cuba, Navassa, and Kingston (Jamaica), where she arrived March 1. She left Kingston March 11, and arrived at Aspinwall, *viâ* Savanilla, March 25. On her return from Aspinwall she will proceed *viâ* Cape San Antonio to Key West, expecting to arrive at the Washington navy-yard about the middle of May. The expedition has been a great success in all respects, numerous satisfactory series of soundings and temperatures having been taken, and large numbers of marine animals obtained. In the collections incidentally obtained during the stay of the steamer at Trinidad were two specimens of the guacharo bird, *Steatornis caripensis*, which is such a rarity in museums, and two of the great fishing-bat.

ON Easter Monday the Essex Field Club held a meeting at Saffron Walden, about sixty members and visitors being present. Alighting at Audley End Station, the party drove to Lord Braybrooke's mansion, where they had an opportunity of inspecting the fine collection of birds and prehistoric and Roman antiquities contained in the museum. The Club was then conducted to a neighbouring hill, known as Ring Hill, where an ancient circular entrenchment is to be seen, and from there proceeded to a wood known as Peverels, where the true oxlip (*Primula elatior*) grows in profusion, the ground being in parts carpeted with the flowers of this interesting species. After luncheon a visit was paid to Mr. Joshua Clarke, F.L.S., at his residence, Fairycroft, and the visitors viewed the magnificent collection of humming-birds and birds of Paradise formed by this gentleman. The Club next assembled in the grounds of Mrs. Gibson, and inspected the site of the ancient Saxon cemetery and the collection of skulls and relics found therein during the excavations undertaken by the late Mr. G. S. Gibson, a full description of which has been published in a recent number of the *Transactions of the Essex Archæological Society*. The splendid library of scientific and other works belonging to the late Mr. Gibson having been hastily viewed, and the party having partaken of the hospitality offered by Mrs. Gibson, they were next conducted to the Saffron Walden Museum, where the various collections were greatly admired, and the curator, Mr. Maynard, much complimented upon the ability and zeal which he had displayed in their organisation and arrangement. In the ruins of the ancient castle adjoining the Museum Mr. Maynard read a paper on the history of these remains, and the party then proceeded to view the church, under the guidance of the Rev. Mr. Stevens. After tea an ordinary meeting of the Club was held, the president, Prof. Boulger, being in the chair. A paper, on the cultivation of the saffron in connection with the old town of Saffron Walden, was read by Mr. Joseph Clarke. With the object of promoting the extension of natural history science throughout the county, the Club proposes to establish local centres in the chief towns of Essex, and arrangements will shortly be made to commence operations at Saffron Walden, where so much interest was shown in the visit of the Club.

On Saturday next, April 19, at three o'clock, a meeting of the Essex Field Club will be held at the British Museum of Natural History, South Kensington, under the direction of Dr. Henry Woodward, F.R.S. Dr. Woodward will deliver an address in the lecture-room on "Wingless Birds," and afterwards give a demonstration of the species, extinct and recent, in the geological and zoological galleries.

The Council of the Linnean Society of New South Wales have been presented by a member of the Society with 100*l*., accompanied with a request that it should be offered as a prize for an essay on "The Life History of the Bacillus of Typhoid Fever." The Council has assented to the proposal, and advertisements to that effect will be immediately inserted in the most prominent scientific publications throughout the world. The essay will be received by the Society not later than December 31, 1884. The intention and wishes of the donor of the prize will be best given in his own words. "The questions chiefly to be solved in the investigation of the life history of the *Bacillus* of typhoid fever, are—1. What are the specific characters of the organism, as distinguished from other *Bacteria*? 2. What are the changes, if any, which the organism undergoes in the human body? 3. What are its modes of development and reproduction in the human body? 4. What changes or metamorphoses, if any, does the organism undergo after ejection from the human body, or in any other condition of its existence? 5. What fluids or other substances seem best adapted for the growth and multiplication of the organism? 6. Can the organism live or be cultivated in pure or distilled water? 7. What are its limits of endurance of heat, cold, dryness, or humidity? As far as these points are concerned the author should confine himself entirely to facts which come under his own observation, and those should be given in detail, with a full explanation of the method of investigation. But in dealing with the results obtained by these investigations, and the consideration of the means whereby a knowledge of the life history of this most dangerous organism may help towards its eradication, the theories and observations of others may appropriately be referred to, but in every such case the authority must be correctly cited. The chief points to be ascertained in this branch of the subject are—1. How, and under what conditions, does the organism get access to the human body? 2. How can its growth be impeded, or its vitality destroyed in the human body without serious injury to the individual affected? 3. How can it be eradicated or rendered innocuous in wells, water-holes, drains, &c."

Among the superabundant "Universities" of the United States, Harvard is unquestionably taking its place as a national institution on a par with British establishments which hold a similar designation. The last quarterly *Bulletin* of its proceedings is before us, which has to acknowledge during that short time nine legacies or donations in money, varying from 200 to 100,000 dollars, and amounting to 168,000 dollars. One of these is 10,000 dollars subscribed for the purchase of meteorites, and another is 2000 dollars from the Massachusetts Society for Promoting Agriculture, to assist in the establishment of a veterinary hospital, to which institution also a collection of pathological models is presented. Other donations are, a new building for the law schools, two portraits of eminent divines, and the anatomical collection of a doctor who had previously founded a museum there. The *Bulletin* is edited by the well-known Harvard librarian, Mr. Justin Winsor, and a very carefully printed catalogue of the chief accessions to the University library in English, French, German, Italian, Spanish, Danish, Russian, Polish, and Hindustani, forms the bulk of it. Many of these additions are treasures which few libraries can acquire possession of, a few only of which have been printed, chiefly for private circulation, others, nevertheless, being both important and familiar books published a year or two ago. The books are divided into ten subjects, and it shows how different technical experience sometimes is from theoretical ideas, when so experienced a librarian finds it convenient to class together "History and Geography," while "Antiquities" are under a separate heading. We doubt, however, whether Izaak Walton or any one else would have looked for "The American Angler's Guide; or the Complete Fisher's Manual for the United States," under the head of "Law and Sociology," even if "Caxton's Game and Play of the Chesse" may in some sense belong to the latter. The advantages possessed by the librarian of such an institution as this are being fully utilised by Mr. Justin Winsor who is issuing in each number of the *Bulletin* most carefully written results of his researches into the bibliography of various subjects—in this January number, of "Ptolemy's Geography" and "The Kohl Collection of Early Maps," specially noting the gradual and irregular spread of the knowledge of America.

A stalactite cavern was recently discovered by accident near Cerdon in the Ain Department (France). It is situated near the old high road connecting Lyons with Geneva. Some country people who ventured into it state that it extends about 300 metres underground, and that its height varies considerably. Lyons and Geneva naturalists are now making a more minute investigation of the cave.

A strong shock of earthquake was felt at Urbino at a few minutes before 8 a.m. on the 9th inst. Its duration was five seconds. A shock was also felt at Belpasso, near Catania, at 10 a.m. on the 10th. It occasioned no damage.

Owing to the frequent earthquakes that have recently occurred in Slavonia, Prof. Pillar has been sent to observe these occurrences by the Hungarian Government, and will shortly present a detailed report to the Government on the subject.

According to Herr Jæger of Rinde, on the Sogne Fjord, who, since 1858, has noted the number of earthquake shocks that have been felt in the district, there have been appreciable shocks from that period till 1879. Since the latter year no shock has been felt. It is worthy of record that on two occasions, viz. in 1860 and 1865, the shocks were perceived on the south side of the fjord, the districts on the northern coast being wholly undisturbed.

THE last number of the *Transactions of the Seismological Society of Japan* (Yokohama, 1884) contains various papers on seismology. The first is by Prof. Milne, on earth pulsations; the next is by Mr. Alexander, on the interpretation of a diagram described by a particular form of earthquake instrument. The object of the writer is to calculate not only the maximum velocity, but also the maximum rate at which the velocity changes, "which is a measure of the effect which an earthquake exerts in overturning and fracturing bodies placed on the earth's surface." Prof. Ewing describes the construction of a pendulum which shall be without a tendency to swing when the point from which it is suspended suffers displacement. Mr. Gergens gives a note on ripple-like marks found on the surface of an iron casting supposed to have been shaken while solidifying, which marks are picturesquely described as "a note in a congealed earthquake." The remainder of the volume is occupied by suggestions for new types of seismographs, a list of earthquakes in Tokio, and a report on systematic earthquake observations.

A CORRESPONDENT in *Naturen* has drawn attention to the great differences of climate observable last winter between Christiania and Stavanger. While in the former place there was a depth of from ten to twelve inches of ice during the month of January, vegetation had never been wholly arrested in the latter region at the same period. The grass plots in the various gardens at and near Stavanger were as green as in summer: daisies, snowdrops, pansies, violets, and primroses had their blossoms well set; peonies had appeared above the ground, and many roses had thrown out vigorous shoots. The thermometer fell only once in January to freezing point.

MM. MIGNON AND TOUARD, who established the refrigerating service at the Paris morgue, have made experiments with their system on hams infected by trichinæ, and are stated to have proved that these are rendered wholly innocuous by exposure during an hour to a cold of – 20° C. It will be proposed for the protection of consumers from trichinosis to render exposure obligatory in the case of importations from America or Germany.

THE great work of lighting the Paris Opera by incandescent light has already begun. The whole house will require 6000 lamps; at present 400 lamps are used.

THE additions to the Zoological Society's Gardens during the past week include a Pig-tailed Monkey (*Macacus nemestrinus* ♀) from Java, presented by Dr. Benthall; a Weeper Capuchin (*Cebus capucinus* ♀) from Brazil, presented by Miss Vincent; a Short-eared Owl (*Asio brachyotus*), British, presented by Mr. Oscar Burrows; a Smooth Snake (*Coronella lævis*), a Common Viper (*Vipera berus*), a Common Snake (*Tropidonotus natrix*), a Slow-worm (*Anguis fragilis*) from Hampshire, presented by Mr. W. H. B. Pain; an Alligator (*Alligator mississippiensis*) from the Mississippi; a Horrid Rattlesnake (*Crotalus horridus*) from Florida, presented by Mr. A. Begg; a Philantomba Antelope (*Cephalophus maxwelli*) from South Africa, deposited; a Moose (*Alces machlis*) from North America, two Mute Swans (*Cygnus olor*), European, a Common Viper (*Vipera berus*), British, purchased; six Long-fronted Gerbilles (*Gerbillus longifrons*), born in the Gardens.

GEOGRAPHICAL NOTES

WE much regret to learn of the death, at Loanda, on March 17, of Dr. Paul Pogge, the successful African explorer. Dr. Pogge, since 1880, was the companion of Lieut. Wissmann in the exploration of the region inland from the Portuguese possessions, and around the kingdom of Muatà Janvo. He accompanied Wissmann as far as Nyangwé in the journey of the latter across Africa, and in May 1882 set out to return to the station at Mukenge. Doubtless the hardships to which he has been subject, combined with fever, have told on Dr. Pogge's health. In 1874 he was a member of the German African Expedition which was sent out to explore the same region, and with only native companions succeeded in penetrating as far as the capital of Muatà Janvo.

THE announcement that Mr. Stanley intends to proceed from the Middle Congo north-east to the Mombuttu country, partly, no doubt, to settle the question of the course of the Aruwimi, the great north-east tributary of the Congo, renders Dr. Junker's discoveries in the Wellé region of special interest. In the map sent home and published in the new number of *Petermann's Mittheilungen* we find in the northern part the Wellé, after receiving the Gádda, proceeding west-north-west, and on the north it is joined by the Mbrúŏle, and not much further westwards by the Gúrba—both considerable rivers rising in the southern A'-Sandeh kingdom. After taking up the waters of the Gúrba, the Wellé curves sharply round, at first southwards, making many windings in its course, and describing a large semicircle round the land of A-Madi, a semicircle variegated by a series of islands. Later on it resumes its west and west-north-west direction. With the exception of the two larger tributaries from the north just mentioned, the Wellé along the whole extent of the sketch receives no considerable waters either from north or south. As far as the southern territory is concerned, this fact is explained by the circumstance that the most important tributary of the Wellé-Makua, the Bomokándi or Májo (Nemajo of Schweinfurth) flows in an extremely long course from east to west and north-west, approximately parallel to the Wellé Hut, an interval of hardly two days' journey. Further to the west, however, it discharges into the Wellé River. The Bomokándi, showing almost half the breadth of the Wellé, rises far in the east, and may also have its source in the mountainous country bordering the Albert Nyanza in the west. In consequence of this approach to each other of the two streams, no other tributaries are developed in the long tongue-shaped peninsula formed by the junction of the Wellé and Bomokándi. Except innumerable little rivulets, few rivers of any size run either northwards to the Wellé or southwards to the Bomokándi from the plateau of this peninsula. It is otherwise, however, with the rivers discharging into the Bomokándi from the south. The watershed whence flow its southern tributaries lying considerably further to the south, there is ample scope here for the formation of larger accessory streams. Proceeding from west to east, we come upon three rivers of almost equal rank with the Mbrúŏle and the Gúrba—the Makongo, Pokko, and Telli. A river no longer paying tribute to the Bomokándi, but discharging further to the west directly into the Wellé, is, according to information, the Mbe'lima, the source of which is not far from that of the Makongo to the east. With these partly indirect tributaries to the Wellé through the medium of the Bomokándi and the direct tributary, the Mbe'lima, the river-system of the Wellé to the south comes to an end. Further south, and flowing from east to west, is the Náwa, belonging, according to information received, to a more southern river-system, forming indeed a northern tributary to the Népoko. Dr. Junker made his way south to the Népoko, four days' journey from the Bomokándi, and reached it in the middle of its course, where it holds the same longitude with the Bomokándi. He evidently travelled a long way from the region in which lie the sources of the Népoko, the Bomokándi, and the Kibuli, that is, the Kibbi (Wellé)—rivers which collectively descend from the mountain and table-lands west of Albert Nyanza; the water-parting must be sought in a line running approximately from south-south-west to north-north-east. That the Népoko, from the point at which he met it, and where probably it describes a northern curve, bends in its further course in an approximately south-west direction, may be inferred from the fact that though indeed known in the western territories, it is yet transferred far to the south beyond the Náwa, which rises in the west, not far from his line of route to the Népoko. In the region between Bomokándi and Népoko traversed by Dr. Junker, the watershed of the two river-systems is hardly perceptible, yet the country of the Népoko tributaries from the north is highly characteristic. Instead of the high trees which everywhere else clothe the banks of the streams, you here meet broad, flat, treeless swamps. A floating vegetation, very like the Ssett in the Nile, forms a bridge by which to cross these swamps, though it is unavailable for riding and for beasts of burden. Dr. Junker closes his remarks on the hydrography of this region with the observation that he feels entitled to identify this Népoko, which does not belong to the Wellé system, with the Aruwimi of Stanley. Proof that the Wellé is the upper course of the Shari he hopes to be able to adduce later on.

In *Petermann's Mittheilungen*, 1884, Heft iii., is a map of the Amambara Creek of the lower Niger region, which we owe to the indefatigable African explorer Eduard Robert Flegel. Just as by way of preparation for his Adamawa expedition he executed maps of the route from Eggan to the Akoko Mountains, and of the Niger tract, till then unknown, from Bussa up the river as far as Gomba, and finally explored the route from Bidda by way of Keffi Abd-es-Senga to Loko on the Benuë; so now as preparatory to his third African exploration he has executed a map of the Amambara which discharges into the lower course of the Niger. While Flegel was waiting at Lagos for a remittance from Germany to enable him to prosecute his travels, the representative of the Marseilles "Compagnie du Sénégal et de la Côte occidentale d'Afrique," J. Zweifel, the well-known discoverer of the sources of the Niger, undertook in July 1883, for trading purposes, an expedition up the Amambara, on the banks of which are planted a series of old commercial establishments, but which, nevertheless, had never yet been mapped out. To this expedition Flegel at once gladly joined himself, and hence the map in question. This must be reckoned as another valuable contribution towards clearing up the geography of the Lower Niger, so complicated by tributaries, arms, deltas, creeks, &c. In an article in the *Mittheilungen* commenting on the map of the Amambara Creek, an interesting sketch is given of the progress of geographical knowledge of the Niger for the last 300 years, or rather of the misconception and vacancy that prevailed up till quite recently regarding that region, our knowledge of which is still so very defective. Since the discovery of the rich produce in palm-oil yielded by the banks of the Niger and Lower Benuë, trade has rapidly developed there, and is now so lively that Flegel, in 1883, counted as many as twenty-three large ships, mostly steamers, constantly plying on their waters, besides a series of flat barges.

We find in the last issue of the Caucasian *Izvestia* the following new information on the Merv oasis, due to M. Alikhanoff:—Its surface is about 2150 square miles, which area could be increased by irrigation, the whole of the oasis having its origin due to the irrigation of the sands by canals drawn from the Murgab. This river, being dug at Kaushut-khan-bend, two canals, subdivided into numerous *aryks* (smaller canals), issue from it, taking in nearly all the water of the river which does not flow beneath the dam. Notwithstanding the southern position of the oasis, it has a cold winter, and there falls every year some snow, sometimes two feet deep; it soon disappears, however, as the temperature rises rapidly, and reaches occasionally 30° Celsius in February. During the summer, strong hot winds, which bring masses of hot sand, blow, mostly from the south-west. Still the climate is healthy enough, and healthier than that of Akhal-tekke; but the mortality is very great, owing to the poverty of the inhabitants and the dirtiness of their habits: the *kara-masta*, or black disease, a kind of pestilence, and the *merghi*, a kind of cholera, are endemic. The population is estimated at 32,700 *kibitkas*, which M. Alikhanoff considers to represent no less than 194,000 or 200,000 inhabitants. This population is, however, too numerous for the oasis, the average area of irrigated land being only six acres per inhabitant. M. Alkihanoff considers the Mervis as the least attractive of the Turcomans, and discovers in them only one good feature—their hospitality.

At the annual meeting of the Bremen Geographical Society it was stated that a young German naturalist intends to start on an exploring expedition to Ovambo-land and further into the interior of Equatorial Africa, accompanied by Dr. Hoepfner. A member of the Society has presented him with good astronomical instruments, and the traveller will report to the Society from time to time, and his cartographic results will belong to the Society. The Society is also preparing a geographical and natural history expedition to the Bonin Islands, lying south of and belonging to Japan. Dr. Gottsche of Kiel, an eminent geologist, who is now in Japan, will be the leader of this expedition.

The Russian Imperial Geographical Society has received the following telegram from Col. Prjevalsky, who is for the fourth time attempting to penetrate into Thibet:—"Alashan, January 8.—We have traversed the desert of Gobi without mishap. In the northern part the cold exceeded the freezing point of mercury. We are all well, and start to-morrow for Koukou-nor. It is said that hitherto the Thibetans pray heaven to shower down stones on our heads."

The Melbourne *Age* has despatched to New Guinea a second exploring party, the members of which include a naturalist and an artist.

One result of Mr. Colquhoun's recent journeys in Indo-China has been the appointment of an English official to reside at Cheng-mai, or Zimmé, on the borders of the Shan States, and an officer of our consular service in Siam has been selected for that purpose, and is now at the post. This town, it may be recollected, forms the centre of the railway communication which Mr. Colquhoun proposes between British Burmah and South-Western China, and it can be reached either from Rangoon or from Bangkok. Mr. Bock travelled from the latter town up the Meinam. With the example of the exploration of the English consuls who have resided at Chung-king on the Yangtsze before him, it is to be hoped that the consul at Zimmé will be able to add largely to our knowledge of the regions, especially of the Shan States, lying between China and Siam. His appointment is certainly another step in the prolonged efforts to obtain a trade route into South-Western China, and he will serve, on the south of the frontier line, the same purpose as the officer at Chung-king on the north.

VOLCANIC ASHES AND COSMIC DUST[1]

In the session of 1876, Mr. John Murray communicated to this Society a paper on the distribution of volcanic debris over the floor of the ocean,[2] and in it announced the discovery of cosmic dust in deep-sea deposits. It was shown that at points where neither the action of waves, rivers, or currents can transport the debris of continents, volcanic materials play the most important *rôle* in the formation of the mineral constituents of the deep-sea deposits. It was pointed out that pumice, on account of its structure, was able to float to great distances, but in time became waterlogged and sank to the bottom, there to decompose. On the other hand, incoherent volcanic matters, ejected in the form of lapilli, sand, and ashes, into the higher regions of the atmosphere, may, *cæteris paribus*, be conveyed, in consequence of their small dimensions and structure, to greater distances than other mineral particles derived from the continents. The possibility was also admitted that submarine volcanic eruptions might also contribute to the accumulation of those silicates and pyrogeneous minerals and rocks whose microscopic characters and distribution at the bottom of the sea we shall presently point out.

During the past few years we have added greatly to the observations which were the subject of Mr. Murray's communication. The present paper has been suggested by the striking analogy which exists between the volcanic products we have found in all deep-sea sediments, and the ashes and incoherent products of a recent celebrated eruption,—that of Krakatoa. The remarkable meteorological phenomena we have recently witnessed have been attributed by some to the presence in the atmosphere of mineral particles derived from this volcanic eruption, and by others to that of cosmic dust. It is said that in several places in America, and even in Europe, matters have been collected which must be regarded as the ashes from Krakatoa, which have been suspended for several months in the upper currents of the atmosphere. The importance of this matter has been recognised by the Royal Society of London, which has appointed a committee of its members to collect all the documents and observations relative to the distribution of these ashes. The present state of the question induces us to make known some results of the detailed researches which we have undertaken upon similar subjects. We desire to make known, to those who wish to study atmospheric dust, the distinctive microscopic characters by the aid of which we have been able to establish the volcanic or cosmic nature of certain particles found in deep-sea deposits, and to show at the same time the enormous area of the ocean over which we have been able to detect their distribution.

We believe that no better example could be found in support of our interpretations than the microscopic study of the ashes from Krakatoa, whose mineralogical and chemical composition M. Renard[1] was the first to make known, and whose observations on this subject have been amply confirmed by the later researches of other mineralogists. On the other hand, the conditions under which floating pumice was found after that eruption agree perfectly with the interpretation given eight years ago by Mr. Murray relative to the mode of transport of these vitreous matters and of the accumulation of their triturated debris on the bottom of the ocean. We shall also see how the sorting which takes place in the transport of the ashes of a volcano has its analogy in what we find in the deep-sea deposits.

---

[1] "On the Microscopic Characters of Volcanic Ashes and Cosmic Dust, and their Distribution in the Deep-sea Deposits." A paper read before the Royal Society of Edinburgh by Mr. John Murray and M. A. Renard.

[2] *Proc. Roy. Soc. Edin.*, 1876-77.

In the first part of this communication we shall give the mineralogical description of the fragmentary products of Krakatoa, and consider generally the observations relative to these ashes. We shall also give the diagnostic characters of this volcanic dust, and of all similar particles which we find in deep-sea deposits. In the second part we will treat of the cosmic matters found in the abysmal regions of the ocean, to which Mr. Murray was the first to draw attention, and discuss their origin and distribution.

FIRST PART

It is unnecessary to refer to the abundance of floating pumice, to its various degrees of alteration, to its conveyance by means of rivers, waves, and currents, and to its universal presence in deep-sea deposits, which have been pointed out in some detail in Mr. Murray's paper above referred to; but we will briefly recapitulate the characters of these volcanic matters, in accordance with the examination we have made of a large number of soundings and dredgings. We need not describe in detail the special characters of the lapilli which have been brought up in the dredge and sounding-rod from great depths. These fragments of more or less scoriaceous rocks belong to the same lithological varieties as those derived from terrestrial volcanoes. They consist of fragments of trachyte of various dimensions, of basalt, and, above all, of augite-andesite; the most remarkable, beyond all question, being lapilli of sideromelan, which are often entirely transformed into palagonite, and pass into the clay which is found so widely distributed, especially in the Pacific.

We do not propose here to take up in detail the wide distribution of the materials ejected from Krakatoa; we are engaged in collecting these, and will place the observations on maps along with those of Mr. Buchan on the upper currents of the atmosphere, which will be published in the *Challenger* Reports.

Before, however, passing to the description of the ashes themselves, we will briefly refer to some points touched upon by Mr. Murray in his paper. It is there pointed out that, in regions far removed from coasts, rounded fragments of pumice were collected on the surface of the sea by means of the tow-net, and that, at certain points on the bottom of the ocean, the greater part of the deposit is composed of vitreous splinters derived from the trituration of pumice-stones. The description of the phenomena connected with the Krakatoa eruption gives us a complete explanation of these observations. The specimens of pumice from Krakatoa, which have been collected floating on the sea and which we have examined, are in like manner rounded. The angular surfaces are all worn away just as in pebbles; the only asperities to be observed consist of crystals and fragments of crystals, which project beyond the general surface of the vitreous matter, which last, on account of its structure, presents less resistance to wear and tear than the minerals which are embedded in it.

We may recall the fact that the Bay of Lampong, in the Straits of Sunda, was blocked by the vast accumulation of pumice, formed in a few hours by the eruption of Krakatoa, which completely filled the bay. This floating bar of pumice-stones was about 30 km. long, 1 km. broad, and 3 m. to 4 m. in depth, 2 m. or 3 m. of which were below the surface of the water, and 1 m. above. These numbers give about 150 millions of cubic metres of ejected matter. This moving elastic wall rose and fell with the waves and tide,[2] and was carried by currents thousands of miles from the point of eruption over the surface of the ocean. The rounded form of blocks of pumice met with everywhere floating on the surface of the sea, as well as of those samples which, after having floated some time, became waterlogged and sank to the bottom, may be perfectly explained if we remember the friability of this rock, and, at the same time, the agitation to which it is submitted by the waves, through which the pieces are continually being knocked against each other. We understand also how this wear and tear gives rise to an immense quantity of pulverulent pumice fragments, which contribute in a great measure to the formation of oceanic deposits. As a matter of fact, rounded fragments of pumice have been met with floating on the surface of every ocean, and during the last few years many samples have been sent to us by captains of ships and missionaries. As has been already pointed out, they are universally distributed in oceanic deposits, although frequently highly altered.

If it be easy to pronounce upon the volcanic nature of these larger fragments, it becomes, on the other hand, exceedingly difficult when we have to deal with particles reduced to powder, and when recourse must be had to the microscope. Let us see what are the microscopic characters by which we recognise the particles of this dust.

We may here point out that it is not so much the presence of volcanic minerals which enables us in a marine sediment, as well as in an atmospheric dust like the ashes of Krakatoa, to recognise that the small fragments have an eruptive origin, as the microscopic structure of the small vitreous particles. It is well known that minerals reduced to small dimensions and irregularly fractured, as in the case of volcanic ashes, often lose their distinctive characters. Their size does not allow us to judge of their optical properties; their form, irregular and fragmentary, renders it difficult to determine the characteristic extinction of the species; the phenomena of coloration, of pleochroism, and the tint peculiar to the mineral, all lose so much of their intensity that they no longer serve for the identification of isolated minerals like those of the volcanic ashes which we have to study. As a result of our observations, we believe that in most cases where a mineral, under the conditions we have just described, reaches dimensions less than 0·05 mm., its determination with certainty is no longer possible, and consequently its origin can no longer be established; whilst a vitreous fragment, like those of volcanic ashes or triturated pumice, continues to be discernible when its dimensions are less than 0·005 mm. A reason for showing that the absence or rarity of crystals, or of fragments of volcanic crystals, ought not to be taken as a proof that a sedimentary matter, either from the atmosphere or from the deep sea, is not of volcanic origin, is the sorting process to which these matters are subjected in the air and in the water, a phenomenon to which we shall presently recur.

The most reliable distinctive character is always found in the structure of the small vitreous particles which are derived from the trituration of pumice or have an analogous origin, inasmuch as they have been ejected from the volcano in the state of ash. The structure peculiar to these materials is seen in their fracture, which leaves its impress upon the smallest fragments of debris, in which the microscope can decipher no characteristic properties except such as have relation to form. In order to assure ourselves that these characters of pumice remain constant to the extreme limits of pulverisation, such as are employed in the preparation of silicates for chemical analysis, we pounded in an agate mortar several varieties of pumice, and the powder thus produced clearly showed itself to be composed of particles in which were recognisable, with little trouble, the characters of the pumice-like material which is constantly met with in the sediments, and of which the ashes of Krakatoa give us beautiful examples. The diagnostic character to which we here make allusion rests on the distinctive peculiarities of incoherent volcanic products. What distinguishes them from lavas is not merely the extraordinary abundance of vitreous matters, but also the prodigious number of gas-bubbles which are inclosed by the pumice and vitreous volcanic sands and ashes. These bubbles are due to the expansion of the gases dissolved in the magma, which also determine the eruption. If we admit, as everything seems to show, that these incoherent volcanic matters are the products of the pulverisation of a fluid magma, we can understand that these particles, on cooling rapidly, will remain in the vitreous state, and, on the other hand, that the dissolved gases, yielding to the expansion, will form numerous pores which will become elongated owing to the mode of projection. It is the existence of these bubbles, or of such a filamentous structure, which points out to us the vitreous volcanic materials in spite of the great fineness of subdivision. It is also this structure which allows these bodies to be carried to such great distances from the scene of eruption.

The examination of the Krakatoa ashes, and of the dust resulting from the pulverisation of the pumice of that volcano, shows markedly the peculiarity due to the bullous structure. If this gray-green pulverulent matter be placed under the microscope, it is seen to be composed of almost impalpable grains, with a mean diameter of 0·1 mm., which are almost exclusively colourless or brownish vitreous particles permeated by bubbles. The bubbles are rarely globular, but often elongated, as we have just pointed out, and they give a drawn-out appearance to the fragments. As often happens, several bubbles are elongated parallel to each other, and in this case the pore becomes a simple streak; the fragment then assumes a fibrous texture, which may cause it to resemble at first sight a striated felspar or an organic remnant; but an examination of the outline will never allow of this confusion. If we examine the terminal contours and lines of these bubble-containing fragments, we never find that they are straight lines, but that they show a ragged appearance, all the sinuosities being curvilinear. This mode of fracture is in correspondence with the vacuolated structure, and, just as in the porous pumice, the vitreous volcanic ashes are permeated by vacuoles; besides, everything goes to show that the fragmentary condition and the fresh fractures are due to a tension phenomenon which affects these vitreous matters in a manner analogous to what is observed in the "Rupert's drops."

---

[2] *Comptes rendus de l'Académie des Sciences*, November 19, 1883, p. 1101.

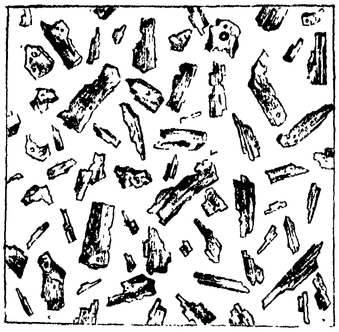

FIG. 1.—Vitreous particles of the ashes of Krakatoa, which fell at Batavia, August 27, 1883 ($\frac{2}{10}$).

We have pointed out that brown vitreous fragments are rare in the ashes of Krakatoa. These, however, contain skeletons of magnetic iron, and are devitrified by microliths.[1] It is scarcely necessary to add that the particles, whose form we have indicated, are isotropic. If under crossed nicols we sometimes see the field illuminated, this is due to crystals in the vitreous matter, or to phenomena of tension, which are sometimes observed in the neighbourhood of the bubbles.

These details on the micro-structure of the vitreous particles from Krakatoa can be applied with most perfect exactitude to the volcanic dusts, which we have determined as such, in the deep-sea deposits. In virtue of their bullous structure, their dimensions, and their mode of projection, they are capable of being widely transported from the point of eruption by aërial currents. It must be admitted, however, that in the deep-sea sediments a very large part of these vitreous splinters has not been derived from the pulverised ejections from a volcano, but from the trituration of floating pumice, of which we have given above a striking example. It will be understood that it is scarcely possible to trace the difference between volcanic ashes, properly so called, and the products resulting from the pulverisation of floating pumice which we have just indicated. As in the incoherent products of Krakatoa, so we find spread out on the bottom of the sea many more vitreous particles, similar to those we have just described, than of true volcanic minerals. This is easily explained, however, when we remember how the distribution of volcanic dust takes place.

Let us now point out the minerals which can be determined with certainty in the ashes of this great eruption; and we may at once remark that they are the same which we have almost always found associated in the deposits with the splinters of glass. In general all the crystals are fractured, except those which are still embedded in a vitreous layer; this vitreous coating is often crackled and bullous. In the ashes of Krakatoa, however, we have not remarked the globules of glass which are often described as glued to the minerals of volcanic ashes, nor have we seen the drawn-out vitreous filaments resembling Peles hair. The minerals of the Krakatoa ashes which are susceptible of a rigorous determination belong to plagioclase, augite, rhombic pyroxene, and magnetite.[1] We shall presently see the peculiarity which distinguishes each of these species in the ashes.

Among the most frequent minerals, but poorly represented in comparison with the vitreous matter, plagioclase felspar comes first. This mineral has about the same dimensions as the vitreous fragments, and, with the exception of the crystals, entirely inclosed in the pumice matter, is in the form of debris. Sometimes twins on the albite plan can be distinguished, and the results of analysis clearly indicate that it is triclinic felspar which should almost exclusively be found in this ash. But the most interesting crystals of plagioclase, and the most characteristic of this ash, although represented very rarely, are in the form of rhombic tables, extremely thin, and covered with a fine lacework of vitreous matter. We know that the crystals described by Penck[2] in a great number of lapilli and of volcanic ashes, upon the nature of which doubts have been expressed, belong incontestably to the plagiocalases, and represent an isomorphic mixture analogous to that of bytownite. It is to Mr. Max Schuster[3] that we owe this specific determination. Having found in numerous sediments of the Pacific these same crystals in the form of rhombic tables, and possessing preparations which would be of great interest to him in his remarkable optical studies on the felspars, we submitted them to this ingenious mineralogist in order to confirm our determination. We believe it will be interesting to give a *résumé* here of the results of the observations of Mr. Schuster, which are perfectly applicable to the characteristic crystals of felspar from Krakatoa, as well as to those which we have discovered in a great number of deep-sea soundings.

This plagioclase occurs for the most part in flat tabular crystals with the clinopinacoid especially developed. Individuals of the columnar type, elongated in the direction of the edge P/M, are rare. These tabular crystals consist essentially of a combination of the clinopinacoid with P and x, more rarely with P, u, and y, and occasionally x and y appear together. In the first case the crystals have the form of a rhomb, in the second case they are elongated through the predominance of either x or P. The dimensions of those crystals which were examined and measured lie between the line 0·61 mm. broad and 1 mm. long as maximum, and 0·015 mm. broad and 0·042 mm. long as minimum. The extinction of the plagioclase is negative. Its value was found to vary between 22° and 32° on the clinopinacoid, and between 8° and 16° on the basal plane. The average values of many measurements made on good crystals are as follows:—24° 12′, 25° 6′, and 29° 6′ on the clinopincaoid, 10° 42′ on the one side, and 10° 18′ on the other side of the twinning line, as this is shown on the basal plane. Polysynthetic individuals, made up of repeated twins on the albite plan, were very rarely observed. The felspar in its optical properties is thus seen to lie between labradorite and bytownite. The twin growths are particularly frequent and interesting on account of the structure of the individuals. In addition to those of the albite type, others were observed in which the edges P/M and P/K could be definitely determined as the axes of twinning, whilst P and K formed the twinning planes. The plane of composition was principally either P or M when penetration twins were not observed.

These fragments and crystals of plagioclase contain inclusions of vitreous matter, and sometimes grains of magnetite. Perhaps a small number of felspathic grains may belong to sanidine, the presence of which is insinuated by the percentage of potass indicated by the analysis which follow (K_2O = 0·97 per cent.).

We have said that the pyroxenic minerals of the ash are augite and a rhombic pyroxene; we distinguish them by the microscope sometimes in the form of fragments—and this is usually the case—sometimes in the form of crystals, which we can isolate from the volcanic glass covering them by treating them with hydrofluoric acid. In the crystals of augite we distinguish the faces of a prism, of the brachypinacoid, and indications of the faces of a pyramid. This augite is pleochroic and has a greenish tint, and extinguishes in certain cases obliquely to the prismatic edges. It is this character which often permits it to be distinguished from rhombic pyroxene with which the augite is associated. The crystals of hypersthene are transparent, of a deep brown colour, strongly dichroic, with green and brown tints. They are in rectangular prisms terminated by a pyramid, and extinguish between crossed nicols parallel to their longitudinal edges. Magnetic iron, which is rather abundant in the ashes, is recognised in the form of grains and octahedrons. We have not been able to detect with certainty either hornblende or olivine. The largest grains of this ash are true microscopic lapilli, where we distinguish in a vitreous mass microlithic crystals of felspar, of magnetite, and more rarely of pyroxene. Finally, we observe with the microscope particles of an organic origin, which are easily recognisable by their fibrous and reticulated structure. These impurities may have been transported by winds, or may have come from the ground where the ashes were collected.

---

[1] Just as we can divide pumice microscopically according as it is acid or basic, so the products of its trituration may be recognised under the microscope, inasmuch as the former often give colourless and more elongated particles, while the fragments of basic pumice have a more pronounced tint and more rounded pores.

[1] Lately the works on these same ashes have made known as accidental elements pyrites, apatite, and perhaps biotite (?). It is to be remarked, however, that these minerals must be extremely rare in comparison with the vitreous matters and mineral species above-mentioned.

[2] Penck, "Studien über lockere vulkanische Auswurflinge," *Zeitschr. d. deutsch. geol. Gesellsch.*, 1878.

[3] Schuster, "Bemerkungen zu E. Mallard's Abhandlung sur l'isomorphisme des feldspaths tricliniques, &c.," *Min. petr. Mitth.*, v, 1882, p. 194.

In spite of all the uncertainties which the exact diagnoses of volcanic dust present, we can consider them often, from the point of view of their mineralogical composition, as analogous with the augite-andesites. We know, besides, that it is to these rocks that the lavas of the volcano of Krakatoa should be referred.

The ashes which fell at Batavia on August 27, 1883, and samples of which were sent to Holland by M. Wolf, resident on that island, have been analysed with the following results :—

I. 1·119 grm. of substance dried at 110° C., and fused with carbonate of soda and potash, gave 0·7799 grm. of silica, 0·1754 grm. of alumina, 0·0911 grm. of peroxide of iron, 0·0401 grm. of lime, 0·398 grm. of pyrophosphate of magnesia, answering to 0·01434 grm. of magnesia. A recent determination of titanic acid has given 0·62 per cent. TiO_2.

II. 1·222 grm. of substance dried at 110° C. gave 0·0335 grm. of loss on ignition (water, organic substances, chloride of sodium) ; the same substance treated with hydrofluoric and sulphuric acids gave 0·1161 grm. of chloride of sodium and potassium, and 0·0118 grm. of chloroplatinate of potassium, answering to 0·0118 grm. of potash and to 0·0188 grm. of chloride of potassium ; by difference = 0·0973 grm. of chloride of sodium, answering to 0·05163 of soda.

III. 1·7287 grm. of substance dried at 110° C. was treated in a closed tube with hydrofluoric and sulphuric acid. The oxidation required 2·3 cc. of permanganate of potash (1 cc. = 0·0212 grm. FeO), answering to 0·047876 grm. of peroxide of iron.

It will be understood that it is barely possible to submit this analysis to discussion. The abundance of vitreous particles in the ashes renders illusory the calculation of the values obtained, and the distribution of the substances among the different species of constituent minerals. This vitreous matter can indeed contain an indeterminate quantity of the different bases. On the other hand, the difficulties of the calculation are all the greater, as the constituent minerals of the ashes may contain, as isomorphs, the bases which the analysis suggests. It is none the less true, however, that the percentage composition expressed by the analysis supports the preceding mineralogical determinations, without permitting the species to be precisely determined. It agrees with the interpretation that the magma from which the ashes were formed belongs to the augite-andesites.

The vitreous and mineral fragments we have just described rom the Krakatoa eruption being identical with those which we encounter in deep-sea sediments, we may conclude that both have a similar origin. In certain cases, however, we have in place of augite a predominance of hornblende, and sometimes black mica is abundant. Again, we find more or less fragmentary crystals of peridote, of magnetite, of sanidine, and, more rarely, of leucite and of hauÿne. We can easily understand this variation in composition, following the nature of the magma from which the ashes collected in different regions of the sea were derived. But in all cases it is the predominance of vitreous particles, with their special structure, which indicates most clearly the volcanic nature of the inorganic constituents of a sediment.

If now we consider the conditions which govern the distribution of ashes in the atmosphere or at the bottom of the sea, we shall be able to show how it is that there is generally a predominance of vitreous particles in these ashes. In the first place, these are vitreous matters rather than minerals, properly so called, from the moment of ejection from the crater. Moreover we should, in a general way, not expect to find that incoherent eruptive matters, which are spread out at a distance from the volcano, present a perfectly identical composition with those other loose products, such as lapilli, volcanic bombs, and scoriæ, which are projected only a short distance from the focus of eruption. Even where there exists a perfect chemical and mineralogical identity, in the crater itself, between the lavas and the pulverulent materials of the same eruption (the supposition being that the ashes arise simply from the trituration of the lavas), we can easily understand that these latter, being carried far and wide by the winds, must undergo a true sorting in their passage through the atmosphere, according to the specific gravity of the amorphous elements or crystalline constituents. It results from this that, according to the points where they are collected, volcanic ashes may, although belonging to the same eruption, present differences not only with respect to the size of the grains, but also with respect to the minerals.

In this mode of transport it is evident that the vitreous particles, other things being equal, will be transported farthest from the centre. In the first place, they are more abundant than the other particles, and again they possess in their chemical nature and in their structure conditions which permit the aerial currents to take them up and carry them to great distances ; they consist of a silicate in which the heavy bases are poorly represented as compared with the other constituent elements ; they are filled with gaseous bubbles which lower their specific gravity, and at the same time are capable of being broken up into the minutest particles. The minerals with which they are associated at the moment of ejection from the crater are not, like them, filled with gaseous bubbles ; they do not break up so easily into impalpable powder, for they are not porous, and are not in the same state of tension as the rapidly-cooled vitreous dust. Finally, many of these species are precisely those whose specific gravity is very high, on account of the bases entering into their composition. These minerals will not then be carried so far from the centre of eruption, and in all cases the vitreous particles are the essential ones in the atmospheric dusts derived from volcanic ashes.

We have a beautiful illustration of this in the ashes of Krakatoa. In proportion as the ashes are collected at a greater distance from a volcano, so are they less rich in minerals, and the quantity of vitreous matter predominates. According to a verbal communication from Prof. Judd, the ashes collected at Japan contain only a relatively small proportion of pyroxene and magnetite.

If we wish to assure ourselves of the nature of an atmospheric dust, and, as has lately been frequently attempted in Europe, to show that the dust is really from the Krakatoa eruption, it is important above all to seek for the presence of vitreous fragments. The characters which we have indicated permit any one to recognise them easily under the microscope. We would remark, however, that the presence of crystals, either of hypersthene, of augite, or of particles of magnetite in an atmospheric dust collected in Europe, does not prove in a certain manner that the dust belongs to the ashes from Krakatoa ; for, besides the difficulties of an exact mineralogical determination of the fragmentary elements, it is difficult to understand how these heavy minerals should have been carried by the aërial currents, while the vitreous dust is absent. As we have just shown, it is the contrary which should have taken place.

It results as a corollary from these considerations that the chemical composition of an ash may vary according to the point at which it has been collected, and it tends also, other things being equal, to become more acid the further it is removed from the centre of eruption. If we admit, for example, that the magma which gave birth to the ashes of Krakatoa is an augite-andesite, as everything seems to indicate, the percentage of silica (65 per cent.) which our analysis shows appears too high, but if we remember, what we have just said, that the ashes become deprived, during their passage through the atmosphere, of the heavier and more basic elements, it will be understood that the vitreous and felspathic materials, which have a lower specific gravity, and are at the same time more acid, will accumulate at points farthest from the volcano. It will be sufficient to have directed the attention to this fact to show how the percentage of silica in the ashes from the same eruption may vary according as they are collected at a variable distance from the crater.

The predominance of vitreous splinters in deep-sea sediments far removed from coasts is even more pronounced than in volcanic ashes collected on land. This arises, as we indicated at the commencement, from the large quantity of pumice carried or projected into the ocean, whose trituration, which takes place so easily, gives origin to vitreous fragments difficult to distinguish from those projected from a volcano in the form of impalpable dust. In addition, we may state that, in the distribution of volcanic materials on the bottom of the sea, the ashes are subjected to a mode of sorting having some analogy to that which takes place during transport through the atmosphere. When these ashes fall into the sea a separation takes place in the water; the heaviest particles reach the bottom first, and then the lighter and smaller ones, descending more slowly, are deposited upon the larger and heavier fragments and crystals from the same eruption. We have a fine example of this stratification of submarine tufa in the centre of the South Pacific, lat. 22° 21′ S., long. 150° 17′ W. This specimen is entirely covered with peroxide of manganese, and at the base of the fragment we see the large crystals of hornblende and particles of magnetite. This lower layer is covered by a deposit in which these minerals and coarser grains are observed to pass gradually into a layer composed of small crystals of felspar, debris of pumice, and more or less fine material.

We do not propose to occupy ourselves here with the mode of formation of volcanic ashes, and with those of Krakatoa in particular. It will suffice to indicate that in the dust of a volcano we find all the characters supporting the interpretation which regards volcanic ashes as formed by the pulverisation of an igneous fluid mass in which float crystals already formed, and from which, when projected by gases, the pulverised vitreous particles undergo a rapid cooling and decrepitation during their passage through the atmosphere. It is not only the microscopic examination of these volcanic matters that leads us to this conclusion, but the prodigious quantity of ashes formed during the eruption of this volcano, which do not agree with the interpretation that regards these ashes as the result of a pulverisation of a rock already solidified in the crater. Indeed one cannot understand how in two or three days the immense quantity of ashes ejected from Krakatoa could be formed by this process, as, for instance, on August 26, 1883, and in the May eruption, which was the prelude to that catastrophe.

SECOND PART

The recent brilliant sunsets have been attributed to the presence in the atmosphere of minute particles of an extra-terrestrial origin, as well as to volcanic dust. This induces us to conclude this brief abstract of our observations by a description of the cosmic particles which we have found, along with volcanic ashes and pumice, in those regions of the deep sea far from land, where the sediment accumulates with extreme slowness. In another memoir[1] we have pointed out the distribution of these particles on the floor of the ocean, and indicated the conclusions which we believe are justified by their relative abundance in the red clay areas of the Central Pacific.

It is known that the atmosphere holds in suspension an immense number of microscopic particles which are of organic and inorganic origin, and are either dust taken up by aërial currents from the ground, or are extra-terrestrial bodies. A large number of scientific men, headed by Ehrenberg, Daubrée, Reichenbach, Nordenskjöld, and Tissandier, have studied this interesting problem, and have brought forward many facts in support of the cosmic origin of some of the metallic particles found in atmospheric precipitations. It is certain that serious objections may be raised against the origin of a large number of so-called cosmic dusts.

In a great many cases it can be shown that these dusts are composed of the same minerals as the terrestrial rocks which are to be met with at short distances from the spot where the dust has been collected, and we can attribute a cosmic origin only to the metallic iron in these dusts. It is somewhat astonishing, however, that no trace is ever found in these dusts of meteoric silicates, although in a great many meteorites it might be said that the iron is only accidentally present, while the silicates predominate. On the other hand, having regard to the mineralogical composition of meteorites, it appears strange that the so-called cosmic dusts should present characters so variable, from the point of view of their mineralogical composition, in the different regions where they have been collected. It might also be objected that even the iron, nickel, and cobalt would come from volcanic rocks in decomposition in which these bodies are sometimes present, and this objection would seem quite natural, especially in our particular case, when we remember the numerous volcanic fragments in decomposition on the bottom of the sea. Again, according to numerous researches, native iron is found, although rarely, in various rocks and sedimentary layers of the globe. A reduction of the oxide of iron into metal might also be admitted under the influence of organic substances. It might still further be objected in opposition to the cosmic origin of the fine particles of native iron that they might be carried by aërial currents from our furnaces, locomotives, the ashes of our grates, and in the case of the ocean, from steamers. All our materials of combustion furnish considerable quantities of iron dust, and it would not be astonishing to find that this, after having been transported by the winds, should again fall on the surface of the earth at great distances from its source.

Such are the objections which present themselves when it is proposed to pronounce upon the origin of particles which we are inclined to regard as cosmic, and of which we propose here to give a short description. We shall see that many of these doubts are at once removed by a statement of the circumstances under which cosmic spherules are found in deep-sea deposits, and it will be found also that all the objections are disposed of when we show the association of metallic spherules with the most characteristic bodies of undoubted meteorites.

In the first place, the considerable distance from land at which we find cosmic particles in greatest abundance in deep-sea deposits, eliminates at once objections which might be raised with respect to metallic particles found in the neighbourhood of inhabited countries. On the other hand, the form and character of the spherules of extra-terrestrial origin are essentially different from those collected near manufacturing centres. These magnetic spherules have never elongated necks or a cracked surface like those derived from furnaces with which we have carefully compared them. Neither are the magnetic spherules with a metallic centre comparable either in their form or structure to those particles of native iron which have been described in the eruptive rocks, especially in the basaltic rocks of the north of Ireland, of Iceland, &c.

Having referred to the objections, let us now see on what we must rely in support of the hypothesis that many of the magnetic particles from the bottom of the sea which are specially abundant in those regions where the rate of accumulation of the deposit is exceedingly slow are of cosmic origin. If we plunge a magnet into an oceanic deposit, specially a red clay from the central parts of the Pacific, we extract particles, some of which are magnetite from volcanic rocks, and to which vitreous matters are often attached; others again are quite isolated, and differ in most of their properties from the former. The latter are generally round, measuring hardly 0·2 mm., generally they are smaller, their surface is quite covered with a brilliant black coating having all the properties of magnetic oxide of iron; often there may be noticed upon them cup-like depressions clearly marked. If we break down these spherules in an agate mortar, the brilliant black coating easily falls away and reveals white or gray metallic malleable nuclei, which may be beaten out by the pestle into thin lamellæ. This metallic centre, when treated with an acidulated solution of sulphate of copper, immediately assumes a coppery coat, thus showing that it consists of native iron. But there are some malleable metallic nuclei extracted from the spherules which do not give this reaction, they do not take the copper coating. Chemical reaction shows that they contain cobalt and nickel; very probably they constitute an alloy of iron and these two metals, such as is often found in meteorites, and whose presence in large quantities hinders the production of the coppery coating on the iron. G. Rose has shown that this coating of black oxide of iron is found on the periphery of meteorites of native iron, and its presence is readily understood when we admit their cosmic origin. Indeed these meteoric

[1] *Proc. Roy. Soc. Edin.*

particles of native iron, in their transit through the air, must undergo combustion, and, like small portions of iron from a smith's anvil, be transformed either entirely or at the surface only into magnetic oxide, and in this latter case the nucleus is protected from further oxidation by the coating which thus covers it.

One may suppose that meteorites in their passage through the atmosphere break into numerous fragments, that incandescent particles of iron are thrown off all round them, and that these eventually fall to the surface of the globe as almost impalpable dust, in the form of magnetic oxide of iron more or less completely fused. The luminous trains of falling stars are probably due to the combustion of these innumerable particles, resembling the sparks which fly from a ribbon of iron burnt in oxygen, or the particles of the same metal thrown off when striking a flint. It is easy to show that these particles in burning take a spherical form, and are surrounded by a layer of black magnetic oxide.

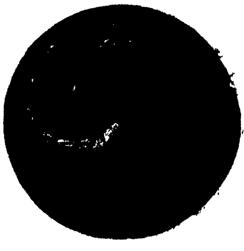

FIG. 2.

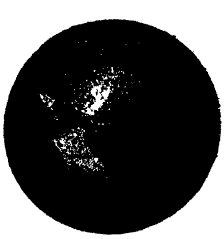

FIG. 3.

FIG. 2.—Black spherule with metallic nucleus (60 : 1). This spherule, covered with a coating of black shining magnetite, represents the most frequent shape. The depression here shown is often found at the surface of these spherules. From 2375 fathoms South Pacific.

FIG. 3.—Black spherule with metallic nucleus (60 : 1). The black external coating of magnetic oxide has been broken away to show the metallic centre, represented by the clear part at the centre. From 3150 fathoms Atlantic.

Among the magnetic grains found in the same conditions as these we have just described are other spherules, which we refer to the *chondres*, so that if the interpretation of a cosmic origin for the magnetic spherules with a metallic centre was not established in a manner absolutely beyond question, it almost becomes so when we take into account their association with the silicate spherules, of which we have now to speak. It will be seen by the microscopic details that these spherules have quite the constitution and structure of *chondres* so frequent in meteorites of the most ordinary type, and on the other hand they have never been found, as far as we know, in rocks of a terrestrial origin; in short, the presence of these spherules in the deep-sea deposits, and their association with the metallic spherules, is a matter of prime importance. Let us see how we distinguish these silicate spherules, and the points upon which we rely in attributing to them a cosmic origin.

Among the fragments attracted by the magnet in deep-sea deposits we distinguish granules slightly larger than the spherules with the shining black coating above described. These are yellowish-brown, with a bronze-like lustre, and under the microscope it is noticed that the surface, instead of being quite smooth, is grooved by thin lamellæ. In size they never exceed a millimetre, generally they are about 0·5 mm. in diameter; they are never perfect spheres, as in the case of the black spherules with a metallic centre; and sometimes a depression more or less marked is to be observed in the periphery. When examined by the microscope we observe that the lamellæ which compose them are applied the one against the other, and have a radial eccentric disposition. It is the leafy radial structure (*radialblättrig*), like that of the *chondres* of bronzite, which predominates in our preparations. We have observed much less rarely the serial structure of the *chondres* with olivine, and indeed there is some doubt about the indications of this last type of structure. Fig. 4 shows the characters and texture of one of these spherules magnified 25 diameters. On account of their small dimensions, as well as of their friability due to their lamellar structure, it is difficult to polish one of these spherules, and we have been obliged to study them with reflected light, or to limit our observations to the study of the broken fragments.

These spherules break up following the lamellæ, which latter are seen to be extremely fine and perfectly transparent. In rotating between crossed nicols they have the extinctions of the rhombic system, and in making use of the condenser it is seen that they have one optic axis. It is observed also that when several of these lamellæ are attached, they extinguish exactly at the same time, so that everything induces us to believe that they form a single individual.

In studying these transparent and very thin fragments with the aid of a high magnifying power, it is observed that they are dotted with brown-black inclusions, disposed with a certain symmetry, and showing somewhat regular contours; we refer these inclusions to magnetic iron, and their presence explains how these spherules of bronzite are extracted by the magnet. We would observe, however, that they are not so strongly magnetic as those with a metallic nucleus.

We designate them under the name of bronzite rather than of enstatite, because of the somewhat deep tint which they present; they are insoluble in hydrochloric acid. Owing to the small quantity of substance at our disposal, we were obliged to limit ourselves to a qualitative analysis. We have found in them silica, magnesia, and iron.

We have limited our remarks at this time to these succinct details, but we believe that we have said enough to show that these spherules in their essential characters are related to the *chondres* of meteorites, and have the same mode of formation. In conclusion, we may state that when the coating of manganese depositions, which surround sharks' teeth, ear-bones of Cetaceans and other nuclei, is broken off and pounded in a mortar to fine dust, and the magnetic particles then extracted by means of a magnet, we find these latter to be composed of silicate spherules, spherules with a metallic centre, and magnetic iron, in all respects similar to those found in the deposits in which the nodules were embedded.

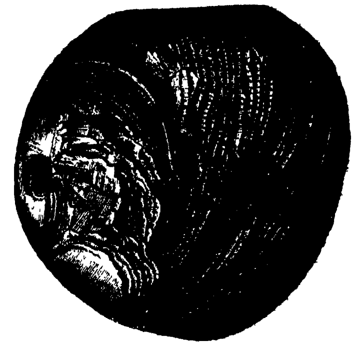

Fig. 4.—Spherule of bronzite (25 : 1) from 3500 fathoms in the Central South Pacific, showing many of the peculiarities belonging to *chondres* of bronzite or enstatite.

We have recently examined the dust collected by melting the snow at the Observatory on Ben Nevis, in order to see whether, in that elevated and isolated region, we should be able to find volcanic ashes or cosmic spherules analogous to those we have described. This atmospheric dust, which we have examined microscopically, has not shown any particles which could with certainty be regarded as identical with those substances which are the subject of this paper. Particles of coal, fragments of ashes, and grains of quartz predominated. Besides these, there were fragments of calcite, augite, mica, and grains of rock of all forms and of variable dimensions. These were associated with fibres of cotton, of vegetables, splinters of limonite and of tin—in short, everything indicating a terrestrial origin.

In order to give an idea of the facility with which the winds may carry these matters even to the summit of the mountain, we may add that Mr. Omond has sent to us fragments of crystalline rocks, some having a diameter of two centimetres, which, he states, were collected on the surface of the snow at the summit after the storm of January 26, 1884.

Arrangements are being made to collect the dust at the top of Ben Nevis during calms with great care.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

COLLEGE OF AGRICULTURE, DOWNTON, SALISBURY.—At the close of the winter session on Wednesday, 16th inst., the certificate of membership and the certificate of proficiency in practical agriculture were granted to Mr. R. A. Benson, F.H.A.S., 11, Caledonia Place, Clifton; Mr. W. de Hoghton Birch, 1, Bathwick Street, Bath; and Mr. C. W. Lincoln Hardy, F.H.A.S., Gittisham, Honiton, Devon; and the certificate of proficiency alone to Mr. B. S. Dunning, 2, Warwick Square, S.W.

THE authorities of University College, Liverpool, have asked that that institution be incorporated with Victoria University.

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, April 3.—Sir J. Lubbock, Bart., president, in the chair.—Mr. W. Brockbank exhibited a series of double daffodils, wild forms of *Narcissus pseudo Narcissus*, which were gathered in a Welsh meadow from among many of both the single and double forms occurring there in every stage of growth. Sections invariably revealed stamens and pistils, and in two of the most double forms ovaries filled with seeds were present. With this evidence he therefore contended against the current notion of cultivation and root-growths having produced a heterogeneous multiplication of the perianth segments, split-up crown, and conversion of stamens into petal-growths, his belief being that the plants in question were propagated in the ordinary seed-bearing manner.—Mr. R. M. Middleton showed a jackdaw with albinism of the wing feathers, causing considerable resemblance in the bird to a magpie.—Prof. P. M. Duncan gave a revision of the families and genera of the Sclerodermic Zoantharia, the Rugosa excepted. Since MM. Milne-Edwards and Haimes' work, 1857-60, no systematic revision of the Madreporaria has appeared, while since then a great number of new genera have been founded; hence the necessity for a revision has arisen, and more especially in consequence of the morphological researches of Dana, Agassiz, Verrill, and Moseley. Prof. Duncan explained that the old sections of the Zoantharia required modification and addition. In his present revision the sections Aporosa and Perforata remain shorn of some genera, the old family Fungidæ becomes a section with three families, two of which are transitional between the sections just mentioned. The section Tabulata disappears, some genera being placed in the Aporosa, and the others are relegated to the Hydrozoa according to Moseley. The Tubulosa cease to be Madreporarian. Hence the sections treated are Madreporia-Aporosa, M.-Fungida, and M.-Perforata. The nature of the hard and soft parts of these forms is considered in relation to classification, and an appeal is made to naturalists to agree to the abolition of many genera, the author having sacrificed many of his own founding. The criticism of 467 genera permits 336 to remain good, and as a moderate number (36) of sub-genera are allowed to continue, the diminution is altogether about 100. The genera are grouped in alliances, the numbers in families being unequal. Simplicity is aimed at, and old artificial divisions dispensed with. There is a great destruction of genera amongst the simple forms of Aporosa, and a most important addition to the Fungida. The genera *Siderastreæ* and *Thamnastreæ* are types of the family Plesiofungidæ, as are *Microsolenia* and *Cyclolites* of the family Plesioporitidæ. The families Fungidæ and Lophoseridæ add many genera to the great section Fungida. There is not much alteration in respect of the Madreporaria-Perforata, but the sub-family Eusamminæ are promoted to a family position as the Eusammidæ.—Mr. Chas. F. White thereafter read a note on some pollen from funereal garlands found in an Egyptian tomb *circa* B.C. 1000. It appears that from among the dried flowers of *Papaver Rhœas* the pollen obtained freely absorbed water, became swollen, and in other respects the grains were barely able to be differentiated by the microscope from the pollen grains of the recent poppy.—A paper was read by Mr. F. J. Briant, on the anatomy and functions of the tongue of the honey bee. Authorities, it seems, are yet divided in opinion as to how the organ in question acts. Kirby and Spence, Newport and Huxley, aver the bee laps its food; while Hermann Müller and others attribute a full share to the terminal whorl of hairs to which the honey adheres, and therefrom is withdrawn. Mr. Briant, on the other hand, from experiment and study of the structures, is inclined to the view that the honey is drawn into the mouth through the inside of the tongue by means of a complicated pumping action of the organ, aided by the closely contiguous parts.

Chemical Society, April 3.—Dr. W. H. Perkin, president, in the chair.—The following papers were read:—On the influence of certain phosphates upon vinous fermentation, by A. G. Salamon and W. de Vere Mathew. It has been suggested that the addition of phosphates to beerworts stimulates the growth of the yeast-plant and increases the rapidity of attenuation of the wort. The authors find that ordinary English wort contains an excess of phosphoric acid over that which is proved by their experiments to be most favourable to fermentation; hence it follows that the addition of phosphates to wort is not advisable. —On the occurrence of rhabdophane in the United States, by W. N. Hartley. The author shows that a new mineral, scovillite, described by Brush and Penfield in the *Amer. Journ. Sci.*, xxv. 459, is but a variety of rhabdophane. In a subsequent number of the journal, March 1884, the identity of the two minerals is recognised by the above authors.

Geological Society, April 2.—Prof. T. G. Bonney, F.R.S., president, in the chair.—Frank Gotto and George Varty Smith were elected Fellows, and Dr. E. Mojsisovics von Mojsvár, of Vienna, a Foreign Correspondent of the Society.—The following communications were read:—The rocks of Guernsey, by the Rev. E. Hill, M.A.; with an appendix on the microscopic structure of some of the rocks, by Prof. T. G. Bonney, F.R.S. The southern part of the island is a high plateau consisting entirely of gneiss. This is very coarse, and the bedding is seldom well marked. The bedding, when visible, coincides with the foliation, and the author hopes that hereafter an order of succession may be established. At Rocquaine Castle occur a few slaty beds intercalated in the gneiss, the origin of which is somewhat difficult to understand. The northern part, low ground with hummocks, consists principally of a group of crystalline or subcrystalline rocks, in constitution diorites or syenites. They are described by Ansted as sedimentary rocks metamorphosed into syenites; but they show no bedding either in the many quarries, or, in general, in the shore outcrops, nor do their varieties occur in any manner indicating an order of succession. They appear at Castle Cornet to meet the gneiss intrusively, and their microscopic structure is igneous. A remarkable appearance of bedded structure at Fort Doyle is the only strong argument for a metamorphic origin, and this may be explained as a caught-up mass in conjunction with crushing-planes. The author therefore regards them as igneous. An oval area between St. Sampson's and St. Peter's Port is occupied by hornblendic rocks, locally called "birdseye," which may be described as hornblende-gabbros. These also have been called metamorphic. They too, at Hogue-à-la-Perre and another point, present appearances of bedding; but on the same general grounds as for the preceding group these also are regarded as igneous. Two granitic masses are described: the coarse pink granite of Cobo, on the west coast, and the finer-grained gray granite weathering pink of Lancresse, on the north. Each is seen to intrude: the Cobo granite into gneiss at Hommet Barracks, the Lancresse granite into diorite at Fort Le Marchant. Besides these are some smaller masses. Dykes are remarkably abundant and various. Granites and elvans are plentiful everywhere; felsites very rare. The majority of the dykes are diorites, varying in coarseness and often of enormous size; there is also mica-trap. In some of these dykes a cleavage has been developed, so that some resemble slates. Infiltration-veins are abundant. In relative age the gneiss appears to be the oldest rock, the hornblende-gabbro to be next, then comes the diorite group, while the granites are newer still. Of the dykes the newest are the compactest diorites. As to the absolute geological age of the rocks no satisfactory evidence at present is known; it will have to be sought for in the other islands and in France.—On a new specimen of *Megalichthys* from the Yorkshire coalfield, by Prof. L. C. Miall.—Studies on some Japanese rocks, by Dr. Bundjiro Kotô. Communicated by Frank Rutley. The author has studied series of Japanese rocks from the collection of the Tokio University and the Geological Survey of Japan. The microscopical investigation was carried on at the Mineralogical Institute at Leipzig, under the direction of Prof. Zirkel, and the chemical analyses were made in the laboratory of Prof. Knop. The most abundant rocks are the pyroxene-andesites, which are not of a glassy texture, but for the most part holocrystalline. The most abundant mineral in these rocks is a plagioclose felspar with twinned and zonal structure, which is proved, by its extinction-angles and by the chemical analysis of its isolated fragments, to be labradorite. Sanadine is present in small quantities. The augites of these rocks present many peculiarities; they are all decidedly pleochroic; and they exhibit the oblique extinction in basal sections first pointed out by Mr. Whitman Cross, and which is characteristic of triclinic and not of monoclinic crystals. A careful examination of the question has led the author to conclude that the mineral which has lately been regarded as a rhombic pyroxene (probably hypersthene) is really only ordinary augite cut parallel to the optic axis. He does not regard the property of pleochroism as distinctive of hypersthene, while the absence of a brachypinacoidal cleavage and the presence of 10 per cent. of lime in the mineral forbids our referring it to that species. The other abundant minerals in these augite-andesites are magnetite, which is always present, and quartz, which occurs in some of them, both as a primary and a secondary constituent. Hornblende is very rare in these rocks, and when present the peripheral portions of the crystals are seen to be converted into augite, probably by the action of the caustic magma upon them. Enstatite is rare in these rocks, but apatite is always found in them, while tridymite occurs not unfrequently. The author described a number of structural variations in the augite-andesite from different localities. Among the most interesting is a variety containing as much as 69 per cent. of silica. Among the less abundant rocks are the enstatite-andesite, the quartz-augite-andesite, and the hornblende-andesites. The plagioclase-basalts of Japan can only be distinguished from the augite-andesites by the presence in them of olivine. Magma-basalts are rare, most of the varieties being of the dolerite type; but under the name of "basalt-lavas" the author describes varieties with a glassy base. In an appendix some account is given of a number of pre-Tertiary rocks, including granite, one variety of which contains the new mineral, reinite, of Fritsch (the tetragonal form of the ferrous-tungstate), quartz-mica-diorite, diorite-porphyry, and diabase.

Victoria Institute, April 7.—A paper was read by the Rev. J. M. Mello, F.G.S., on the prehistoric flint implements at Speinnes, implements used by man before the mammoth and rhinoceros had disappeared in Europe. The author described the works at Speinnes, and afterwards said there was one question, namely, were these early men of Europe always in the condition in which they appear to have been living, or were they offshoots of the parent stems of humanity, and had their ancestors no higher civilisation?

EDINBURGH

Mathematical Society, April 10.—Mr. Thomas Muir, F.R.S.E., president, in the chair.—Dr. Alexander Macfarlane, F.R.S.E., submitted a note on simple, combination, and cumulative voting, after which Mr. A. J. G. Barclay read a paper on the teaching of geometry.—Mr. Muir gave an explanation of an algebraical theorem communicated by Prof. Tait to the January meeting of the Society.

MANCHESTER

Literary and Philosophical Society, February 5.—Charles Bailey, F.L.S., in the chair.—On the introduction of coffee into Arabia, by C. Schorlemmer, F.R.S.

February 19.—H. E. Roscoe, Ph.D., LL.D., F.R.S., &c., president, in the chair.—Notice of the geology of the Haddon district, eight miles south-west of Ballarat, Victoria, by F. M. Krausé, Professor of Geology in the School of Mines, Ballarat. Communicated by the President.

PARIS

Academy of Sciences, April 7.—M. Rolland in the chair.—An exact or highly approximate calculation of the thrust of sandy masses against their retaining walls, by M. de Saint-Venant.—On the specific heats of water and of carbonic acid at very high temperatures, by MM. Berthelot and Vieille.—Note on Brioschi's theorem respecting symmetrical functions, by M. Sylvester.—Documents relating to the liquid air condensers for several years employed in the piercing of the Mount Cenis Tunnel, by M. A. de Caligny.—Tabulated results of the various circumstances attending electric discharges during the thunderstorms that occurred in France during the second half of the year 1883, communicated by the Minister of the Posts and Telegraphs.—Telegraphic determinations of the differences of longitude in South America, by M. de Bernardières.—Charts of the atmospheric movements passing over Europe in the various *régimes*; remarks on their application to the prediction of storms, by M. A. Poincaré.—Note on the influence of luni-solar attraction on the action of pendulums, by M. A. Gaillot.—On the solar spots observed in Rome during the first three months of the year 1884, by M. P. Tacchini.—Note on the halos of diffused light observed round the sun on March 31 at Auteuil, by M. Ch. Moussette.—On the aspect presented by the Pons-Brooks comet on January 13, 1884, by M. L. Cruls.—Note on an error committed in determining the exact moment of the chief eruption at Krakatoa last year, by M. A. A. Buijskes. This disturbance, generally stated to have occurred a few minutes before noon on August 27, really took place exactly at eight o'clock in the morning of that day. Hence the calculations of the velocities of marine and atmospheric currents based on the former date must be rectified accordingly.—On the principle of the prism of greatest thrust laid down by Coulomb in the theory of the equilibrium of sandy masses, by M. J. Boussinesq.—On the quaternary quadratic formulas, and on the corresponding hyperabelian groups, by M. E. Picard.—On the theory of quaternions in connection with Prof. Sylvester's recent solution of equations in which all the given quaternions are found on the same side as the quaternion sought for, by M. Ed. Weyr.—Note on the application of Faraday's law to the study of the conductivity of saline solutions, by M. E. Bouty.—Note on the verification of the laws of transverse vibrations in elastic rods, by M. E. Mercadier.—Fresh experiments in the liquefaction of hydrogen; solidification and critical point of pressure for nitrogen, by M. K. Olszewski.—On the chief circumstances attending the transformation of superheated octahedral sulphur into prismatic sulphur, by M. D. Gernez.—Quantitative analysis of the phosphoric acid found in arable lands and in rocks, by M. Ad. Carnot.—On the artificial production of fayalite, by M. Alex Gorgeu. The author's experiments show that the protochloride of iron, fused with silica, produces fayalite under conditions in which the chloride of manganese yields tephroite. It appears incapable of producing a bisilicate corresponding to rhodonite, and yields chlorosilicate of iron with difficulty. Highly crystallised magnetite and hausmannite may be obtained under analogous conditions by the fusion of their respective chlorides in contact with the air.—Claim of priority of discovery in connection with recent communications on the vitality of virus and of the yeast of beer; letter addressed to the President by M. Melsens.—Researches on the incubation of hens' eggs in confined air, and on the part played by ventilation in the development of the embryo, by M. C. THE EDINBURGH UNIVERSITY FESTIVAL

THE brilliant celebration of its three hundredth anniversary by the University of Edinburgh last week suggests some reflections on the connection between University progress and the growth of Science. One of the most remarkable features in these festive proceedings has been the preponderance given to the recognition of the claims of scientific research to University distinction. A hundred years ago and less, had such a gathering been thought of, the great men who would have been invited to receive the highest academic honours would have been learned scholars, eminent professors of the mediæval branches of education, with perhaps a few distinguished medical men and doubtless a good many candidates whose only claim would have been the possession of a hereditary title of nobility. But now a new host of competitors has arisen, and upon them have the laurels of the University been mainly bestowed. Physicists, chemists, physiologists, botanists, geologists, and other representatives of modern science have almost elbowed the older philosophies out of the field. In the pæan sung at every meeting of the festival the brilliance of scientific discovery, the prowess of scientific discoverers, and the glory shed on the University by its connection with both have been the chief themes.

This great change in the objects of University recognition has been silently in progress for several generations. But it has never been so openly and strikingly proclaimed as during these recent meetings at Edinburgh. It is not that any formal alteration has there been made in the curriculum of study. On the contrary, the same subjects are still required for degrees in Arts as were demanded centuries ago. Outside the conservative government of the University there has, however, been a steady growth of modern ideas, modern life, and modern science. To the Medical School, in the first place, must the credit be assigned of fostering this wider culture. Its professors have thrown open their old monopoly of teaching, and work harmoniously with their competitors outside the walls of the University. They have cast aside the ancient inefficient system of mere prelections, and have introduced practical teaching into every branch of their science. To pass from the state of things in the youth of these teachers to what they have now made it is to cross a gulf such as might be thought to mark an interval of some centuries. Everywhere we see practical scientific research taking the place of musty lecture-notes and dry unproductive text-books. Not only have the professors aimed at being successful teachers, but many of them have themselves led the way in original discovery. They have likewise kept themselves and their students abreast of the progress of research all over the world. Hence the names of Continental men of science have become household words among the rising generation. We can readily understand and sympathise with the uncontrollable outburst of enthusiasm with which the students greeted the actual appearance among them of a Pasteur, a Helmholtz, and a Virchow.

Silently and unconsciously perhaps the Universities are passing from the exclusive domination of the older learning. At Edinburgh the emancipation is far advanced, but has yet to take shape in a definite rearrangement of the curriculum of study. No thoughtful scientific man would advocate a merely scientific education. The foundations of every man's culture should be laid broad and deep in those humanising departments of thought which the experience of centuries has proved to be admirably fitted for the mental and moral discipline of youth. But the day is not far distant when it will be acknowledged that modern science must be admitted to a place with ancient philosophy and literature in the scheme of a liberal education, when in all our Universities provision will be made for practical instruction in scientific methods, and when at least as much encouragement will be given by fellowships and scholarships to the prosecution of original scientific research as has hitherto been awarded to classical study or learned indolence.

To those who hopefully look forward to the widening and broadening of University culture the Edinburgh festival is full of encouragement. Such a gathering of representative intellect has probably never before been assembled. Delegates from the oldest and youngest Universities of the world, from scientific societies and other learned bodies, brought their congratulations to their northern sister. But they felicitated her not so much because she had been a successful educational centre for three hundred years, as because she had held up the torch of scientific discovery, because her professors and graduates had widened the boundaries of knowledge and deciphered new pages in the great book of Nature. If such has been the result of the trammelled past with all its hampering traditions and vested interests, its obstructions and jealousies, what may we not anticipate for the liberated future! After the lapse of another century, what new conquests will there not be to chronicle, what new realms of discovery to celebrate! In this ever-advancing progress, the University of Edinburgh, which has done so much in bygone years, will doubtless more than hold her own. No centre of education and research has greater advantages in its favour. The comparatively small size of the city, the proximity of its lecture-rooms, laboratories and libraries to each other; its vicinity to the sea on the one hand and to a varied and picturesque country on the other, combine to offer exceptional advantages to the student. Not the least of its attractions is its own unchanging beauty, which never ceases to appeal to the eye and to stimulate the imagination. Long may Edinburgh remain a beacon of light in educational advancement, in the cultivation of scientific methods, and in the march of scientific discovery.

PRJEVALSKY'S TRAVELS IN CENTRAL ASIA

Third Journey in Central Asia. From Zaisan through Khami to Thibet and the Sources of the Yellow River. By N. M. Prjevalsky. Russian. (St. Petersburg, 1883.)

THIS large work is the complete account of the third journey of Col. Prjevalsky to Thibet, notices of the progress of which from time to time appeared in our pages during the year 1880. The first journey, it will be remembered, was performed during the years 1870-73, when this distinguished traveller reached as far as the Lama monastery of Cheibsen near Lake Koko-Nor, and to Tsaidam, but was forced to abandon his intention of going to Lhassa, and so retraced his steps to Alashan. From thence he went to Pekin, and returned to Siberia across the Desert of Gobi. The second journey was undertaken from Kuldja to the Lake Lob Nor across the Tian-shan Mountains. On the third journey Col. Prjevalsky started from Zaisan, passing through Barkul Khami, Sa-tzhei, and Tsaidam, where he reached the country he had explored on his first journey. He now proceeded to carry out his former intention of going to Lhassa, and he struggled over the great plateau of Tan-la till he reached the town of Boomtza. At Nap-chu, in the neighbourhood of this town, he was informed that he would be allowed to proceed no further in the direction of the capital of the Dalai Lama. He was then a little more than 160 miles from Lhassa. Negotiations were useless: he was not allowed to proceed. Contenting himself with taking a portrait of the messengers from the Dalai Lama, he turned northwards and retraced the long and wearisome march across the Tan-la plateau. The winter of 1879 80 was occupied with this march and with the observations upon the manners and customs of the people, as well as investigations into the flora and fauna of the district he was passing through. Prjevalsky possesses in an eminent degree the buoyant spirit of the traveller which enables him to observe calmly and critically the surroundings in which he finds himself, even though he is overcome with hardship or pressed by the weight of disappointment. Returning to Tsaidam, he set out on his way to Lake Koko-Nor, where he had been in the year 1873. He remained in this neighbourhood for some time, and he followed the course of the Hoang-ho for about 150 miles. This part of his journey took him over new ground, and his explorations of these upper waters of the Yellow River or Hoang-ho are of the utmost value. He followed the course of the river as far as Gui-dui, which forms an oasis amidst great arid mountain-chains It was so difficult to advance and forage was so scarce that Prjevalsky turned back from the Hoang-ho and directed his steps towards Lake Koko-Nor. The rain, which had stopped for a time, recommenced, and was often accompanied with severe cold, which added materially to the discomforts of the journey. The monastery of Cheibsen was revisited after the lapse of about seven years, and there Prjevalsky was well received by the priests, whose acquaintance he had made on his former visit. The journey was continued through Nan-shan and Alashan amidst the wildest mountain scenery, till a descent was made upon the great Desert of Gobi. The change was great from the high mountains of Pan-cu to the waterless expanse of the desert, but Prjevalsky was always ready with his notebook as well as with his gun; and the result is that this volume contains a mass of information for the ethnologist as well as for the naturalist. The return was made in safety through the desert to Urga and Kiakhta. This is a brief outline of the journey recorded in these pages, and the only regret one has is that so few amongst us can read the language in which it is written. It is to be hoped that the volume will ere long be translated into our own language.

The simplicity of the style, the novelty of the subject, the interest of the narrative, and the personality of the writer, who has reached such a high position amongst adventurous travellers, combine to make this a most invaluable acquisition for the library of the naturalist as well as of the geographer. Very many new species have been obtained of both plants and animals, and one of the most important of the discoveries recorded is that of a new species of horse. Polyakoff has proposed to call this new species (of which a specimen is to be found in the museum of the Academy of Sciences in St. Petersburg) after the discoverer—*Equus Prjevalskii*. But the new species of plants and animals are so numerous that it has been proposed to apply a special name to the flora and fauna of the district, which are found to differ considerably from those of Western China.

OUR BOOK SHELF

Deutsche Kolonien. Ein Beitrag zur Besser Kenntniss des Lebens und Wirkens unserer Landleute in allen Erdteiler. Von Karl Emil Jung. (Leipzig: Freytag, 1884.)

DR. JUNG is well known as an accomplished writer, both on the scientific and economical aspects of the Australian colonies, in which he spent some years His present *brochure* is one of much interest, though its immediate subject is beyond our scope. It is a curious fact that though the Germans have no colonies, they are probably, next to the English, the greatest colonisers of any European nation. Even according to the census returns, the German population of the United States is very great, and as Dr. Jung shows, it is much greater than it seems, for many of the earlier colonists have Anglicised their names, and been absorbed in the general population. To the culture of the States, and indeed to the intellectual side of all the colonies in which they have settled, the Germans have largely contributed. Dr. Jung gives interesting details of German migrations into England, Russia, Australia, South Africa, as well as the States, and from the ethnological standpoint his little work deserves the attention of the scientific student.

Catalogue de la Bibliothèque Japonaise de Nordenskjöld. Coordonné, revu, annoté, et publié par Léon de Rosny. (Paris, 1883.)

THIS collection of Japanese works in all departments of literature, which appears to have been collected by Baron Nordenskjöld while in Japan, has been presented by him to the Bibliothèque Royale at Stockholm. The editor, the veteran Japanese scholar, M. de Rosny of Paris, has not been satisfied with a bald catalogue, but has in many instances added descriptive and analytic notes of the contents, the character of the work, and its place in Japanese literature; and although the collection can hardly equal in extent and value those of several European libraries, we are not aware that such an excellent catalogue exists in any European language. The whole contains about 1000 works in over 5000 volumes, and is divided and subdivided by M. de Rosny with much nicety. The scientific works are not very numerous. On the exact sciences (arithmetic, geometry, algebra, astronomy, &c.) there are only 104 volumes, and on the natural sciences 445. But most of these are dated prior to the opening of the country to foreigners, and to the student who could examine them they would present an interesting picture of the state of scientific knowledge at various periods.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Dust of Krakatão

IN the interesting paper by Mr. John Murray and the Abbé Renard, which appears in your last number (p. 585), there is an erroneous reference which it may be well to correct without delay. I am made responsible for a verbal statement concerning Krakatoa dust which fell in Japan. In your issue of the 3rd inst. (p. 525) a letter from myself will be found, stating, on the authority of Prof. John Milne of Tokio, that, contrary to the original statements made on the subject, no dust of Krakatoa is known to have fallen in Japan. My friend M. Renard must have misunderstood the communication which I made to him, which was to the following effect:—I have had the opportunity of examining a great number of specimens of the dust of Krakatoa which fell at different distances from the volcano, ranging from 50 to nearly 1000 miles. The dust collected at the greatest distance from Krakatoa, with which I am acquainted, is that which fell on board the *Arabella* in lat. 5° 37′ S. and lat. 88° 58′ E., Java Head bearing E.½S. about 970 miles. It is certainly true that the dust which has fallen at the greater distances from the volcano contains less magnetite, augite, and hypersthene than that descending nearer to the source of eruption; and the obvious explanation of this is found in the greater density and compactness of the particles of those minerals as compared with the associated glassy fragments. At the same time it must be remembered that this is not the *only* explanation of the high silica-percentage in these ashes. The prevailing rock in the islands and on the shores of the Sunda Strait appears to be a hypersthene-augite-andesite, containing an unusually large proportion of a brown, glassy base. This base contains a far higher proportion of silica than the included minerals; and hence, as shown by Verbeek and Fennema, these rocks have a percentage of silica ranging up to, and even exceeding, 70 per cent. The same is true of the pumices formed from the glassy andesite rocks, including that of Krakatoa itself.

JOHN W. JUDD

Hurstleigh, Kew

ON January 13 I collected a sample of snow from an open field, and examined under the microscope the residue left by its evaporation. This residue showed a number of objects which are not usually found in atmospheric dust. Great precautions were taken to prevent the entrance of dust during evaporation, the vessel being kept covered with filter-paper. Crystals of common salt were very abundant. There were numbers of rather large prismatic crystals, colourless, insoluble in water, and doubly refracting. But the most characteristic objects were minute granules, transparent, colourless, and scattered in thousands all over the field of the microscope. These were insoluble in water. Many black particles were visible and some of these were attracted by the magnet. In fact, when the magnet was swept slowly over the residue, its poles became covered with fine black crystalline particles, evidently magnetic oxide of iron. However, there are large iron-works in this vicinity, which *may* account for the presence of the magnetic dust. To determine this and other interesting points, it is my intention to examine the snow and rainfall regularly during the next twelve months at least.

A specimen of snow, freshly fallen on March 10 showed none of the prismatic crystals referred to above. With a high power very small crystals of similar shape and properties were observed. The small granules were, however, to be seen along with crystals of common salt and ammonic nitrate. No magnetic dust was found in this specimen.

These results are, in my opinion, in favour of the dust theory of the remarkable sunset phenomena of the past winter.

W. L. GOODWIN

Queen's University, Kingston, Canada, March 31

P.S.—Snow fell to-day (April 1), and a sample was examined for dust. The insoluble prisms have completely disappeared, and the minute dust is present in much smaller proportion.

W. L. G.

"Earthquakes and Buildings"

PROF. JOHN MILNE, of Tokio, refers in an article under this heading (NATURE, vol. xxix. p. 290) to *buildings in Caracas, which are low, slightly pyramidal, have flat roofs, and are bound along their faces with iron.* Being for more than twenty years a resident of this city, I hope I may be credited with knowing something of its architecture, and as such I must say that certainly the houses are generally one-story buildings, but all the remainder of the foregoing description is quite erroneous. However, I do not wish to make Mr. Milne answerable for its inaccuracies, as it appears to be taken from a ridiculous article published by one Horace D. Warner in the *Atlantic Monthly*, March 1883. This article is a most audacious fiction from beginning to end, and in none of the statements it pretends to give with graphic seriousness is there any shadow of truth, as I have pointed out in the *American Journal of Science*, July 1883, with respect to the principal assertion of an earthquake said to have been witnessed by the author on September 7, 1882, in Caracas.

House-building in our good city is of the most ordinary type, and certainly not what it ought to be in a place which already once was ruined by an earthquake (1812): the walls are built of brick and mortar; the roofs are very seldom flat, but have a very slight inclination, say 15 to 20 degrees. They are, however, made too heavy by a thick stratum of loamy mud, spread over the closely-joined laths (generally the stems of the arborescent grass, *Arundo saccharoides*), on which the tiles are set in alternately convex and concave rows.

The earthquake of Cua (NATURE, vol. xviii. p. 130) is an instance of the remarkable influence of the soil on the intensity of destruction: all the houses built on the rocky hill in the middle of the town were ruined, whilst those on the surrounding alluvial plain suffered scarcely any damage. The same happened in 1812 in Caracas: the northern part of the city, where the stratum of detritus is less deep, was almost completely laid waste; but the southern part, built on a far deeper deposit of loose matter, experienced comparatively small destruction.

A. ERNST

Caracas, March 16

On the Transmission of Organic Germs through Cosmical Space by Meteoric Stones

IN his *addendum* to his well-known lecture on "The Origin of the Planetary System" Prof. Helmholtz uses the following remarkable sentence, to which so far as I am aware, attention has not hitherto been directed:—

"But even those germs which were collected on the surface when they reached the highest and most attenuated layer of the atmosphere would long before have been blown away by the powerful draught of air, before the stone reached the denser parts of the gaseous mass, where the compression would be sufficient to produce an appreciable heat."

Helmholtz is contending in favour of the possible transmission of germs from one heavenly body to another, and his point here is that the germs, owing to their being small and light, will be more rapidly retarded (blown back) on reaching the first traces of our atmosphere than the stones on which they reside, and will thus escape the great rise in temperature to which the stones are subject in consequence of friction and air compression.

Now when a germ just leaves its meteorite its velocity is equal to that of the meteorite. If m be the mass of the germ, $\frac{mv^2}{2J}$ will be the heat developed in destroying its velocity. Were all this heat to go to raise the temperature of the germ, the rise in temperature would be $t = \frac{v^2}{2Js}$, s being the thermal capacity of the germ. This shows that the rise in temperature is independent of the mass of the body brought to comparative rest by the atmosphere. In reality, since the germ experiences a greater retarding acceleration than the stone, its temperature must rise much more rapidly and consequently higher than that of the stone. Further, the terminal velocity of the germ will be less than that of the stone, which will conduce to further raise the temperature of the former. Of course neither the stone nor the germ will get all the heat generated, but this cannot materially affect the question.

J. H. STEWART

Physical Laboratory, Royal College of Science for Ireland

Instinct of Magpies

I HAVE read in NATURE (p. 428) your correspondent's letter relative to the instinct shown by magpies in Scotland as to the time for commencing their nest-building, which goes so far as to assume that this particularly cunning bird is capable of fixing a certain day in March (the Sunday after the 16th as I remember) as the invariable time to start the nest. And the writer observes that it would be well to ascertain if difference of latitude made any difference in the magpies' calculation. Now I live in the south-east of Ireland, a good many degrees south of your correspondent's Scotch magpies' locality, and it so happens that I have for the last twenty years observed the nest-building of magpies, who have enjoyed undisturbed possession, and who invariably build in the trees close to my house. It is curious that this colony (if a single pair may so be called) never increases—four young "mags" are brought out every year—but though I have observed congregations of ten or fourteen at times, the breeding birds never exceed two. The young birds never, like rooks, join a colony near their paternal nests, but are shipped off to new localities. I could mention many traits of my magpies' instinct—"their tricks and their manners"—but will confine myself to the nest-building. They never repair or re-occupy an old nest. A new one is constructed every year, and always, each year, in a different tree. Their nest-building is a serious labour, and takes a long time. So they begin early in *February*, selecting the sites often with much deliberation. The work is entered on very early in the morning, and the "mags" seldom work in the daytime. About the end of March this domed nest with its two openings is finished, and the laying of eggs commenced. I am quite certain that the middle of March is not the time of beginning the nest, and this is important, as the claim set up for the magpies instinctive knowledge of dates therefore falls to the ground. I do not conceive it possible to prove that in this particular magpies have a more highly developed instinct than most other birds; all have their normal time of nesting, although there may be cases of abnormally late or early building; but as to the magpies or any other bird being able to fix dates exactly to the day, it is unproved and incredible.

Inisnag, Stonyford, Co. Kilkenny JAMES GRAVES

Cats at Victoria Station

THAT the cats should repose comfortably amidst all the noise and vibration of a busy railway is not, after all, to be much wondered at. Animals much more defenceless and timid have found out that they need not be afraid of either the vibration or the trains, although they do not seem to have discovered that if they get in the way of the trains they are either maimed or killed. For instance, along the London and North-Western Railway between Manchester and Liverpool, which carries an enormously heavy traffic, rabbits burrow almost immediately beneath the ballast forming the permanent way, and I have often seen them sitting nearer to the train than most human beings would like to stand. It is strange, however, that along this line of railway, which is one of the oldest in England, neither the rabbits nor the grouse and partridges have learnt that, though the train is not to be dreaded as a man is dreaded, it is usually fatal to those who are struck by it. All these creatures, as well as hares, pheasants, &c., are constantly being run over by passing trains. A hen grouse or partridge will frequently take her brood on to the railway, no doubt for the purpose of dusting themselves, and meet with this fate. The survivors, however, do not seem to take warning by the occurrence. The same may be said of the telegraph-wires, against which the birds are constantly flying. The number killed in this way is considerable. This is the more remarkable because along this line wild animals have had such a lengthened experience of rail and wire that one would suppose it might have taught them wisdom.

ROOKE PENNINGTON

Wild Duck laying in Rook's Nest

WITH reference to Mr. Willmore's note in NATURE (p. 573), I have met with several instances in Lincolnshire of wild ducks nesting at a considerable height above the ground—once in an oak in a plantation in the old nest of a carrion crow—in ivy on a ruined wall, and on the top of a straw stack; once also on the roof of an old bean stack in the marches. I have known a wild duck nest on the ground amongst brambles and rough grass in the centre of a plantation a mile or more from pond or running stream. JOHN CORDEAUX

Junior Athenæum Club, April 21

Science and the Public Service

THE public are greatly indebted to your correspondent for drawing attention in NATURE of March 27 (p. 511) to the astounding proposal of the War Office to adopt the scheme of examination described by Lord Morley in the House of Lords on March 27—a scheme so absolutely retrogressive, and opposed to the recommendations of the Public School Commission of 1862 and of the Commission on Scientific Instruction in 1872 (composed of many eminent men and presided over by the Duke of Devonshire), and to the rapidly strengthening opinion in favour of education in science. The Government must be asked to withdraw the scheme. S.

Whittington, Chesterfield, April 16

THE HONG KONG OBSERVATORY

1. IT was found to be impossible to select a suitable site for the new Observatory near the city of Victoria, as the mountains shut off from view a large section of the southern sky, extending up to 25° of altitude. It is for the same reason impossible to determine the direction and velocity of the wind accurately near the town. Besides it is likely that the ferruginous rocks would deviate the plumb-line, not to mention the magnetic needles.

2. The Observatory was therefore built on the peninsula of Kaulung opposite. It stands on the top of Mount Elgin, a small hill built up of decomposed granite, rising abruptly on all sides from the surrounding level ground, and culminating in two humps distant over 300 feet from each other. The top of one of these is flat, and forms, roughly speaking, a circle of about 200 feet in diameter, and 110 feet above mean sea-level. Here the main building is situated, about 75 feet south-west of which the stands for the meteorological instruments, including the self-recording rain-gauge, are placed. It commands an unobstructed view of the sky, the tops of the hills rising only about seven degrees above the horizon. The magnetic hut is erected on the other prominence, the top of which was levelled, and forms a rectangle 36 feet by 30 feet.

3. The situation of the Observatory is rather secluded. It is surrounded by villas and summer residences; and the picturesque town rising opposite on the side of the steep mountain at a distance of a couple of miles, and the harbour, filled with the most bewildering mixture of men-of-war and merchant ships belonging to nearly all nationalities, and literally swarming with boats and sampans, make up a charming view from the verandas of the Observatory, which, on the other hand, forms a prominent object as seen from the town and harbour.

4. I was appointed to take charge of the Observatory on March 2 last year, and when I arrived in the colony on July 28, the foundations of the building had been already laid. It was then erected under my superintendence, and I was allowed to arrange every detail to suit the requirements. By January 1 the main building was so far finished that I could take up my residence there, and start tri-diurnal meteorological observations, and issue a daily weather report, containing also information concerning the direction and force of wind indicated by the gradients, based on telegrams received from the Treaty Ports, Manilla, and Nagasaki. I receive a telegram from Wladivostock in addition. The observations are made at 10 a.m. and at 4 p.m. on the previous day.

5. The main building of the Observatory is a rectangular block, 83 feet long and 45 feet wide (not including the transit-room), the architecture of which does credit to the Surveyor-General's department. The upper floor is devoted entirely to my quarters. The ground floor com-

prises four rooms, each 20 feet long, 16 feet wide, and 14 feet high. In the entrance hall is placed the telegraphic apparatus; to the right is my private office, where the library is placed, contained in glazed teak-wood bookcases, to protect the books from insects in the summer. I have already received extensive donations from scientific institutions in all parts of the world. The room next to this contains the clocks, which are fixed to brick piers neatly covered with teak wood. The piers, which rest on cement concrete, are carried down 6 feet below the ground in holes lined with bricks. Behind this is a small room in which the galvanic batteries are placed.

6. The mean-time clock, which is to discharge the time-ball automatically, is furnished with a magnetic apparatus for setting to correct time without touching any part of the clock. The time-ball will be dropped at Tsim-sh'at-sui Point, opposite the harbour, about a mile from the Observatory. It is 6 feet in diameter. Opposite the mean-time clock is the sidereal standard clock, which is of the most finished construction. It communicates by wire with a sympathetic dial placed in the transit-room. The face of the latter is black, and the hands and the figures are white, which I found very convenient at Markree Observatory, but unfortunately, Messrs. Dent and Co., who made all the horological apparatus, have omitted a second every minute. For marking a chronograph such an arrangement is most desirable, but it is rather awkward in observing with eye and ear. The clock-room contains the relays, and also one sidereal and two mean-time chronometers.

7. The transit instrument, by Troughton and Simms, is placed in a wing room painted dark gray, 14 feet square and 14 feet high, next the clock-room. The meridian opening is 1 foot wide. The transit instrument has also a delicate level for observing zenith distances according to Talcott's method. The pivots are made of chilled bell-metal, a material which, I believe, was introduced to astronomical instrument-makers by Brinkley of Dublin, whose instruments remain serviceable up to this day, while the pivots of transit instruments of much later date are corroded, being made of steel—a material that should not be used except where unavoidably necessary. An adjustable meridian mark is placed on a pier 66 feet north of the transit instrument. It is observed through a lens of that focal length, which is fixed in the meridian opening of the transit-room.

8. To the left of the entrance hall is the general office and computing room, next to which is the room where the barometers, as well as the self-recording thermograph and barograph, are placed. Behind this is a small room that serves as a photographic laboratory. Every part of these two rooms, including ceilings, floors, and furniture is painted dark red, and there are only a few panes of glass in the windows, which are glazed with double red glass. The thermograph is supported by massive blocks of wood fixed on solid masonry, but the barograph is placed on a stand merely screwed to the floor. The screw that holds the self-registering thermograph is made of zinc.

9. Over the upper story of the building a turret rises 8 feet above the flat roof. This holds the self-recording parts of the anemometer, which is erected on top of it. The cups are 45 feet above the ground. The roof forms a convenient platform for making observations. The sunshine-recorder is placed in a groove in the coping-stone on the parapet, 34 feet above the ground. Lightning conductors are placed on the two chimneys. They rise a few feet higher than the anemometer.

10. A one-storied block of outbuildings, containing servants' quarters and store-rooms, communicates with the main building by a covered passage.

11. The magnetic hut is 17 feet long, 13 feet broad, and the roof rises 11 feet high. It is made of wood, painted pure white outside and inside. Bamboo chips instead of nails were used in its construction, as well as in that of the furniture. It has double doors, louvered and glazed, to the north and south, and two windows on either side, as well as two windows in the roof, which is convenient for reading the verniers. On top of massive teak-wood blocks sunk 3½ feet in the ground and rising 4 feet above the floor are placed the dip-circle and the unifilar magnetometer. All the instruments were brought out safely, except the dipping needles, which appear not to have been sufficiently cleaned before packing. The hut is very comfortable, and forms therefore, in my opinion, a contrast to other structures used for making magnetic observations, in arranging which the importance of attending to the comfort of the observer in the hut is but too often lost sight of. The deviation is only 47 minutes easterly. The dip is 32 degrees (north end dipping). A broad road leads from the main building to the magnetic hut. This road is broken in the middle by a depression, across which a bridge will shortly be built.

12. Beside this road, at a distance of about 75 feet from the main building, it is intended to build a small house for the assistants, and near this has been selected the site for the refractor of 6 inches aperture, the loan of which I was promised by the Astronomer-Royal. That will complete the outfit.

Hong Kong Observatory, March 11

THE CEDAR FOREST OF CYPRUS

IN 1879 Sir Joseph Hooker communicated to the Linnean Society[1] the unexpected discovery of a form of the cedar of Lebanon (*Cedrus libani* var. *brevifolia*, Hook. f.) by Sir Samuel Baker in Cyprus.

The following extract from a letter lately received by the Director of the Royal Gardens, Kew, from Sir Robert Biddulph, K.C.M.G., C.B., the High Commissioner, gives a more detailed account of the forest, and will no doubt be interesting to many readers of NATURE:—

"*Cyprus, March* 25

"With regard to the cedars, I went last summer all through the thickest part of the forests, including the cedar forest, and I am able to give you some of the particulars you ask for, having noted them at the time. The cedar forest occupies a ridge on the principal watershed of the southern range, and about fifteen miles west of Mount Troodos. The length of the forest is about three miles, its breadth very much less. A few outlying cedar-trees were visible on neighbouring hills, but on the ridge they were quite thick, and probably many thousands in number. I took the height above the sea by an aneroid barometer, and found it to be 4300 feet. The trees are very handsome and in good condition, but comparatively young. The smallest seemed to be from ten to fifteen years old; the largest, I am told by the principal forest officer, are probably not over sixty or seventy years. The worst feature is that there were *no* seedlings or young trees under ten years; and indeed this is the same with regard to the pine forests. It would seem as if the great influx of goats has been comparatively recent. I made a tour through the heart of the forest last August. I started from a point on the west coast, and from thence ascended to the main watershed, and kept along the top till I reached Mount Troodos, taking three days to do it. The country through which we passed on the first day was perfectly uninhabited, and a mass of hills and forest, chiefly *Pinus maritima* [*P. halepensis*] and the Ilex. The trees were in very great number, but there was a scarcity of young trees, and most of the old ones had been tapped for resin. On the second day we passed through the cedar forest, and the same sort of country as before, the *Pinus Laricio* beginning at an altitude of 4000 feet. We got as far as the monastery of Kikko that day, and the next day I continued along the watershed to the camp at Troodos. Our road as far as Kikko was a mere track on the side of the hill, in some parts rather dangerous, and we had to lead our ponies on foot, in many parts very steep. The difficulty on the road is the want of water at that elevation. We halted the first night at a beautiful spring, but we had to carry with us food for man and beast for the whole party, muleteers, &c. The scenery was wild and romantic. This spot is the centre of the '*moufflon*' ground; three of them were at the spring when we approached it. It gave me a clearer idea of the forests of Cyprus than I ever had before.

"We have had a great deal of rain this winter, and the country is clothed with vegetation."

MINERAL RESOURCES OF THE UNITED STATES[1]

THIS volume, published by the United States Geological Survey, is the first statistical report upon the condition of the mining industries of the United States, and contains much valuable information concerning the great and ever-increasing production of metals, especially in the States west of the Missouri and the Rocky Mountains.

In addition to the columns of figures of weights and values constituting the statistical matter proper, the author, or rather his coadjutors, for the volume is the work of many contributors, have furnished notices and descriptions of processes, especially in the metallurgical section; and a review of the course of the markets for the preceding eight years (to 1875) is given for each important metal. By a curious provision in the Act of Congress providing for the publication of these statistics, the field is restricted to mineral products other than gold and silver, but, in order to present as complete a view of the total output as possible, the best available figures of the production of precious metals are given in a concise form. This, though valuable, is rather disappointing, as we miss the interesting accessory descriptions which are given in other parts of the volume. How important the production of these metals has been during the last quarter of a century is seen in the statement that the aggregate yield up to the middle of last year has been 2707 tons of gold and 15,680 tons of silver, and of these enormous quantities less than 1 per cent. of the gold, and none of the silver was raised before 1858 At the present time the annual production varies from 12 to 16 millions sterling coinage value, divided about equally between gold and silver, the latter being usually a little in excess.

The coal raised in the different States is a little over 87 million tons, of which 29,120,000 tons were anthracite and the remainder bituminous coal and lignite of all kinds, and some anthracite mined "outside" of Pennsylvania, the recorded value being 29,326,000*l.* The above totals represent 1·8 ton per head per annum of the population, which is, however, somewhat less than the consumption, in addition to enormous quantities of wood and charcoal. Among the most interesting recent developments are the Tertiary and Cretaceous coal-basins which extend along the base of the Rocky Mountains and are also seen at different points on the Pacific Coast, the total area of these being reported as greater than those of the Carboniferous formations proper in the Eastern States. These areas are, however, marked as doubtful by the author. At Crested Butte and Irwin, in the very heart of the Rocky Mountains, both anthracite and good coking coals are found in these newer formations, the quality of the latter especially being comparable with the coal of Connellsville or the best coking coal in Pennsylvania.

The iron industry of the United States is now of first-rate importance, and the subject is well treated in a paper contributed by Mr. J. M. Swank, the well-known secretary of the American Iron and Steel Association. The iron ore raised is in round numbers 9 million tons, and the pig iron made from it 4,623,000 tons. The value of the latter is given at 21,267,000*l.*, which is only a few pounds less than that of the gold, silver, copper, and lead taken together. The largest production of iron ore is in the district producing the richest quality, namely Lake Superior, whose yield of 2,948,000 tons is comparable with those of the other great hematite districts of the world, Furness, Whitehaven, and Bilbao.

The United States are now among the largest producers of copper, and here we are met by the peculiarity of the unequal distribution of the producing centres. Thus, of a total product of 40,903 tons, 25,439 tons were from a single district, namely, Lake Superior, and of this again the larger proportion, 14,309 tons, was from a single mine, the "phenomenal" Hecla and Calumet of Houghton, Michigan. The Lake copper is entirely produced from the native metal, and is of the highest degree of purity. Latterly, however, a competitor of some importance has arisen in the south, in the barren desert country of Arizona, where masses of carbonates and oxides have been discovered in considerable quantity under conditions resembling some of the famous mines of South Australia. The handling of these ores is not, however, easy. The smelting must be done on the spot, and when the furnaces are at a distance from railways, the coke used may cost from 10*l.* to 15*l.* per ton. The most remarkable mine in this district, the Copper Queen, has already paid 200,000*l.* in profits, and produces copper at a cost of 4½*d.* to 5*d.* per pound.

Lead is another metal in which the United States have taken a prominent position during the last few years, the product being now 132,890 tons, while in 1870 it was only 17,830 tons. This great increase is due to the development of several important groups of mines in the Western States, but more particularly in Utah, Nevada, and Colorado, the latter State alone producing 58,642 tons, or nearly half the total production of the country; while in 1873 the State was credited with only 56 tons. This enormous increase is due to the development of the carbonate deposits of Leadville, in the Rocky Mountains, where ores containing only 10 to 20 per cent. of lead are smelted in enormous quantities to obtain the silver and gold contained, which are relatively high in proportion; the pig lead or "base bullion" produced being sent eastward by railway to the refineries at Omaha, Chicago, St. Louis, Pittsburg, and even New York. The information given in the volume concerning this important branch of industry is so full that it will be a welcome one to the library of every metallurgist.

Another important and almost specially American mineral industry is that of petroleum, the production being restricted to the States of Pennsylvania, New York, California, West Virginia, Ohio, and Kentucky, the last four being, however, insignificant as compared with the first three. Here again there is a considerable disparity, the States of Pennsylvania and New York yielding 61,200 barrels daily, while in California the annual total is only 70,000 barrels. The barrel contains 42 gallons U.S. measure, which is the same as the old English wine gallon of 231 cubic inches. The consuming power of the world seems in this article to have been passed by the supply, the average price of 41*s.* 2*d.* per barrel in 1864 having fallen to 3*s.* 4*d.* in 1883. Notwithstanding this great fall in price the total produce of the year is valued at £4,740,000, or about one-half more than that of the copper.

The minor metallic and other minerals are of less importance, but their statistics are set forth in considerable detail in other parts of the volume, which we hope to see reprinted, if not annually, at least at short intervals of years, as furnishing one of the most valuable contributions to economic geology.

H. B.

THE LATE DR. ENGELMANN

So many years have elapsed since Dr. Engelmann, whose death was recently announced in your columns, wrote his academic dissertation "De Antholysi Prodromus, 1832," that it is no matter for surprise if many among the younger generation of botanists have forgotten this little treatise, or have failed to associate its author with the historian of American conifers and other selected orders. This is the less surprising as, although in Dr. Engelmann's systematic memoirs there are frequent traces of his early morphological studies and of the interest he felt in them, he, so far as I know, wrote no treatise specially devoted to teratology other than the one already mentioned. A few words on this little book may therefore not be unacceptable to those who honour Engelmann's memory. It would be an interesting and not an unprofitable task to trace out the connection between teratology and the modern views of evolution, which is much closer than is generally imagined, albeit the ideas of natural selection and survival of the fittest find no place in the older teratological literature. For such a task I have neither the requisite ability nor the necessary leisure. My object in alluding to the matter is to call to mind the light in which Engelmann considered the subject, influenced as he was by the writings of his great fellow-countryman Goethe, whose views, originally published in 1790, were by no means universally accepted, even in 1832. Schimper and Alexander Braun were among those who appreciated the value of Goethe's theory, and those two learned men and acute morphologists were Engelmann's teachers, and as we learn from himself, exerted great sway over him.

It is curious to contrast the modest pamphlet "De Antholysi Prodromus," written in Latin, which I at least do not find very easy to construe, with the more elaborate "Élémens de Tératologie Végétale" of Moquin-Tandon, published nearly ten years later (1841). Moquin's work is written in a style which even a foreigner can read with pleasure. Its method, too, is clear and symmetrical, but when we compare the two works from a philosophical point of view, and consider that the one was a mere college essay, while the other was the work of a professed botanist, we must admit that Engelmann's treatise, so far as it goes, affords evidence of deeper insight into the nature and causes of the deviations from the ordinary conformation of plants than does that of Moquin. A few illustrations will suffice to make this clear. Speaking of progressive development, or as he calls it "*evolutionis progressus*," Engelmann says that while it is only obscurely indicated in celestial bodies, and with difficulty studied in animals, "*clarissime apparet in plantis*." Plant-history is for Engelmann the narrative of the progress of evolution—"*evolutio progrediens*"—and variations from the ordinary course are to be accounted for, "*ex nimio motu, et ex nimio impeditione*," or, as we should now say, from excess or from arrest of development.

The main end of a plant is to produce seed, and the morphology of the plant appears to have been considered by Engelmann as the result of a compromise between this tendency (*nisus*) and the progressive development of each individual part. The morphological unit for him, as for Goethe, from whom he derived the notion, was the leaf—"*unitas autem in foliis posita est*"—and the variations from the leaf-type were, as we have seen, attributed to arrest of development, to reversion (*regressus*), or to progression. But these changes were looked upon then chiefly in relation to the greater or less development and specialisation of individual parts with little or no reference to their possible genealogical significance as elements in a general pedigree of plants, or at any rate as suggestive of such elements. Hereditary influence, however, was not wholly overlooked; on the contrary, Engelmann speaks of it as "*magni momenti*," and goes on to show how woody plants frequently show, year after year, the same malformations, how perennial plants less frequently do so, and how such repetition is much less frequently observable in annuals and plants propagated wholly by seed. Only "*antholyses epiphyticæ hereditariæ esse possunt*" (§ 69), says our author, by which he means that partial changes are not perpetuated by descent, but only those in which "*omnes plurimive flores morbosi sunt*." It is not necessary to stop to consider what amount of truth there is in this assertion, but it is interesting to see the use then made of the word "epiphyte." Engelmann, influenced by his medical studies, spoke of "local," "epiphytical," "sporadic," "enchoric," and "enchronic" affections; enchoric changes being limited to certain localities, enchronic alterations occurring at definite times. These terms have not been generally adopted, while the signification now attached to the word "epiphyte" is widely different from that which Engelmann intended. He, at least, had not the right of priority in this matter, for Bischoff, in his "Botanische Terminologie" (1830), speaks of epiphytes as external parasites (citing as examples *Cuscuta* and *Viscum*), in contradistinction to entophytes. It would seem from this that in matters of terminology custom overrides priority. But this by the way. Our present concern is with the fact that certain changes, or certain degrees of change, are more likely to be perpetuated than others. Similarly we find Engelmann calling attention to certain "critical" regions of the plant,—spots, that is, more subject than others to teratological change,—the apex of the stem in definite inflorescences for instance (§ 67), a point subsequently dwelt on by Darwin at some length, though he does not seem to have been aware of what Engelmann had previously written on the subject.

Lastly, reference may be made to the assertion made by Engelmann that plants of a high state of relative structural perfection "*structurâ magis evolutâ et typo magis composito*," are specially liable to retrograde metamorphis. This is a statement that from the nature of things seems so reasonable that it is generally accepted without question. Nevertheless, it is one which requires qualification and further investigation. To take one case which occurs at the moment. Let any observer call to mind the number of instances in which he has seen the carpels the subjects of retrograde metamorphosis, and he will probably find that such changes are far more common in cases where the carpels are free and superior, than in those in which they are in union one with another and with the thalamus, as in the so-called inferior ovaries, which are considered to represent a higher type of structure than do the free carpels.

But the object of this note is not to discuss any particular view that Engelmann may have held, but merely to call attention to his claims as a morphologist, claims which are overlooked by reason of his greater—numerically greater—claims as a systematist.

MAXWELL T. MASTERS

SIWALIK CARNIVORA [1]

By the publication of the present memoir on the Siwalik and Narbada Carnivora, Mr. Lydekker completes the second volume of the series of the "Palæontologia Indica" devoted to the Indian Tertiary and Post-Tertiary

---

[1] "Palæontologia Indica," Series x. Indian Tertiary and Post-Tertiary Vertebrata, Vol. ii. Part 6. Siwalik and Narbada Carnivora. By R. Lydekker, B.A., F.G.S., F.Z.S. Published by order of His Excellency the

Vertebrata. Both these volumes, it may be remarked, treat of mammalian forms, and, with the exception of a memoir on *Rhinoceros deccanensis*, by Mr. R. B. Foote, are from the pen of Mr. Lydekker. Each volume contains about 300 pages and forty-five plates.

No traces of mammals have yet, it would appear, been detected below the Eocene in India, and even in this formation only some very fragmentary bones have been obtained from the Punjab. From the Miocene the remains of a rhinoceros have been found. In the Pliocene mammalian remains begin to be pretty numerous. Thirty-three species of Carnivora from Siwalik are described in the present memoir; they belong to the following families: Mustelidæ, Ursidæ, Viverridæ, Hyænidæ, Felidæ, and Hyænodontidæ. Of the first of these families, two species of the genus Mellivora are described; one of these, *M. sivalensis*, was first noticed in the supplemental plates of the "Fauna Antiqua Sivalensis," and the original is in the British Museum. A second skull and the ramus of a mandible are in the Science and Art Museum, Dublin. The annexed woodcut shows the right side (Fig. 1, *a*) of the palate of this latter. The original describers of these specimens, Colonels Sir W. Baker and Sir H. Durand, remark on their close affinity to the recent *Mellivora indica*, and Mr. Lydekker says that in most respects the forms of the recent and fossil jaws are exceedingly alike. In the fossils the *pm*.2 and *pm*.3 are slightly larger in the upper jaw than in the recent form, and the true molar (*m*.1) of the former differs from that of the latter by being much less expanded at its inner extremity. In the mandible (Fig. 1, *b*) there is not much difference between the fossil and recent forms. The difference, however, between the extinct and recent Indian ratel may be summed up as being about the same in degree as between the recent Indian and African forms, leaving it probable that India may have been the original home of the genus. A second species is described as new, *M. punjabiensis*. A new genus (Mellivorodon) is formed for a form intermediate in size between the ratel and the glutton, while the form and relative proportions of its teeth indicate that it was more nearly allied to the former than to the latter. Two species of Lutra, *L. palæindica*, F. and C., and *L. sivalensis*, F. and C., are described from the region of Ganges and Jumna Valleys, and one, *L. bathygnathus*, Lyd., from the Siwaliks of the Punjab; this last is of extreme interest, as, while presenting no sort of affinity to any of the existing Indian species, it is most closely allied to the recent South African otter (*L. lalandi*), and thus affords another well-marked example of the intimate connection of the Tertiary mammalian fauna of India with the present African fauna.

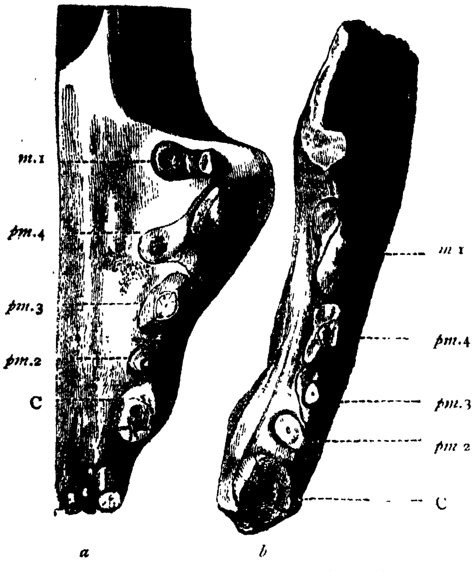

FIG. 1.—*Mellivora sivalensis* (F. and C.). The right half of the palate (*a*) and the left ramus of the mandible (*b*). Natural size.

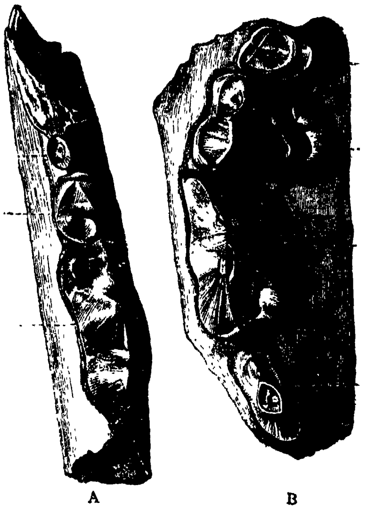

FIG. 2.—*Canis cautleyi* (Bose). Part of the left ramus of the mandible (A) and the left side of the palate (B).

The evidence of the close relationship of the bears and the dogs appears to Mr. Lydekker too strong to refer them, at all events for palæontological purposes, to separate families. We therefore have the Ursidæ comprehending the two modern families Ursidæ and Canidæ, these being formed into groups as Ursinæ and Caninæ. The author does not, however, attempt to form a definition of the family as thus extended, nor is he even quite certain as to the limits of the sub-groups. Of the species described, one, *U. namadicus*, F. and C., is from the Pleistocene Narbada beds; the other, *U. theobaldi*, Lyd., was obtained by Mr. Theobald from the Siwaliks of the Kangra district. It would seem to be nearly related to the recent *U. labiatus*, which itself seems to stand quite isolated from all the other recent bears, its strangely modified molar dentition being the result of the nature of its food. Three species of Hyænarctos are mentioned: *H. sivalensis*, F. and C., *H. punjabiensis*, Lyd., and *H. palæindicus*, Lyd. The line of descent of the genus is thought to be from the bears, through Dinocyon, to the true dogs. *Amphicyon palæindicus*, Lyd., is redescribed and refigured; it approaches *A. intermedius*, Myr., described from the Miocene of Bohemia on the eastern side of Europe. Of the genus Canis the following are described :—*C. curvipalatus*, Bose, and *C. cautleyi*, Bose. The occurrence of this latter species in the Siwaliks is one "of extreme importance in regard to the Pliocene age of at least a large portion of those deposits, for in the Tertiaries of Europe, with which the Siwaliks are in many respects closely allied, true wolves are unknown before the Pliocene." Among the Siwalik fossils in the Science and Art Museum, Dublin, there is an associated portion of the skull and two fragments of the mandible of this wolf, portions of which are represented in the woodcut (Fig. 2). In A are shown *m*.1 and *m*.2 in a very perfect and almost unworn condition, and also the broken fang of *m*.3. In B the left side of the palate shows the

Of the Viverridæ we find the following:—*Viverra bakeri*, Bose, and *V. durandi*, Lyd. Of the Hyænidæ four species of Hyæna are described, based on specimens in the collections of the British, Indian, and Dublin Museums, and there are not wanting evidences of a fifth form. It is remarkable to find so many species of hyæna existing contemporaneously in India; but, when the large number of Proboscidia and other ungulate forms that existed at the same time is recalled to memory, to find the genera of Carnivora equally strongly represented in species is perhaps only what might have been expected. The earliest notice of the remains of Hyæna from the Siwaliks appeared in 1835 in the *Journal of the Asiatic Society of Bengal*, where Sir W. L. Baker described a specimen as "the most perfect fossil we have yet been so fortunate as to meet with." This specimen is figured in the annexed woodcut (Fig. 3), and is at present in the Dublin Museum. The species has been described by Mr. Bose as *H. felina*. Its affinities are towards the recent *H. crocata* of South Africa, a species common in Europe during the Pleistocene period; and this fact points, Mr. Lydekker thinks, to the conclusion that Asia rather than Africa may be regarded as the cradle of the race of hyænas. *H. colvini*, Lyd., *H. macrostoma*, Lyd., the latter a species that seems to constitute an important link between the more typical members of the genus and the viverroid and canoid Carnivora. *H. sivalensis*, Bose, is redescribed and figured. A new genus, Lepthyæna, is made for a species previously recorded as *Ictitherium sivalense*.

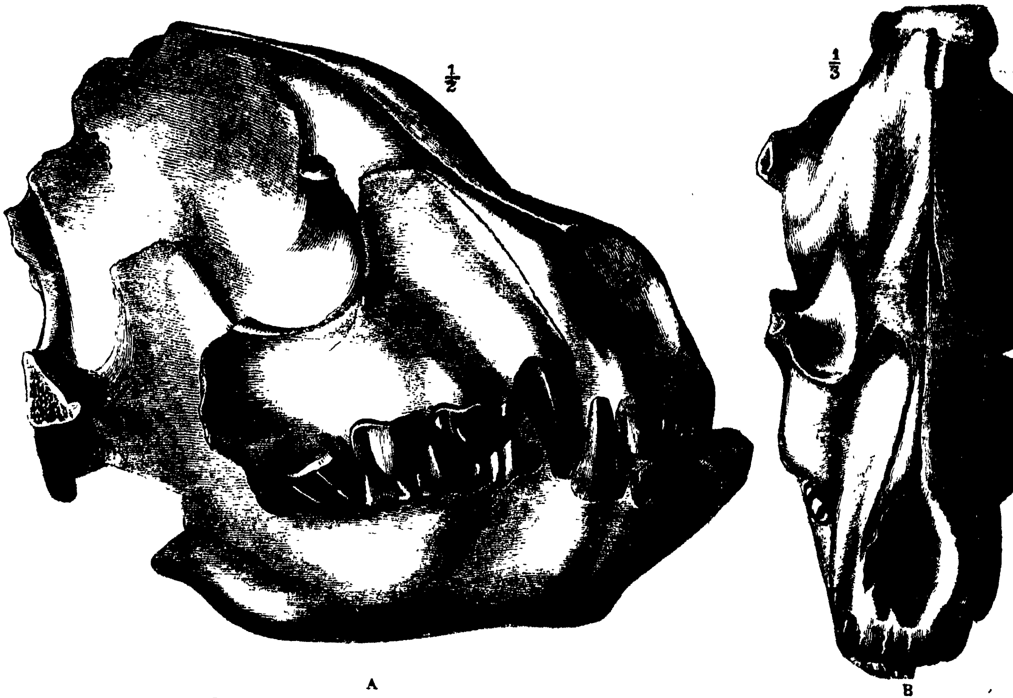

FIG. 3.—*Hyæna felina* (Bose). A, oblique view of right side of cranium; B, front view.

The Siwalik Felidæ embrace *Æluropsis annectans*, Lyd., a new genus and species of which but little is known; *Ælurogale sivalensis*, Lyd., for a carnivore intermediate in size between the Thibetan lynx and the leopard. Six species of Felis are either described or indicated; of those described are *F. cristata*, F. and C., *F. brachygnathus*, Lyd., and *F. subhimalayana*, Bronn. Of the genus Machærodus two species are included in the list of Siwalik forms. *M. sivalensis*, F. and C.: a nearly complete left ramus of the mandible of this species is in the Dublin Museum, and is represented in Fig. 4; posteriorly it is complete, with the exception of the coronoid process, while anteriorly it is broken through the symphysis; it shows part of the alveolus of the canine and the greater portion of the descending expansion. The three cheek teeth are preserved, but in a more or less broken condition; a large part of the outer surfaces of *pm*.4 and *m*.1 have been chipped away. These teeth agree with the type specimen in the British Museum, with the exception that *pm*.3, though still small, is inserted by two distinct fangs. The last family, that of Hyænodontidæ, is one considered by Prof. Huxley as occupying a position connecting the Carnivora with the Insectivora. Only one species belonging to the genus Hyænodon has been found. This genus has hitherto only been recorded from Europe and North America. The species *H. indicus*, Lyd., is represented by teeth from the Siwaliks of Kúshalghar and the Punjab.

Perhaps the most striking feature in this list of extinct forms is the fact that by the side of ratels, bears, jackals, and civets, some hardly to be distinguished from living species, there are to be found essentially primitive forms, proving the survival in India of old types long after they had disappeared from other parts of the world. Equally noteworthy is the apparently contemporaneous existence

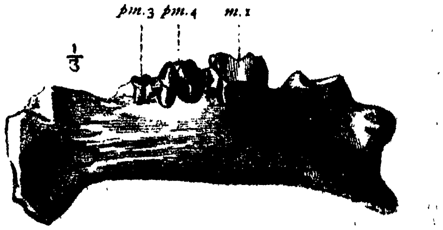

FIG. 4.—*Machærodus sivalensis* (F. & C.). Outer view of left ramus of mandible of a male.

of specialised and generalised forms of the same genus; this is well seen in the hyæna. It will also be seen that the Siwalik carnivorous fauna fill up many gaps in the chains of relationship, such as that between the bears and dogs, the viverroids and hyænas, and these latter and the cats.

The rock series in which these fossils occur is therefore one of very great interest. From the Brahmaputra to the Jhelum, for a distance of 1500 miles along the base of the Himalayas, there extends with varying width a succession of ridges or ranges which are known as the sub-Himalayan hills. Physically and constitutionally they are readily distinguished from the ranges belonging to the mass of the Himalayas proper. The rocks forming them are all of Tertiary age, and they are divisible into an upper (the Siwalik) and a lower (the Sirmur) series; these again are further divisible respectively into upper, middle, and lower groups. This is the principal and classic area of these rocks, but they occur also in Burmah, Perim Island, and in Sind.

With the Sirmur series, which in part consists of marine (Nummulitic) strata, we have no special concern at present. It is from the rocks of the Siwalik series alone that the vast harvest of remains of fossil vertebrates has been collected in the sub-Himalayan region during the past fifty years. The fossil-bearing beds are principally conglomerates of undoubtedly fresh-water origin, indeed, owing to their local development at the gorges of the existing great rivers, where they emerge from the Himalayas, it is clear that they were deposited at a time when, so far, the configuration had been established; but, as the very highest beds exhibit signs of intense disturbance and crushing, it is no less apparent that, although the main drainage lines have not altered, there has been much movement and upheaval, which, however, appears to have been effected, not by sudden, but rather by slow and gradual action.

After much discussion as to the correlation of these fossiliferous conglomerates with the established order of sequence in Europe, it would appear to have been finally adopted that, in spite of a certain Miocene facies in the fauna, the general characteristics are such as to indicate a Pliocene age. Fossil-bearing beds of Post-Pliocene age occur, it may be here remarked, in other parts of India.

Numerous and varied as the fossils from these rocks are which are now preserved in the museums of Calcutta, London, Dublin, and elsewhere, they do not appear to be found anywhere concentrated in great quantities, the specimens having for the most part been found at widely separated intervals, where they lay more or less weathered out of the enveloping matrix. Though naturally mineralised, and with but a small percentage of residual animal matter, they are often beautifully preserved, but occasionally, owing to the hardness and tenacity of the matrix, it has required the utmost patience and skill to chisel out the details of structure, while sometimes it has been found impossible to do so.

Mr. Lydekker is to be warmly congratulated on the completion of this important volume, and we are glad to know that he is busy with volume iii., which is to include an account of the Siwalik Suina and Birds.

AN EARTHQUAKE IN ENGLAND

AT last the people of these islands have been enabled to realise the meaning of the term "earthquake," so terrible in its significance in many other parts of the globe. On Tuesday morning, at a time variously given from 9.15 to 9.30, a shock which was really alarming and did considerable damage was felt over the Eastern Counties and as far west as London and even Rugby. The centre of disturbance seems to have been at Colchester, and the wave apparently travelled from south-east to north-west, though impressions vary on this point. At Colchester, in addition to the undulations of the earth, subterranean rumblings were heard, buildings rocked to and fro, the streets were strewn with debris of fallen chimneys, a chapel spire was thrown to the ground, and other signs of seismic disturbance were evident, familiar enough to those who have been in countries where such phenomena are common occurrences. The shock, when it was most intense, commenced with a rumbling sound, increasing in intensity for about twenty seconds, and then suddenly stopped. It extended to Chelmsford, Cambridge, Northampton, Ipswich, Sudbury, Rugby, Leicestershire; it included London and the surrounding district in its sweep, and even caused some alarm in the Strand. At Woolwich it was so strong that some persons attributed the shock and noise to the bursting of a heavy gun.

We have received the following communications with reference to the earthquake:—

ONE of the most severe earthquake shocks which has occurred in England for many years took place this (Tuesday) morning in the Eastern Counties. The area of its chief operation lay over South Suffolk and North Essex, and the principal focus of the disturbance seems to have been the neighbourhood of Colchester. A great deal of harm has been done to property there: houses are partially unroofed, many chimneys and gable-ends of the very old houses in Colchester have been demolished, part of the spire of the Lion Walk Congregational Chapel (a well-known building), to the amount of twenty feet from the apex, was thrown down, and other details of mischief done are fast coming in. Langenhoe Church, about twenty-four miles from Colchester, is said to be all but demolished, the entire eastern end being shaken down. The Rectory also severely suffered, so that little more than the walls are standing. At Wyvenhoe, near Colchester, the church steeple is thrown down and many houses are much damaged. Other villages around Colchester have more or less suffered: Lexden, Abberton, Greenstead, Hythe, &c., all show evidences of the disturbance in their more or less shattered buildings. The shock was severely felt here at Ipswich. I was sitting down at 9.18 a.m. when the first shock occurred, and it nearly overbalanced me. I felt it must be an earthquake oscillation, although I had never experienced anything like it before, and accordingly waited and watched for the next. The oscillations followed each other for about three seconds, and apparently travelled in a north-north-easterly direction. I underwent quite a new experience, so vivid that I am not likely to forget it. The sensation approached that of nausea. In the town of Ipswich many people were alarmed, for the bells were set ringing, the pictures on the walls shaking, &c. The occurrence is too recent, however, to carefully note the direction of the oscillations. The London Clay in Suffolk and North Essex, when cut into, abounds with small faults and creeps, and this shock may be leaving another such token behind it.

J. E. TAYLOR

Museum, Ipswich, April 22

AT about 9.20 this morning I distinctly felt a slight earthquake. The motion though slight was unmistakable, the chair on which I sat, and the whole house, seemed to move to and fro for the space of, as near as I could judge, ten seconds. I regret I cannot give the exact time when I felt the shock, as I had omitted to put my watch in my pocket.

A. PERCY SMITH

Rugby, Tuesday, April 22

THIS morning the earthquake was very perceptible here at exactly 9.22. It was travelling from north to south in short rapid undulations. It lasted for thirty-three seconds. My chief object in writing is to draw attention to the fact that this is the second earthquake which has shaken

London this year. On Sunday afternoon, January 13, about 4.5 p.m., while sitting in my rooms here along with my wife and my brother, I was suddenly sensible of a severe earthquake; I pulled out my watch to take the exact time, and while I was in the act of drawing their attention to the phenomenon, my wife, who has experienced with myself, numerous shocks in the Malay Archipelago, exclaimed also that an earthquake was occurring. My brother distinctly felt the shock, but was unaware what it was. It was composed of two severe shocks, with an interval of short duration between them. The house was quite still, and nothing was passing in the street, nor for more than twenty minutes did any carriage come along it. Being accustomed for several years to observing earthquake movements, I am perfectly confident of the occurrence of an earthquake at that time; and in the hope that some other observer has noted the fact, I have sent this note to NATURE. HENRY O. FORBES

87, Queen's Crescent, Haverstock Hill, N.W.,
April 22

MR. E. B. KNOBEL, F.R.A S., F.G.S., writes to the *Times* from Bocking, near Braintree:—"A sharp shock of earthquake was experienced here at about 9.18 a.m. this morning. A slight trembling was first felt, followed by an oscillation sufficient to make one stagger and cause some alarm. Among the incidents which resulted, house bells were set ringing, one or two doors of cottages burst open, and clocks stopped. The safety-valve of a boiler was lifted and steam blown off for an instant. The phenomenon lasted from two to three seconds, though perhaps the latter estimate is slightly in excess of the true duration of the oscillation. The following facts may be useful in determining the direction of the wave. Three pendulum clocks in different houses stopped, the line at right angles to the plane of oscillation of the pendulum being in all cases north-west and south-east. Pendent gaslights in a factory were caused to sway in the same direction, north-west and south-east. A door was burst open, the position of which when closed was north by west and south by east. These facts would indicate a south-easterly origin of the earthquake wave."

A CORRESPONDENT at Southend states that the wave seemed to travel from north to south, while in the neighbourhood of Oxford Street the direction seemed east to west, and so also at Gray's Inn, where a correspondent felt as if the bed were slipping from under him. Doubtless by next week we shall have fuller and more precise details.

NOTES

THE final meeting of electricians to determine the practical units of electricity and light assembles in Paris on the 28th inst., when England will be represented by Sir William Thomson, Messrs. Preece, Hughes, Adams, Jenkin, Foster, Graves, and Hopkinson and Capt. Abney. The Congress is expected to last or several days.

DR. KOCH and the members of the German Commission sent last autumn to Egypt and India to investigate the cause of cholera have left Alexandria on their return to Europe.

THE Senate of Glasgow University have resolved to confer the degree of LL.D. on Prof. Osborne Reynolds, Victoria University, and Mr. Thomas Muir, High School, Glasgow.

AT Ekhmeem, a large provincial town of Upper Egypt, situate about half way between Assiout and Thebes, Prof. Maspero, returning from his annual trip of inspection up the Nile, has just found a hitherto undiscovered and unplundered necropolis of immense extent. As far as has been yet ascertained, the necropolis dates from the Ptolemaic period; but as the work of exploration proceeds, it will probably be found that it contains more ancient quarters. The riches of this new burial field would meanwhile seem to be almost inexhaustible. Five great tombs or catacombs already opened have yielded 120 mummies, and within the short space of three hours Prof. Maspero verified the sites of over 100 more similar catacombs, all absolutely intact. The necropolis of Ekhmeem, at a rough estimate, cannot contain fewer than five or six thousand embalmed dead. Of these perhaps not more than 20 per cent. will turn out to be of archæological or historical value; but the harvest of papyri, jewels, and other funeral treasures cannot fail to be of unprecedented extent. Ekhmeem is the ancient Khemnis—the Panopolis of the Greeks. Its architectural remains are insignificant.

THE Granton Zoological Station was formally opened last week; the ceremony was to have been performed by Prof. Ernst Haeckel, but illness prevented him from coming to Edinburgh, as he had intended, to be present at the tercentenary celebration.

THE annual meeting of the Iron and Steel Institute will be held on Wednesday, April 30, and May 1 and 2, at the Institution of Civil Engineers, 25, Great George Street, commencing each day at 10.30 a.m. The list of papers and subjects for discussion is as follows:—Adjourned discussions: (1) On the tin plate industry, by Mr. E. Trubshaw, Llanelly; (2) on the coal-washing machinery used by the Bochumer Verein, by Mr. F. Baare, Bochum; (3) on the manufacture of anthracite pig iron, by Mr. J. Hartman, Philadelphia, U.S.A. Adjourned papers: (1) On recent results with gas puddling furnaces, by Mr. R. Smith-Casson, Brierly Hill; (2) on a new form of gas sampler, by Mr. J. E. Stead, F.C.S., Middlesborough. New papers: (3) On the use of raw coal in the blast furnace, by Mr. I. Lowthian Bell, F.R.S., &c., Rounton Grange, Northallerton; (4) on the behaviour of armour of different kinds under fire, by Capt. C. Orde-Browne, Lecturer on Armour at Woolwich; (5) on recent progress in iron and steel shipbuilding, by Mr. William John, Barrow-in-Furness; (6) on the most recent results obtained in the application and utilisation of gaseous fuel, by Mr. W. S. Sutherland, Birmingham. In addition we believe that a paper may be expected on the important subject of iron or steel sleepers, as now used largely in Germany, in place of the timber sleepers with which we are all familiar; and possibly papers on other subjects may be at the last moment forthcoming. It will be seen that the programme presents several features of interest. Mr. Lowthian Bell, we have every reason to believe, will exhibit the conditions attending the use of raw coal instead of coke in the blast-furnace in a clearer and more satisfactory form than has ever before been achieved. Again, the great duel being fought out between armour and guns is always a matter of keen interest, and Capt. Orde-Browne's position as a skilled and yet independent observer of the struggle gives him a special right to speak upon it. He will be able to give the last results obtained with the compound or steel-faced armour now coming so much into fashion. The ordinary business of the meeting includes the election of members, reading of the Council's report, and the presentation of the Bessemer gold medals to Mr. E. P. Martin, late of Blaenavon, but now General Manager of the great works at Dowlais, and to Mr. E. Windsor Richards, General Manager to Messrs. Bolckow, Vaughan, and Co., Middlesborough, to whom we are indebted for the practical realisation of the basic process of steel-making.

COL. KINCAID, Political Agent, Bhopal, writes to us under date March 30:—"We have had a renewal of the after-glow here lately, but not nearly so intense as we had in September October, November, and part of December. The natives of the country have naturally been much exercised by the prolonged phenomenon, and still believe it portends war and tumult." Col. Kincaid also sends us an extract from Malcolm's "History of Persia," referring to an "extraordinary change in the appearance of the sun" in the year 1721, which greatly alarmed the Persians of the period.

MR. SYDNEY HODGES, of Ealing, sends us a letter he has received from Mr. C. St. Barbe, of Wellington, New Zealand, dated February 17, on the green moon. "The phenomenon of a green moon," Mr. St. Barbe writes, "has been distinctly visible here during the last week or two. The colour was sufficiently decided to attract the attention of many people, and the local journals took notice of it. The moon at the time was east of north (though very little), while the crimson after-glow was in the south-west, and consequently at the back of an observer looking at the strange colouring of the moon. I am not aware whether these positions would have anything to do with the question of complementary colours, as I know nothing about such matters, and I am unfortunately unable to say whether the green tint appeared on the moon before the crimson after-glow appeared, as the latter has become such a commonplace occurrence here as hardly to be noticed." Mr. Hodges has also received a letter from his son, who reached New Zealand from Calcutta on February 13. In it he says: "I don't know whether you heard of the volcanic eruptions in Java last September. To show what a quantity of stuff was thrown up, we were sailing for *twelve days* through a sea of pumice-stone. You could see nothing else as far as the horizon on every side, and this four months after the eruption."

DR. L. WALDO, *Science* states, has just completed the erection of a normal clock at the Yale College Observatory, to be used as a mean-time standard in the horological work of that institution. The movement and pendulum are parts of the gravity escapement clock built by Richard Bond (No. 367), and which had a phenomenal record under Mr. Hartnup at Liverpool, and later under Prof. W. A. Rogers of Cambridge. The case, from Dr. Waldo's designs, is built of cast-iron, with planed back and front, to which are clamped the plate-glass doors. The entire case rests upon two brick piers, which rise to the height of the movement, and insure stability to the pendulum suspension. Thermometers, a barometer, and a cup of calcic chloride are placed within the case, which can be exhausted to any barometric pressure desired by an air-pump attached to its side. The escapement and arc of vibration can be observed and adjusted with the greatest accuracy. The clock is erected in the clock-room of the Observatory, which was specially built to secure uniformity of temperature.

CAPTAIN BLAKISTON, who has been resident in Japan for more than twenty years, has recently issued an amended list of the birds of that country, with the ornithology of which he certainly possesses a better practical acquaintance than any living man. The list is founded on a previous catalogue, published in 1882 by Capt. Blakiston and Mr. H. Pryer, but the species are now arranged geographically, so as to show the distribution of birds through the different islands of Japan. The author draws attention to the natural division in the fauna of Japan, which is marked by the Strait of Tsungaru, to the southward of which the true Japanese avifauna is emphasised, while north of this strait the avifauna is Siberian in character.

THE following meetings of the Society of Arts have been arranged:—Ordinary meetings (on Wednesday evenings)—April 30, "The New Legislation as to Freshwater Fisheries," by J. W. Willis-Bund. May 7, "Bicycles and Tricycles," by C. V. Boys. May 14, "Telpherage," by Prof. Fleeming Jenkin, F.R.S. May 21, "Telegraph Tariffs," by Lieut.-Col. Webber, R.E. May 28, "Primary Batteries for Electric Lighting," by I. Probert. In the Foreign and Colonial Section the following paper will be read on April 29, "The Transvaal Gold Fields; their Past, Present, and Future," by W. Henry Penning. In the Applied Chemistry and Physics Section on May 8 a paper will be read on "Cupro-Ammonium Solution and its Use in Waterproofing Paper and Vegetable Tissues," by C. R. Alder Wright, F.R.S., D.Sc.; and on subsequent evenings in the Indian Section the following papers will be read:—"Economic Applications of Seaweed," by Edward C. Stanford, F.C.S. May 9, "Indigenous Education in India," by Dr. Leitner. May 30, "Street Architecture in India," by C. Purdon Clarke, C.I.E. This paper will be illustrated by means of the oxy-hydrogen light.

DURING the next few weeks the following Penny Lectures will be delivered on Tuesday evenings at the Royal Victoria Coffee Hall, Waterloo Road:—April 22, "Camping out on the Thames," by the Rev. P. H. Wicksteed. April 29, "A Visit in the *Sunbeam* to the West Indies," by Sir Thomas Brassey, M.P. May 6, "Ice, and its Work in Earth-shaping," by Dr. W. B. Carpenter. May 13, "Fire, Electricity, and other Forms of Power," by Mr. Vernon Boys. May 20, "A Working Man's Dinner," by Prof. H. G. Seeley. May 27, "The Recent Eruption of Krakatão," by Mr. J. Norman Lockyer.

WE have received two pamphlets on the vivisection question, viz. "Vivisection in its Scientific, Religious, and Moral Aspects," by E. P. Girdlestone (Simpkin, Marshall, and Co., pp. 68, price one shilling), and "The Utility and Morality of Vivisection," by G. Gore, LL.D., F.R.S. (F. W. Kolkmann, 2, Langham Place, W., pp. 32, price sixpence). These pamphlets are alike in that their authors argue the question on general grounds of common sense. The essay by Mr. Gore is issued by the Association for the Advancement of Medicine by Research, and is an admirable contribution to the subject of which it treats. Not being himself a physiologist, Mr. Gore's pleading is of all the more force from its non-professional character; while the fact of his being so busy a worker in other departments of science, as well as a man who has made a special study of the methodology of research, or "the art of discovery," enables him to speak not only with authority, but with unusual lucidity. The calmly forcible style in which he writes contrasts favourably with the hysterical vituperation which he quotes from the other side. This pamphlet ought to be read by every one who desires to obtain a rational as well as a truly moral view of the subject.

THE fourth edition of Henfrey's "Elementary Course of Botany" will be published by Van Voorst early in May. The morphology of flowering plants has been revised and added to by Dr. Maxwell Masters, who has also made great additions to the physiological portions, while Mr. A. W. Bennett has re-written the sections relating to Cryptogamia. This new edition will be still further enriched by numerous additional illustrations.

HARTLEBEN of Vienna has issued the first part of a work on the oceans and their life, entitled "Von Ocean zu Ocean, eine Schilderung des Weltmeeres und Seines Lebens," by A. von Schweiger-Leichenfeld.

AT a recent meeting of the Asiatic Society of Japan (reported in the *Japan Weekly Mail*), Mr. O. Korschelt read a paper on "The Chemistry of Japanese Lacquer." The paper opened with a brief account of the source and preparation of the lacquer, and of the conditions under which it hardens to the best advantage. The interest of the paper lay, however, in the very complete discussion of the chemical constituents of the substance, and the synthetic determination of which of these were most essential. The summary of results was given in these terms:—1. The raw lacquer juice is an emulsion which contains—(*a*) a peculiar acid called urushic acid (*urushi*, the native name for lacquer), (*b*) a gum, (*c*) a nitrogenous body, (*d*) water, and (*e*) a volatile acid in traces. 2. The hardening of the lacquer juice, which takes place when the latter is exposed in a thin layer of moist air of 20° to 27° C., is due to the oxidation of urushic acid into oxyurushic acid. 3. This oxidation is caused by the nitrogenous body, which is an albuminoid and acts as a ferment.

4. The oxidation is not accompanied by hydration. The water must be present only to keep the ferment in solution, which else would not act. 5. The oxidation takes place within narrow limits of temperature, ranging from about zero Centigrade to that of the coagulation of albumen. 6. The gum seems to have a favourable influence in keeping the other substances in emulsion; but in the hardened lacquer its presence is injurious, causing it, when in contact with water, to rise in blisters. 7. By a mixture of the raw juice with urushic acid, the quantity of gum present is diminished, and the dried lacquer is enabled better to resist the injurious influence of water, besides obtaining a greater transparency. 8. The admixture of more than five parts urushic acid with one part juice weakens the action of the ferment, and so deteriorates the quality of the lacquer. 9. The gum is very similar to gum-arabic, but gives a sugar with two-thirds only of the reducing power of arabinose. 10. The ferment has the composition of albumen, except that it contains much less nitrogen. 11. Diastase and the ferment in the saliva cannot replace the lacquer ferment. 12. The difference between good and bad lacquers seems to depend mainly on the relative quantities of urushic acid and water present, the inferior lacquer having less acid and more water than the superior kind. 13. The durable quality of lacquer is a property of the oxyurushic acid, which is singularly negative in its actions, resisting all solvents tried, and affected by strong nitric acid only. In the course of the discussion which followed it was observed that probably the direct effect of the investigations would be the improvement of the lacquer process, which was peculiarly a Japanese art; also that lacquer poisoning was due to the urushic acid, which only gradually disappeared during the hardening process, the best and oldest lacquers having none at all. Sugar of lead was mentioned as the best antidote for the poison.

THE last number of *Naturen* contains an interesting report by Herr L. Stejneger of the result of his last summer's exploration of Ostrof Mednij, or Copper Island, the smallest of the Komandorski group (Commodore Islands). On his arrival the chief town was found to be nearly empty, its numerous roomy and gaudily painted houses and church having been deserted while the inhabitants had gone for the fishing season to the "Lesjbitscha," or fur-seal fishing-grounds, on the other side of a rocky promontory. The dense mists which never fail at that season interfered with the naturalist's field work, but he was so fortunate as to discover a new species of Anorthura, differing equally both in form and colouring from the earlier described *A. alascensis* of of Prof. Baird, and from the Japanese *A. fumigata*, which is believed to belong also to the Aleutian Islands. Herr Stejneger, who has given this new form the name of *Troglodytes (Anorthura) pallescens*, considers that, although essentially the same as its Norwegian representative, it is still more closely allied to the Eastern Central Asian forms. Since his visit to Copper Island Herr Stejneger has found on Behring's Island another Anorthura, which differs widely from *A. pallescens*, and which he believes may prove to be the same as *A. fumigata*, common in Kamchatka. *A. pallescens* is of frequent occurrence on Copper Island. It builds its nest in the clefts of rocks at inaccessible points, and in the sound of its note, as well as in its general habits, it resembles its European kindred. The rosy finch (*Leucosticte griseinucha*), supposed to be American, was found on the Aleutian Islands, and has not been observed, as far as we know, in any other part of the Old World. Its brilliant colouring, hoarse, unmelodious song, and its preference for steep, inaccessible, rocky peaks which abound on Copper Island, make it one of the most characteristic of the local birds. Herr Stejneger has largely availed himself of the opportunities opened to him of studying the various representatives of Otariidæ and Phocidæ, which abound on the Aleutian shores, and in his paper on *Callorhinus ursinus* (the Kólik, sea-cat of the Russians, and well known as the fur-seal of the American and English traders), he has given the readers of *Naturen* an extremely interesting and comprehensive description of the appearance, habits, and commercial importance of these valuable animals. He graphically describes the forcible tactics employed by the older seals, "Sichatchi" (Russ. husbands), in keeping the juniors, "Cholustjaki" (bachelors), within their allotted grounds, and supplies many hitherto unknown details concerning distinctive characteristics dependent upon differences of age, &c.

THE last number (thirtieth) of the *Mittheilungen der deutschen Gesellschaft für Natur und Völkerkunde Ostasiens* (Yokohama) commences with an article on mines and mining in Japan, by Herr Metzger—the third important work on this subject published by Germans. The writer, who has been for five years at the copper mines at Ani, professes merely to supplement the previous writings of his countrymen. Herr Metzger's account of Japanese practical mining is somewhat melancholy reading; on all hands he finds ignorance, incompetence, waste. There is a total absence of technical officials, everything appears to be in the hands of contractors, the mining law is in a most unsatisfactory condition, and the position of the foreign mining engineer is such that he can do little to remedy evils which he sees plainly. In this respect the complaint is everywhere the same. "The scope of the foreigner is much less than might be expected under the circumstances. It seems at present to be the full intention of the Japanese to do everything themselves; and at the most to use their Europeans as advisers, although their contracts call them engineers, &c. It not unfrequently occurs that foreigners get the impression that the advice of Japanese of the lowest rank, with or without technical training, is of equal weight with their own." Herr Metzger further alleges that since Europeans have been withdrawn the production of the gold mines of Sada has considerably diminished. He asserts that by avoiding the extraordinary waste caused by ignorance and mismanagement, the mineral production of the whole country could be increased by at least fifty per cent. Herr Lehmann writes on the indoor games of the Japanese. From the reports of the meetings it appears that the capital of Japan had its Fisheries Exhibition last year. There were 15,205 exhibitors—an unexpectedly large number; and, as a consequence, the Exhibition was divided into forty-seven separate exhibitions, corresponding to the various administrative divisions. This method rendered a journey through the Exhibition wearisome by constant repetition, and added greatly to the difficulties of a systematic study of the exhibits, which were not lessened by the absence of a catalogue. The number of articles connected with fishing amounted to 3967, while the various goods made from fish and water plants reached 6474. The fishing population of Japan is given at 1,601,406. Some interesting information respecting the rearing of fish in Japan is also given.

THE Tiflis *Isvestia* contains an interesting paper on the population of the Caucasus, a new census having been made in the course of the year 1882 in several of the larger provinces of the country. It appears from this census, although incomplete, that the population has much increased since the last census of 1877. In 1867 the whole population of the Caucasus was reckoned at 4,661,800; it rose to 5,391,700 in 1876-77. It is now more than 6,500,000—the total being reckoned at 6,449,850—which figure is still considered below the reality. This large increase of more than 1,200,000 in five or six years is partly due to the recent annexations (162,980 in the province of Kars, and 92,450 in the district of Batoum), to immigration, to natural increase, and to the incompleteness of the former census. As to the natural increase, due to the surplus of births over deaths, it is estimated at an average of 13 per thousand every year in the Government of Tiflis (1875 to 1880), and at 12 per thousand in the Government of Erivan. Altogether, the mortality is, however, very great, and it is compensated only by a great number of births. As to the density of population, the 224,221 square kilometres occupied by the Northern Caucasus have 10·3 inhabitants per square kilometre, which figure reaches as much as 13·6 in Transcaucasia (248,445 square kilometres), where the density of population is the same as in European Russia. The Governments of Kutais (the valley of the Rion), Erivan, and Tiflis have respectively 33·6, 20·8, and 17·8 inhabitants per square kilometre.

AMONG the recent additions to Chinese scientific literature are translations of Margutti's "Elementary Chemistry" and Fresenius's "Chemical Analysis." These works have been translated into Chinese by M. Billequin, one of the professors of the Jung Wên Kwan, or Foreign College, at Pekin.

THE Secretary of State for India in Council has appointed Mr. David Hooper, F.C.S., of Birmingham, to the Nilgiri Government Cinchona Plantations in the Madras Presidency.

THE additions to the Zoological Society's Gardens during the past week include a Ludio Monkey (*Cercopithecus ludio*) from West Africa, presented by Mr. F. W. Robinson; a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. E. Drew; a Vulpine Phalanger (*Phalangista vulpina*) from Australia, presented by Mr. J. C. Martin; a Central American Agouti (*Dasyprocta isthmica*) from Central America, presented by Mr. Hugh Wilson; a Herring Gull (*Larus argentatus*), European, presented by Mr. Thomas Daws; a Common Viper (*Vipera berus*), British, presented by Mr. H. German; a Burchell's Zebra (*Equus burchelli* ♀) from South Africa, three Michie's Tufted Deer (*Elaphodus michianus* ♂ ♀ ♀), four Darwin's Pucras (*Pucrasia darwini* ♂ ♂ ♂ ♀), an Elliot's Pheasant (*Phasianus ellioti* ♂) from China, deposited; three Corn Buntings (*Emberiza miliaria*), British, purchased.

OUR ASTRONOMICAL COLUMN

SOUTHERN COMETS.—Dr. Oppenheim of Berlin has published elements of the comet discovered by Mr. Ross of Elsternwick, Victoria, on January 7, founded upon the Melbourne observations in *Astron. Nach.*, No. 2579, though, as he remarks, they were calculated with difficulty, owing to the existence of three oversights in the seven positions there given; hence their connection for an orbit would involve a troublesome tentative process. The position for January 17 is in error nearly two degrees.

Mr. Tebbutt has also computed elements from his own observations at Windsor, New South Wales, on January 19, 23, and 28, which represent closely the observation on February 2, the last he was able to obtain, the comet having become very faint; on January 19 he had considered it just beyond naked-eye vision. He remarks upon the discordance of his elements with those calculated by M. Barachi of the Melbourne Observatory, and observes: "I cannot account for these discrepancies, unless there be some error in the Melbourne data." We subjoin both orbits:—

	Tebbutt		Oppenheim
Perihelion Passage, 1883,	Dec. 25·30038 ...	...	Dec. 25·3027
	° ′ ″		° ′ ″
Longitude of perihelion	125 44 24	...	125 46 12
,, ,, ascending node	264 24 0	...	264 25 14
Inclination	65 0 55	...	65 0 51
Log. perihelion distance ...	9·491046	...	9·49094

Motion retrograde.

The time of perihelion passage is for the meridian of Greenwich, and the longitudes are referred to the mean equinox of 1884·0. It will be seen from the close agreement of the two orbits how completely Dr. Oppenheim succeeded in eliminating the Melbourne errors from his work.

In a communication to the *Observatory* of the present month Mr. Tebbutt refers to a notice in the Sydney journals copied from a Tasmanian newspaper, reporting that a bright comet had been seen at New Norfolk at 4 a.m. on December 27, bearing about east, and a few degrees above the horizon; he had searched for it in the morning sky without success. In the *Sydney Morning Herald* of March 5, Mr. Tebbutt writes:—"Within the past few days I have received, through Commander J. Shortt, R.N., the Meteorological Observer at Hobart Town, communications respecting a fine comet which was seen in Tasmania on December 25 and 27 in the morning sky. It is described as rising above the eastern horizon a few minutes before the sun; and I am strongly inclined to the opinion that this is no other than the comet whose elements I have just communicated" (the comet found by Mr. Ross). There are difficulties, however, in the way of accepting this identification, judging from such information as we have to hand. The great increase of light near perihelion passage is not explained by the elements of the comet of January 7, which by theory would only have possessed five times the intensity of light that it had at the first Melbourne observation on the evening of January 12.

THE OBSERVATORY OF PALERMO.—In *Pubblicazioni del Real Osservatorio di Palermo, anni* 1882-83, Prof. Cacciatore, the director, has collected a large number of interesting observations made chiefly in the year 1882. Prof. Riccò's astro-physical observations of the planet Jupiter extend from December 1881 to June 1883, and his descriptions of the appearance of the disk are accompanied by eighteen well-executed tinted lithographs. An extensive series of observations of the great comet of 1882, also illustrated, follows; it was last perceived with difficulty on April 7, 1883. After the conjunction of the comet with the sun it was again sought for; with a power of 110 on the refractor, and in the best condition of atmosphere, the search was unsuccessful on three evenings in September. There are other cometary and planetary observations and an appendix with the meteorological results obtained at the auxiliary station of Valverde.

GEOGRAPHICAL NOTES

THE meetings of the International Polar Conference began in Vienna last week under the presidency of Herr Heinrich Wild, the Director of the Physical Central Observatory of St. Petersburg. In his address the President praised the great merits of Count Wilczek with regard to Polar research, referred to the lamented death, since the last conference, of the Secretary of the Polar Commission, Capt. Hoffmeyer of Copenhagen, and finally gave an outline of the work done since the St. Petersburg meeting by the various expeditions and observing stations. Herr R. Müller, Director of the Hydrographic Office at Pola, was elected secretary in the place of Capt. Hoffmeyer, deceased. The principal subject discussed at the first meeting was the determination of the minimum extent to which each expedition party is bound to work out and publish its own observations at its own expense, and the establishment of a universal form of publication of results for their easier comparison. First of all the meteorological observations were discussed in this regard. The debate turned on the uniform way of noting down the obligatory observations at each station, *i.e.* the observations of temperature, atmospheric pressure, humidity, wind, clouds, hydrometeors, rainfall, and temperature of the ground, snow and ice. Among those who have arrived at Vienna are the following:—MM. R. Lenz (Professor at the St. Petersburg Technological Institute), H. Mohn (Director of the Christiania Meteorological Institute), R. H. Scott (Director of the London Meteorological Office), Lieut. P. H. Ray of Washington, Lieut. E. von Wohlgemuth (Vienna), Herr Wijkander, Prof. Guido Cora (Turin University), Capt. Dawson (Chief of the Fort Rae Expedition), Dr. Giese of Hamburg (Chief of the German Antarctic Expedition), H. Paulsen of Copenhagen (Chief of the Danish Polar Station at Godthaab), Lieut. Payen (Paris), Dr. Snellen (Director of the Utrecht Meteorological Observatory), Aksel S. Steen (of the Christiania Meteorological Institute), Count Hanns Wilczek (Vienna). The following were expected to arrive shortly:—Prof. G. Neumayer of Hamburg (Director of the German Seewarte), Prof. E. Mascart (Director of the Paris Meteorological Central Bureau), Dr. Börger (of the Kiel Marine Observatory), Prof. Lemström (Helsingfors), E. Riese (Chief of the Finnish Polar Station at Sodankyla).

THE *St. Petersburger Zeitung* contains the following details concerning the expedition which Col. Prjevalsky is now leading in Thibet. The points of departure of the expedition were Kiakhta and Ourga. From thence it was to go to Tsaidam by Alashan and Koko-Nor. In Tsaidam, at the foot of Burkhan Buda, it was the intention to establish a camp, and leave behind a section of the party and of the escort. Col. Prjevalsky, with his companions, will push forward to the sources of the Yellow River, and even to the towns of Chambo and Batanou. If the circumstances are propitious, the expedition will devote the spring and summer of 1884 to the exploration of the region of Sifanei, between Koko-Nor and Batanou, where it will surely find abundant natural riches to explore. In autumn the expedition will return to its encampment. A part of the baggage will be sent to Gast, in Tsaidam, where they will establish a second camp. From Gast the expedition will traverse Northern Thibet in the direction of Lhassa, and will try to penetrate as far as the Lake Tenegri-Pora, to reach afterwards, if circumstances permit, either the province of Dsang, or to the Brahmaputra. If not successful, however, the expedition will return part of the way and then go northwards to Ladak and to Lake Daigro-Jum-Tcho. From thence it will return to Gast, and try afterwards to go across the plateau of Thibet in another direction. From Gast, which they expect to reach in the spring of 1885, a part of the expedition will go towards Lob-Nor, and the other part towards Keria, that they also may reach Lob-Nor by way of Tcherkin. The two sections of the expedition will afterwards go together to Karakorum, and along the Khoton, and then return by Alsa to Asiatic Russia, near the Lake Issak-kul. Col. Prjevalsky left St. Petersburg on August 3, 1883, accompanied by Sub-Lieutenant Roborovsky, his assistant, and a volunteer, Kozloff. At Ourga they were joined by twenty soldiers for an escort, and on November 8 they left Ourga to cross the Desert of Gobi. The telegram just received from Alashan (dated January 20) tells of the safe arrival there of the expedition.

GEOGRAPHERS will be glad to find in the last volume of the *Izvestia* of the Caucasus Geographical Society a number of astronomical determinations of positions of places in the Transcaspian region, by M. Gladysheff. We find in the list a number of points in the oases of Akhal-tekke and Merv, and in Khorassan, and notice that the exact position of Sarakhs (western corner of the citadel) is 36° 32′ 14″·5 N. lat. and 61° 10′ 10″ E. long., 860 feet above the sea; that of Merv (garden at Kaushut-khan-kala) 37° 35′ 18″·3 N. lat. and 60° 47′ 16″ E. long., 900 feet above the sea; and that of Meshed (cupola of Imam Riza) 36° 17′ 25″·6 N. lat. and 59° 37′ 27″ E. long. The same volume contains a great number of heights measured in Asia Minor by Russian officers.

THE last issue of the *Izvestia* of the Russian Geographical Society contains a preliminary report of a journey made by MM. Adrianoff and Klementz in the still little-known islands to the south-west of Minusinsk; a note by MM. Hedroitz and Lessar, being a reply to M. Konshin's paper on the Kara-kum sands and the former bed of the Amu; a note, by M. Malakhoff on the remains of prehistoric man on the Nyeman, close by Druskeniki; the necrology of Admiral Putyatin, by Baron Osten-Sacken; and a note by M. Piltchikoff, on a magnetic anomaly between Kursk and Kharkoff.

ON THE PROGRESS OF GEOLOGY[1]

IN addressing you to-night at the opening of the session 1883 of Canterbury College, may I be allowed to appeal first to your kind indulgence? On an occasion like this you have a right to expect that only the best and most refined English should reach your ear; and if this to-night is not the case, you will, I trust, be lenient with me, as only very few foreigners have ever been able to master the beautiful and expressive English language so thoroughly that they would not now and then offend the ear of an educated audience.

When I look round me in this fine hall, and see before me such a large audience, of which a number consists of graduates of Canterbury College, it appears almost like a dream and not a reality—a reality of which we have every reason to be proud.

It is about sixteen years ago that a few earnest men, having the intellectual advancement of Canterbury at heart, met and proposed to found a university in Christchurch; but they were told by a not inconsiderable number of our citizens, some in high positions, that we were about a hundred years in advance of the wants of the colony. However, we persevered, and at last succeeded; and the best proof of the correctness of our views is the number of the graduates of the New Zealand University, of whom there are now twenty-one Masters of Arts and forty-nine Bachelors of Arts, together seventy; of whom Canterbury College can claim twenty-nine of its own, many of whom would be an ornament to any university of the home country.

And although the greater portion of our graduates mostly apply the knowledge gained to the education of others, they continue their studies for their further intellectual progress long after they have gained their well-earned degrees.

To my mind no more ennobling or higher sphere can be selected by anybody than that of the teacher. What mental energy, what moral devotion are required in the teacher, who can only be successful if he has his whole heart in the work, so that the chain of human sympathy, the most powerful tie in mankind, unites him with his pupil. In a young country, where wealth is generally considered to give power, position, and influence, and the "*auri sacra fames*" is much developed, only a refined mind can gladly and willingly turn away from those pursuits by which wealth is more easily obtained, in order to devote himself entirely to the education of the young.

Moreover, nothing shows us more clearly than teaching that we have only put our foot on the first step of the ladder leading to knowledge. We remain students our whole life; and I trust that none of our graduates will ever overrate the step gained, but that they will consider that the degree obtained has only given them an insight into the dominion of Knowledge, and has shown them how much they have still to learn; and that in fact they have become masters of the art how to learn to the advantage of themselves as well as of others.

Before entering into the subject I have chosen for to-night's address, I wish to make only a few remarks upon the development the University of New Zealand ought to take, so as to satisfy the present and future wants of our population. It was only to be expected that in the beginning its founders should have been guided by the curriculum of the great centres of learning in Great Britain, although even then some of the newer improvements were not adopted; but I may point out that under the different circumstances in which we live in a colony, we ought to have more cosmopolitan views, and profit by the experience of those States and communities which our conditions resemble most. In fact, the University of New Zealand ought to be eclectic, and to select for assimilation in its constitution the best as to manner and matter of teaching from all parts of the world.

According to my views it ought not to be at present the highest aim of a university course to offer a mass of knowledge of a chaotic character in a number of subjects, but to make the student acquainted with the general principles of the stock of knowledge possessed by the world and its application to life; to know in what direction that general stock is most deficient, and in what manner it can be augmented and made more useful both intellectually and practically.

The study of philosophy, in the highest and most general acceptance of the term, is one of the greatest wants for any university that intends to educate thinkers, men and women who not only wish to use their acquired knowledge for earning their daily bread, but to advance the human understanding.

Advancing to the subject upon which I wish to address you to-night, I have thought that some remarks on the progress geology has made and is daily making would not be inappropriate. I should also like to show, though owing to the short time assigned to me this can only be done in a fragmentary manner, how from an empirical science it has gradually been raised to be an inductive science fully deserving, as far as actual observations go, to claim the position of an exact science.

If we consult "The Cyclopædia, or an Universal Dictionary of Arts and Sciences," by E. Chambers, F.R.S., London, four large folio volumes, of which the first appeared in 1779 and the fourth in 1783, an excellent work, for which some of the most eminent men of the last century wrote, we find that the word geology, or geognosy, did not exist at that time, the principal information upon the formation and constitution of our earth being contained in the articles on basaltes, earth, fossils, geography, lithology, marine remains, mineralogy, mountain, rocks, stone, and volcano.

The explanation of the formation of "stones" is in many instances exceedingly erroneous, and appears ludicrous to us; whilst the explanation of the nature and occurrence of fossils is given quite correctly, although the theory of Tournefort, proposed in 1702 to the Royal Academy of France, that all stones, fossils included, were derived from liquid stone seeds, is gravely considered and rejected.

---

[1] An opening address delivered to the students of Canterbury College on March 28, 1883, by Julius von Haast, Ph D., F.R.S., Professor of Geology and Palæontology in Canterbury College (N.Z. University).

The description of volcanoes, both active and extinct, is also given in a lucid manner; but the opinions as to the cause of vulcanicity are sometimes very peculiar, including the theory of Dr. Lister—that they are originated by an inflammable mineral called pyrites.

The origin of basalt (basaltes) is correctly given, according to the researches of Desmarest in Auvergne, and Raspe in Germany, so that before Werner no erroneous views on that subject were held.

But it is a most remarkable fact that there was not even an attempt made to give an explanation of stratigraphical geology, and how the different rocks were formed, or to connect certain sets of fossils with certain rocks in which they occur; so that in many respects we can claim that geology is a child of the last hundred years.

Abraham Gottlob Werner, the great teacher of the Freiberg Academy of Mining, may be considered one of the founders of modern geology. In 1785 he delivered the first course of geognosy, as distinct from mineralogy, and by his great knowledge of all matters connected with the latter science and mining, and his excellent method of teaching, he had an enormous influence upon the advancement of geology. Therefore, as far as I am aware, the word geognosy was first used two years after the last volume of Chambers' "Cyclopædia" appeared.

A great retrograde step was, however, made by Werner when he brought out his famous theory of the aqueous origin of basalt, usually named the theory of Neptunism. After the war between the Neptunists and the Plutonists (those who maintained the igneous origin of basalt) had been raging for some years, most of the disciples of Werner—acting as partisans, and instead of trying to elucidate the truth, were only bent upon making by all means in their power the cause advocated by them victorious—for a time managed to get the upper hand. Those scientific men, who knew from their own experience that Werner's doctrines on the subject were incorrect, preferred to retire from the contest, and refused to fight with the same unfair weapons.

Of equal, if not of greater importance, are the labours of James Hutton, who, in 1788, published his "Theory of the Earth," in which, for the first time, the complicated structure of the surface of the earth is explained by the agency of natural forces, still at work at the present day. With this the foundation of modern geology was securely established, and though in some respects the great Scotch philosopher went too far, his system was, nevertheless, the only true one on which his successors could build that branch of knowledge now claiming a prominent rank amongst its sisters as an inductive science. And when William Smith, the modest English land surveyor, in 1790 published his "Tabular View of the British Strata," in which the first attempt was made to connect certain fossils with certain strata, an attempt turning out a masterpiece of patient research and skill, a further great step was made in advance, and instead of merely theorising on disconnected facts, the greater portion of geological students began to rely more upon the facts collected by them and others, than upon speculative views, however fascinating they might be.

In entering upon a short review of the physics relating to the great system of which our earth is only a very inconsiderable speck, we find that although men of the highest scientific merit had tried to explain the origin and nature of the Cosmos, and the laws by which it is governed, not one speculation had been adopted at the time of the publication of the "Cyclopædia" of Chambers, as possessing all the necessary precision for the entire satisfaction of inductive reasoning.

It was only at the end of last century that Pierre Simon Laplace published his two great works, "Exposition du Système du Monde" in 1796, and "La Mécanique céleste" in 1799. This cosmogony, usually called the "Nebular Hypothesis," has hitherto stood the test of inquiry nearly a whole century; all the facts—and they are innumerable—tending invariably to testify at least to the great probability of its general correctness. In justice I ought here to mention that Immanuel Kant published in 1755 his cosmical theories in his work "Allgemeine Naturgeschichte und Theorie des Himmels," in which the great Königsberg philosopher came to the same conclusions afterwards so convincingly demonstrated by the French mathematician.

But when we leave the Cosmos and confine ourselves to our small planet, we find ourselves surrounded by such difficulties that we appear just as far now from a true conception of the constitution of the earth's interior as our predecessors were at the beginning of this century.

Numerous theories, based upon careful calculations, as to the thickness of the crust of the earth have been advanced. Some physicists give to our earth so thin a crust that it has been compared to the rind of an orange, the fruit inclosed in it representing the molten matter of the globe; others affirm that the crust is of much greater thickness, while there are some who maintain that our planet has cooled so thoroughly that it now forms a mass of rock of various density from the surface to the very centre. Other theories (or, better stated, hypotheses) giving to our globe a crust of more or less thickness, with a hard metallic nucleus in the centre, and matter in a high state of fusion filling the space between both, have been advocated by other scientific men, and mathematical proofs in support have not been wanting. However, objections apparently fatal to them all have been brought forward at one time or another by physicists, astronomers, or geologists, according to their particular line of study, and we can therefore only wait patiently and follow attentively the careful researches continued in all civilised countries, applying at the same time every new discovery to the elucidation of a problem, the more tantalising as its solution has for many years appeared to be within our grasp.

The great hopes that the deep borings lately obtained in artesian wells, or careful temperature observations in deep mines, would supply us with some material for advancing this question, by offering important and reliable data of a uniform character, have not been fulfilled. It appears, on the contrary, from the deep borings at Sperenberg, in Germany, reaching nearly to 4200 feet, that the increase of heat exhibits a remarkable retardation of its rate the deeper we descend. And even if we take convection and conductivity of the rocks into account, there are scarcely two localities where the same ratio of increase in the temperature has been observed, in some that ratio being more than treble that of others. There may once have been a uniform cooling of the original crust of the earth, now almost entirely removed or remodelled, but there is no doubt that this difference in the increase of temperature depends now either upon local generation of heat by hydro-chemical action or mechanical agencies of enormous power still at work. Thus in localising the variable increase of temperature, the *vera causa* both for the crumpling and metamorphism of rocks, for the formation of mountain chains, as well as for the origin of volcanic action, might be traced with more reliance than to seek to establish a general law that most probably no longer existed when the strata accessible to our examination were formed.

Leaving the dominion of theory and returning to the actual work of the geologist in the field, I need scarcely say that the task already accomplished has been truly gigantic. Patient research in the civilised countries of Europe, in the United States of North America, and most of the English colonies, as well as the work of travellers to almost every part of the globe—of the latter I wish only to allude to Baron von Richthofen's excellent late researches in China—have made us acquainted with such remarkable and innumerable data that it is impossible for any man, however studious he may be, to gain more than an imperfect knowledge of the material already accumulated.

The relations of the plutonic, metamorphic, sedimentary, and volcanic rocks to each other have been clearly defined, and most valuable facts have been brought together, from which the past history of our globe is being constructed, while the palæontologist has done his work equally well in classifying the wonderfully complex animal and vegetable life, always in harmony with the conditions of the earth's surface, gradually and during untold ages reaching, by evolution, the present stage of existence and perfection.

It would lead me too far to enter into a discussion of all the theories advanced as to the cause or causes by which mountain chains and seas have been formed, and volcanoes and earthquakes—because in most instances the two latter are intimately connected with each other—have been originated. Elie de Beaumont's theory of the sudden upheaval of parallel mountain chains, first published in 1833, although at one time finding great favour on the continent of Europe, was never adopted by any geologist of note, the teachings of Hutton and Lyell leaving no room for the doctrines of the paroxysmal school. Moreover, when the size and direction of mountain chains were taken into account, and the rocks composing them were carefully examined, it was found that the explanations offered by the eminent French geologist could not be adopted.

Many valuable publications have been issued upon these subjects, of which those of Robert Mallet may in many respects claim our greatest attention. Another work of great value is that of Prof. E. Suess, the eminent Professor of Geology in the University of Vienna, "Die Entstehung der Alpen," the formation of the Alps, in which this difficult question is treated in a masterly manner. Prof. Green's "Physical Geology" contains also an exhaustive *résumé* of the physics of the earth's crust, in which all the newest researches and theories are thoroughly examined and sifted by an excellent observer and practical geologist. However, there is another distinguished geologist and physicist, Constant Prevost, whom I should not omit to mention, he having already explained, in 1822, the elevation of mountain chains by tangential and lateral pressure, now mostly adopted as the correct theory. The deep-sea dredgings have also offered us considerable material to elucidate the former history of our globe, both from a stratigraphical and palæontological point of view.

The oscillation of land and sea is another subject of great importance that has hardly received that attention it deserves, whether we take the so-called glacial period into account or not. There may be with many geologists the fear of appearing heterodox if they state their belief that the hydrosphere is, like the lithosphere, subjected to considerable oscillations, by which great changes in the climate of the globe may have been brought about in past geological ages. For years I have held and stated this opinion.

However, I find that lately a great deal of attention has been paid to this subject. Thus, for instance, Ph. Fischer, Heinrich Bruns, and others, in discussing pendulum observations, have come to the conclusion that the sea-level is not a regular spheroid, but may vary many hundreds of feet even along the same parallel of latitude. Dr. Penck will also explain raised beaches and other signs of the glacial period by the oscillation of the sea-level. Penck's views in this respect are different from those of Adhemar and Croll.

Another factor for explaining great changes on the earth's surface, brought about in geological periods long past, has lately been put forward under the name of Tidal Evolution, a very ingenious theory, first worked out in its entirety by G. H. Darwin. It is based upon the action of the moon, once a part of our planet, on the earth, producing the tides and retarding its motion, as well as upon the reaction of the earth upon its satellite. Gradually the moon was driven away from our planet, and the length of day has thus at the same rate become more considerable.

However, when Prof. Robert Ball, in Dublin, and others attempt to make out that the former much larger tides, when the moon was closer to the earth, formed a powerful agent for the destruction of rocks existing at that time, and for the formation of newer beds from them, by which the thickness of the older sedimentary and fossiliferous strata can be explained, I think we have to pause before we can accept such a sequence.

Moreover, according to Sir William Thomson, there has not been any great change in the ellipticity of the earth's figure since its consolidation, consequently Mr. Darwin's views as to higher tides have to be modified, as he presupposes a more considerable ellipticity for his calculations. However, even assuming Prof. Ball's calculation, that when the moon was only 40,000 miles distant from the earth the tides at that time would rise and fall between 600 and 700 feet twice in twenty-four hours, to be correct, I have no doubt that it was long before the Cambrian or lowest fossiliferous rocks with which we are acquainted were deposited. The occurrence of numerous fossils in the oldest beds, belonging to animals that could live only in clear water, and minute ripple marks on the rocks, speak clearly against Prof. Ball's hypothesis.

This speculation in physical geography has already been tested by various geologists to account for the so-called marine denudation. This expression was first introduced by Sir Andrew Ramsay for the higher portions of ridges over large areas, that, if laid down on an imaginary plane, appear to have once formed one surface with a very gradual slope in one direction.

However, this peculiar appearance can, as I have repeatedly suggested in former publications, be easily explained by the fact that when the land gradually rose above the sea-level, abrasion on a gigantic scale must have taken place, by which, in the case of our Southern Alps, the whole had the appearance of a shallow dome, of which the western side was much steeper than the eastern, till the subaërial erosion by atmospheric agencies, or, as I called it, ridge-making, took place.

Before leaving this subject, to which I have devoted more time than perhaps I ought to have done, I may add that many speculations have been built upon it. Thus, Mr. O. Fisher attempts to prove that the ocean basin represents the scar whence the mass forming the moon separated from the earth.

Another cause of gradual retardation in the rotation of our planet, and to which, as far as I am aware, very little attention has hitherto been paid, is the increase of the bulk of our planet by meteorites and cosmic dust.

There is not the least doubt in my mind that matter, even in the most diffused state, cannot leave the outermost or gaseous portion of our planet, but that an enormous amount of matter in the form of meteorites must have been accumulated year by year. If we add to this the cosmic dust falling upon the surface of the earth, which, according to a calculation by Nordenskjöld, may amount to half a million tons yearly, the size of our planet must have been gaining in dimensions and weight to an almost inconceivable degree, even since a rich and diversified flora and fauna inhabited it. But even assuming that Nordenskjöld's estimate is far too high, and reducing it to a tenth, or to 50,000 tons yearly, the result of any calculation upon this basis is most astounding. Thus, if we take only a period of twenty millions of years, a short interval in the life-history of our planet, the cosmic dust falling during that time would add not less than 1,000,000,000,000 or one billion of tons.

And this result is obtained without accounting in any way for the further addition by the fall of meteorites, without doubt of very considerable magnitude. Such a factor, as Prof. von Nordenskjöld forcibly points out in his last work, ought certainly not to be overlooked if we wish to account for various changes in the form, position, and rate of rotation of our planet since it began to consolidate.

I am well aware that several scientific men, who have carefully examined some of the cosmic dust, have come to the conclusion that it is in most cases of terrestrial origin; but the fact remains that some of the dust collected shows its cosmic origin by its constituent parts, and that all the meteorites reach us from far beyond the atmosphere of our earth.

The importance of the great doctrine of evolution as first fully established by Darwin cannot be overestimated by the palæontologist. Applying the leading facts of the origin and distribution of animal and vegetable life, as at present existing, to the numberless past generations preserved in the marvellous stone-book of Nature, he is able to unravel more fully their history, to account for the missing leaves, and to estimate at their just value those few remaining, and of which he now and then is privileged to decipher a small portion. Darwin himself, in his classical chapter "On the imperfection of the geological record," in his "Origin of Species," has pointed out to us in his usual masterly manner how to avail ourselves of the scant material at our command, and how future discoveries, adding to the palæontological stock, will open out new vistas in the past history of our globe.

I need scarcely add that every new addition to our knowledge will assist us to gain more fully day by day an insight into the harmonious unity of the whole.

It is not yet a quarter of a century (1859) since the "Origin of Species" appeared, but if we compare our knowledge of palæontology at that time with that obtained at present, we find that striking progress has been made. Instead of a collection of facts, more or less loosely connected, we now possess a system of remarkable strength and harmony, a powerful aid to an inductive science like geology.

Evolution might be compared to an architect, who succeeds in raising an edifice of pure and noble proportions, placed upon a stable and firm foundation, from a large accumulated material of finely and ingeniously wrought building stones stored up promiscuously without any apparent plan or order.

Since the appearance of the "Origin of Species" I have always held this opinion; and I may be allowed to mention that as far back as 1862, in my opening address as first president of the Philosophical Institute, I spoke of this incomparable book as "the great work of the age."

The researches of the palæontologist have shown already convincingly that there are innumerable intermediate links between present species and those which lived in past ages. I may here, to give only one instance, refer to Huxley's important researches into the relations of the members of the family Equidæ, the Anchitherium, Hipparion, and Equus. At the same time the gulf between the different classes of vertebrates is being gradually bridged over by careful research. Thus Prof. O. C. Marsh has shown that the jurassic bird Archæopteryx from Solenhofen is closely connected with the Dinosaurs, generally considered to be most nearly allied to birds. Archæopteryx has besides true teeth in sockets, bi concave vertebræ, the pelvic bones are separate, and the metatarsals either separate or at least imperfectly united. American fossil birds, such as Ichthyornis, have also bi concave vertebræ (like fishes and some Saurians), and teeth in sockets. The skull of *Otontopteryx toliapicus*, found in the Isle of Sheppey, in the London Clay, has also true teeth in sockets.

There is, however, in palæobotany still a great deal that is in many respects unsatisfactory and inconclusive. This is mainly owing to the fragmentary material at our command, consisting mostly of leaves, the determination of which in many instances may lead us to wrong inferences. To give only one instance, I wish to refer to O. Feistmantel's latest researches on the palæozoic and mesozoic flora of Australia, with which our own fossil flora is closely connected.

The eminent palæontologist of the Indian Geological Survey comes to the conclusion that Phyllotheca, in Europe and Siberia of jurassic age, is palæozoic in New South Wales, and upper mesozoic in Victoria; Glossopteris, palæozoic in Australia, is jurassic in India and Russia. Noeggerathiopsis, beginning to appear in palæozoic beds in Australia, is represented by the jurassic Rhiptozamites in Siberia.

It is unquestionable that such conclusions, before they can be adopted, have to be confirmed by evidence of a still more reliable character than the present material for comparison can have afforded.

Returning to the physical conditions under which the surface of our globe has been formed and is still forming, I may here point out that since evolution has been adopted by most scientific men as a beacon to guide them to truth, the greater portion of the so-called uniformitarian school of geologists, following in the footsteps of Lyell, has become somewhat modified in its views, and may now be called the evolutional school. But let me hasten to add that Lyell himself, with his great love for truth, may be claimed as one of its first disciples, he having reviewed his own writings by the light Darwin held up to us, which is sure to advance geology even more than we can at present realise.

There is one question of great importance, in the solving of which both the geologist and the palæontologist have to go hand in hand with the archæologist. There is no doubt that the human race existed already in pliocene times; and if we can trust the reports of discoveries in Portugal and other portions of Southern Europe, man may have lived as early as the miocene age.

However, we want further and clearer evidence before this latter view can be adopted. If we consider the enormous space of time that separates us from our first ancestors, the oldest historical facts preserved seem to us as of to-day; and taking into account the wonderful progress the human race has made from the condition of the cave-dwellers, with their rude stone implements, to our present state of civilisation, we ought to look proudly upon the position mankind has attained. And we can therefore scarcely conceive the high degree of perfection, both physically and mentally, the human race may reach in future.

Although, as far as our researches go, the autochthones of New Zealand cannot boast of great antiquity when compared with the inhabitants of the Northern Hemisphere or of the tropical regions, there is nevertheless strong reason to believe that this country has been inhabited for a much longer time than was formerly generally assumed.

It is, however, possible, that some of the traces we have hitherto found of the oldest occupancy of these islands may have been left behind by occasional visitors, adventurers in search of new countries, or by crews of wrecked ships coming from distant shores.

But we have only begun to examine these questions; and although, as is always the case, the wiseacres will first shake their heads, if our researches are only continued without fear and without preconceived conclusions, we may be certain that valuable results will be in store for us.

The existence of loess beds, often of considerable thickness, in numerous parts of New Zealand, of which many have begun to be deposited before the beginning of our great glacier period, will be of great use, and offer us an excellent field for research in this direction. These beds being of subaërial origin, not only the remains of land animals are preserved in them, but we shall find in them also the traces of man. I may here mention the strange fact that the true nature of these beds has for a long time been misunderstood and misinterpreted by most English geologists. Even in the last edition of Lyell's "Elements of Geology," the loess of the Rhine is described as fluviatile loam, whilst the author himself shows that only the remains of land shells and land vertebrates are embedded in it. It has always been inconceivable to me how such an error should have remained so long uncorrected; the more so as, as far back as 1847, Alex. Braun, in "Leonhard and Bronn's Neues Jahrbuch," has shown the true state of things, and German geologists have repeatedly furnished new facts in illustration and given analyses of loess and of recent and older fluviatile deposits of the Rhine for comparison.

But, as I have previously pointed out, the peculiar nature of the loess deposits—the minute vertical capillary structure caused by the empty spaces once filled by the rootlets of innumerable generations of grasses—is a sure guide even to a tyro in geology. This structure amongst these localities is well exhibited in the fresh cuttings near Lyttelton.

I fear that the time allotted to me will not allow me to enter more fully into a review of what has already been accomplished to make geology an inductive science, and what remains still to be done, but I may be permitted to allude to one of the principal causes that retarded geology from taking its present position. This was the fear of the student to enter into antagonism with the established religious cosmogony. It is unnecessary to allude to the middle ages, because the stake or disappearance in the dungeons of the holy inquisition were the rewards of fearless physical research, and men like Galileo and Descartes were obliged to use often evasive language, unworthy of such great thinkers, in order to preserve their lives or freedom, and therefore my remarks will only apply to our own times. In proof of this I wish only to quote one work, "Vestiges of the Natural History of Creation," of which the first edition appeared in 1844. If we read this book at the present time, we can scarcely understand how it could have created such intense indignation amongst a large portion of the community, or that so much could have been written against it. Lyell himself, when publishing his "Principles of Geology," a work of a true philosopher, was, judging from some letters in his biography, very careful not to hurt too much the prejudices of his time, not wishing to mar the usefulness of his work. Even at the present time are there not thousands and thousands of well-meaning but narrow-minded persons, at once entering into strenuous opposition when there is any reference made to scientific cosmogony differing from that they have been accustomed to from their youth, and that cannot stand before the light of modern research?

However, the great principle of liberty for the teacher, so well expressed by the German word "Lehrfreiheit," cherished by the whole Teutonic race, a principle even preserved in the German universities during the darkest days of absolutism, is a safeguard of inestimable value, possessed fortunately also by our New Zealand University, the *Alma Mater* for whose advancement to the highest attainable position and general utility we ought willingly to devote our whole strength and best energies.

DUST-FREE SPACES [1]

WITHIN the last few years a singular interest has arisen in the subject of dust, smoke, and fog, and several scientific researches into the nature and properties of these phenomena have been recently conducted. It so happened that at the time I received a request from the Secretary of this Society to lecture here this afternoon I was in the middle of a research connected with dust, which I had been carrying on for some months in conjunction with Mr. J. W. Clark, Demonstrator of Physics in University College, Liverpool, and which had led us to some interesting results. It struck me that possibly some sort of account of this investigation might not be unacceptable to a learned body such as this, and accordingly I telegraphed off to

---

[1] Lecture to the Royal Dublin Society by Dr. Oliver J. Lodge, April

Mr. Moss the title of this afternoon's lecture. But now that the time has come for me to approach the subject before you I find myself conscious of some misgivings, and the misgivings are founded upon this ground: that the subject is not one that lends itself easily to experimental demonstration before an audience. Many of the experiments can only be made on a small scale and require to be watched closely. However, by help of diagrams and by not confining myself too closely to our special investigation but dealing somewhat with the wider subject of dust in general, I may hope to render myself and my subject intelligible if not very entertaining.

First of all, I draw no distinction between "dust" and "smoke." It would be possible to draw such a distinction, but it would hardly be in accordance with usage. Dust might be defined as smoke which had settled, and the term smoke applied to solid particles still suspended in the air. But at present the term "smoke" is applied to solid particles produced by combustion only, and "dust" to particles owing their floating existence to some other cause. This is evidently an unessential distinction, and for the present I shall use either term without distinction, meaning, by dust or smoke, solid particles floating in the air. Then "fog": this differs from smoke only in the fact that the particles are liquid instead of solid. And the three terms, dust, smoke, and fog, come to much the same thing, only that the latter term is applied when the suspended particles are liquid. I do not think, however, that we usually apply the term "fog" when the liquid particles are pure water: we call it then mostly either mist or cloud. The name "fog," at any rate in towns, carries with it the idea of a hideous, greasy compound. consisting of smoke and mist and sulphur and filth, as unlike the mists on a Highland mountain as a country meadow is unlike a city slum. Nevertheless the finest cloud or mist that ever existed consists simply of little globules of water suspended in air, and thus for our present purpose differs in no important respect from fog, dust, and smoke. A cloud or mist is, in fact, fine water-dust. Rain is coarse water-dust formed by the aggregation of smaller globules, and varying in fineness from the Scotch mist to the tropical deluge. It has often been asked how it is that clouds and mists are able to float about when water is so much heavier (800 times heavier) than air. The answer to this is easy. It depends on the resistance or viscosity of fluids, and on the smallness of the particles concerned. Bodies falling far through fluids acquire a "terminal velocity," at which they are in stable equilibrium—their weight being exactly equal to the resistance—and this terminal velocity is greater for large particles than for small; consequently we have all sorts of rain velocity, depending on the size of the drops; and large particles of dust settle more quickly than small. Cloud-spherules are falling therefore, but falling very slowly.

To recognise the presence of dust in air there are two principal tests: the first is the obvious one of looking at it with plenty of light, the way one is accustomed to look for anything else; the other is a method of Mr. John Aitken's, viz. to observe the condensation of water vapour.

Take these in order. When a sunbeam enters a darkened room through a chink, it is commonly said to be rendered visible by the motes or dust particles dancing in it; but of course really it is not the motes which make the sunbeam visible, but the sunbeam the motes. A dust particle is illuminated like any other solid screen, and is able to send a sufficient fraction of light to our eyes to render itself visible. If there are no such particles in the beam—nothing but clear, invisible air—then of course nothing is seen, and the beam plunges on its way quite invisible to us unless we place our eyes in its course. In other words, to be visible, light must enter the eye. [A concentrated beam was passed through an empty tube, and then ordinary air let in.]

The other test, that of Mr. Aitken, depends on the condensation of steam. When a jet of steam finds itself in dusty air, it condenses round each dust particle as a nucleus, and forms the white visible cloud popularly called steam. In the absence of nuclei Mr. Aitken has shown that the steam cannot condense until it is highly supersaturated, and that when it does it condenses straight into rain—that is, into large drops which fall. The condensation of steam is a more delicate test for dust than is a beam of light. A curious illustration of the action of nuclei in condensing moisture has just occurred to me, in the experiment—well known to children—of writing on a reasonably clean window-pane, with, say, a blunt wooden point, and then breathing on the glass: the condensation of the breath renders the writing legible. No doubt the nuclei are partially wiped away by the writing, and the moisture will condense into larger drops with less light-scattering power along the written lines than over the general surface of the pane where the nuclei are plentiful and the drops therefore numerous and minute. Mr. Aitken points out that if the air were ever quite dustless, vapour could not condense, but the air would gradually get into a horribly supersaturated condition, soaking all our walls and clothes, dripping from every leaf, and penetrating everywhere, instead of falling in an honest shower, against which umbrellas and slate roofs are some protection. But let us understand what sort of dust it is which is necessary for this condensing process. It is not the dust and smoke of towns, it is not the dust of a country road; all such particles as these are gross and large compared with those which are able to act as condensers of moisture. The fine dust of Mr. Aitken exists everywhere, even in the upper regions of the atmosphere; many of its particles are of ultra-microscopic fineness; one of them must exist in every raindrop, nay, even in every spherule of a mist or cloud, but it is only occasionally that one can find them with the microscope. It is to such particles as these that we owe the blue of the sky, and yet they are sufficiently gross and tangible to be capable of being filtered out of the air by a packed mass of cotton-wool. Such dust as this, then, we need never be afraid of being without. Without it there could be no rain, and existence would be insupportable, perhaps impossible; but it is not manufactured in towns; the sea makes it; trees and wind make it; but the kind of dust made in towns rises only a few hundred yards or so into the atmosphere, floating as a canopy or pall over those unfortunate regions, and sinks and settles most of it as soon as the air is quiet, but scarcely any of it ever rises into the upper regions of the atmosphere at all.

Dust, then, being so universally prevalent, what do I mean by dust-free spaces? how are such things possible? and where are they to be found? In 1870 Dr. Tyndall was examining dusty air by means of a beam of light in which a spirit-lamp happened to be burning, when he noticed that from the flame there poured up torrents of apparently thick black smoke. He could not think the flame was really smoky, but to make sure he tried first a Bunsen gas-flame and then a hydrogen flame. They all showed the same effect, and smoke was out of the question. He then used a red-hot poker, a platinum wire ignited by an electric current, and ultimately a flask of hot water, and he found that from all warm bodies examined in dusty air by a beam of light the up-streaming convection-currents were dark. Now of course smoke would behave very differently. Dusty air itself is only a kind of smoke, and it looks bright, and the thicker the smoke the brighter it looks; the blackness is simply the utter absence of smoke; there is nothing at all for the light to illuminate, and accordingly we have the blankness of sheer invisibility. Here is a flame burning under the beam, and, to show what real smoke looks like, I will burn also this spirit-lamp filled with turpentine instead of alcohol. *Why* the convection-currents were free from dust was unknown: Tyndall thought the dust was burnt and consumed: Dr. Frankland thought it was simply evaporated.

In 1881 Lord Rayleigh took the matter up, not feeling satisfied with these explanations, and repeated the experiment very carefully. He noted several new points, and hit on the capital idea of seeing what a cold body did. From the cold body the descending current was just as dark and dust-free as from a warm body. Combustion and evaporation explanations suffered their death-blow. But he was unable to suggest any other explanation in their room, and so the phenomenon remained curious and unexplained.

In this state Mr. Clark and I took the matter up last summer, and critically examined all sorts of hypotheses that suggested themselves, Mr. Clark following up the phenomena experimentally with great ingenuity and perseverance. One hypothesis after another suggested itself, seemed hopeful for a time, but ultimately had to be discarded. Some died quickly, others lingered long. In the examination of one electrical hypothesis which suggested itself we came across various curious phenomena which we hope still to follow up.[1] It was some months before what we now believe to be the true explanation began to dawn upon us. Meanwhile we had acquired various new facts, and first and foremost we found that the dark plane rising from a warm body was only the upstreaming portion of a dust-free *coat* perpetually being renewed on the surface of the body. Let me describe the appearance and mode of seeing it by help of a diagram. [For full description see *Philosophical Magazine* for March 1884.]

---

[1] For instance, the electric properties of crystals can be readily examined in illuminated dusty air; the dust grows on them in little bushes and marks out their poles and neutral regions, without any need for an electrometer. Magnesia smoke answers capitally.

Surrounding all bodies warmer than the air is a thin region free from dust which shows itself as a dark space when examined by looking along a cylinder illuminated transversely, and with a dark background. At high temperatures the coat is thick ; at very low temperatures it is absent, and dust then rapidly collects on the rod. On a warm surface only the heavy particles are able to settle—there is evidently some action tending to drive small bodies away. An excess of temperature of a degree or two is sufficient to establish this dust-free coat, and it is easy to see the dust-free plane rising from it. The appearances may also be examined by looking along a cylinder *towards* the source of light, when the dust-free spaces will appear brighter than the rest. A rod of electric-light carbon warmed and fixed horizontally across a bell-jar full of dense smoke is very suitable for this experiment, and by means of a lens the dust-free regions may be thus projected on to a screen. Diminished pressure makes the coat thicker. Increased pressure makes it thinner. In hydrogen it is thicker, and in carbonic acid thinner, than in air. We have also succeeded in observing it in liquids—for instance, in water holding fine rouge in suspension, the solid body being a metal steam tube. Quantitative determinations are now in progress.

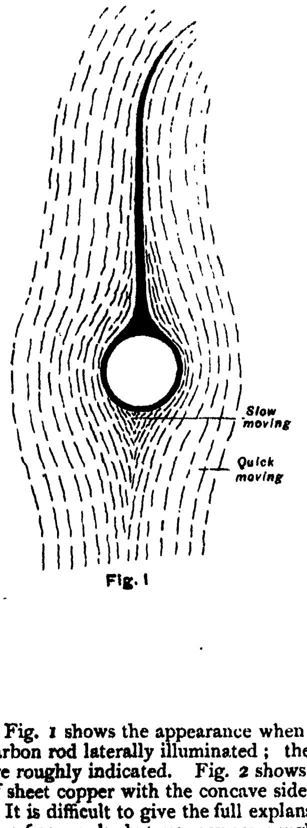

Fig. 1

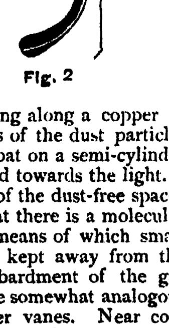

Fig. 2

Fig. 1 shows the appearance when looking along a copper or carbon rod laterally illuminated ; the paths of the dust particles are roughly indicated. Fig. 2 shows the coat on a semi-cylinder of sheet copper with the concave side turned towards the light.

It is difficult to give the full explanation of the dust-free spaces in a few words, but we may say roughly that there is a molecular bombardment from all warm surfaces by means of which small suspended bodies get driven outwards and kept away from the surface. It is a sort of differential bombardment of the gas molecules on the two faces of a dust particle somewhat analogous to the action on Mr. Crookes' radiometer vanes. Near cold surfaces the bombardment is very feeble, and if they are cold enough it appears to act towards the body, driving the dust inward—at any rate there is no outward bombardment sufficient to keep the dust away, and bodies colder than the atmosphere surrounding them soon get dusty. Thus if I hold this piece of glass in a magnesium flame, or in a turpentine or camphor flame, it quickly gets covered with smoke—white in the one case, black in the other. I take two conical flasks with their surfaces blackened with camphor black, and filling one with ice, the other with boiling water, I cork them and put a bell-jar over them, under which I burn some magnesium wire ; in a quarter of an hour or so we find that the cold one is white and hoary, the hot one has only a few larger specks of dust on it, these being of such size that the bombardment was unable to sustain their weight, and they have settled by gravitation. We thus see that when the air in a room is warmer than the solids in it—as will be the case when stoves, gas-burners, &c., are used—things will get very dusty ; whereas when walls and objects are warmer than the air —as will be the case in sunshine or when open fireplaces are used, things will tend to keep themselves more free from dust. Mr. Aitken points out that soot in a chimney is an illustration of this kind of deposition of dust ; and as another illustration it strikes me as just possible that the dirtiness of snow during a thaw may be partly due to the bombardment on to the cold surface of dust out of the warmer air above. Mr. Aitken has indeed suggested a sort of practical dust or smoke filter on this principle, passing air between two surfaces—one hot and one cold—so as to vigorously bombard the particles on to the cold surface and leave the air free.

But we have found another and apparently much more effectual mode of clearing air than this.[1] We do it by discharging electricity into it. It is easily possible to electrify air by means of a point or flame, and an electrified body has this curious property, that the dust near it at once aggregates together into larger particles. It is not difficult to understand why this happens : each of the particles becomes polarised by induction, and they then cling together end to end, just like iron filings near a magnet. A feeble charge is often sufficient to start this coagulating action. And when the particles have grown into big ones they easily and quickly fall. A stronger charge forcibly drives them on to all electrified surfaces, where they cling. A fine water-fog in a bell-jar, electrified, turns first into a coarse fog or Scotch mist, and then into rain. Smoke also has its particles coagulated, and a space can thus be cleared of it. I will illustrate this action by making some artificial fogs in a bell-jar furnished with a metal point. First burn some magnesium wire, electrify it by a few turns of this small Voss machine, and the smoke has become snow ; the particles are elongated, and by pointing to the charged rod indicate the lines of electrostatic force very beautifully : electrify further, and the air is perfectly clear.· Next burn turpentine and electrify gently : the dense black smoke coagulates into black masses over an inch long ; electrify further, and the glass is covered with soot, but the air is clear. Turpentine smoke acts very well, and can be tried on a larger scale : a room filled with turpentine smoke, so dense that a gas-light is invisible inside it, begins to clear in a minute or two after the machine begins to turn, and in a quarter of an hour one can go in and find the walls thickly covered with stringy blacks, notably on the gas-pipes and everything most easily charged by induction. Next fill a bell-jar full of steam, and electrify, paying attention to insulation of the supply point in this case. In a few seconds the air looks clear, and turning on a beam of light we see the globules of water dancing about, no longer fine and impalpable, but separately visible and rapidly falling. Finally make a London fog by burning turpentine and sulphur, adding a little sulphuric acid, either directly as vapour or indirectly by a trace of nitric oxide, and then blowing in steam. Electrify and it soon becomes clear, although it takes a little longer than before ; and on removing the bell-jar we find that even the smell of SO_2 has disappeared, and only a little vapour of turpentine remains. Similarly we can make a Widnes fog by sulphuretted hydrogen, chlorine, sulphuric acid, and a little steam. Probably the steam assists the clearing when gases have to be dealt with. It may be possible to clear the air of tunnels by simply discharging electricity into the air—the electricity being supplied by Holtz machines, driven say by small turbines—a very handy form of power, difficult to get out of order. Or possibly some hydro-electric arrangement might be devised for the locomotive steam to do the work. I even hope to make some impression on a London fog, discharging from lightning-conductors or captive balloons carrying flames, but it is premature to say anything about this matter yet. I have, however, cleared a room of smoke very quickly with a small hand machine.

It will naturally strike you how closely allied these phenomena must be to the fact of popular science that "thunder clears the air." Ozone is undoubtedly generated by the flashes, and may have a beneficial effect, but the dust-coagulating and -expelling power of the electricity has a much more rapid effect, though it

[1] See NATURE, July 26, 1883 (p. 297).

may not act till the cloud is discharged. Consider a cloud electrified slightly; the mists and clouds in its vicinity begin to coagulate, and go on till large drops are formed, which may be held up by electrical action, the drops dancing from one cloud to another and thus forming the very dense thunder-cloud. The coagulation of charged drops increases the potential, as Prof. Tait points out, until at length—flash—the cloud is discharged and the large drops fall in a violent shower. Moreover, the rapid excursion to and fro of the drops may easily have caused them to evaporate so fast as to freeze, and hence we may get hail.

While the cloud was electrified, it acted inductively on the earth underneath, drawing up an opposite charge from all points, and thus electrifying the atmosphere. When the discharge occurs this atmospheric electrification engages with the earth, clearing the air between, and driving the dust and germs on to all exposed surfaces. In some such way also it may be that "thunder turns milk sour," and exerts other putrefactive influences on the bodies which receive the germs and dust from the air.

But we are now no longer on safe and thoroughly explored territory. I have allowed myself to found upon a basis of experimental fact a superstructure of practical application to the explanation of the phenomena of nature and to the uses of man. The basis seems to me strong enough to bear most of the superstructure, but before being sure it will be necessary actually to put the methods into operation and to experiment on a very large scale. I hope to do this when I can get to a suitable place of operation. Liverpool fogs are poor affairs, and not worth clearing off. Manchester fogs are much better and more frequent, but there is nothing to beat the real article as found in London, and in London if possible I intend to rig up some large machines and to see what happens. The underground railway also offers its suffocating murkiness as a most tempting field for experiment, and I wish I were able already to tell you the actual result instead of being only in a position to indicate possibilities. Whether anything comes of it practically or not, it is an instructive example of how the smallest and most unpromising beginnings may, if only followed up long enough, lead to suggestions for large practical application. When we began the investigation into the dust-free spaces found above warm bodies we were not only without expectation, but without hope or idea of any sort, that anything practical was likely to come of it: the phenomenon itself possessed its own interest and charm.

And so it must ever be. The devotee of pure science never has practical developments as his primary aim; often he not only does not know, but does not in the least care, whether his researches will ever lead to any beneficial result. In some minds this passive ignoring of the practical goes so far as to become active repulsion; so that some singularly biased minds will not engage in anything which seems likely to lead to practical use. I regard this as an error, and as the sign of a warped judgment, for after all man is to us the most important part of Nature; but the system works well nevertheless, and the division of labour accomplishes its object. One man investigates Nature impelled simply by his own genius and because he feels he cannot help it: it never occurs to him to give a reason for or to justify his pursuits. Another subsequently utilises his results, and applies them to the benefit of the race. Meanwhile, however, it may happen that the yet unapplied and unfruitful results evoke a sneer, and the question, "Cui bono?" the only answer to which question seems to be: No one is wise enough to tell beforehand what gigantic developments may not spring from the most insignificant fact.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The following are the University and College lectures in natural science for the summer term:—

In the Physical Department of the Museum Prof. Clifton lectures on the instruments and methods of measurement employed in optics; Mr. Heaton lectures on problems in elementary physics; and practical instruction is given by the Professor and Messrs. Heaton and Walker. At Christ Church Mr. Baynes lectures on conduction of heat, and gives practical instruction on the measurements of electricity and magnetism; at Balliol Mr. Dixon lectures on elementary electricity and magnetism.

In the Chemical Department of the Museum Dr. Odling will hold an informal discussion on chemical constitution, Mr. Fisher lectures on inorganic and Dr. Watts on organic chemistry. At Christ Church Mr. Harcourt lectures on quantitative analysis and Mr. Veley on the relation between the physical properties and the constitution of organic compounds.

In the Morphological Department of the Museum Prof. Moseley lectures on the relations of the anthropoid apes and man, Mr. S. Hickson on the embryology of the chick, Mr. Jackson on Osteological Types, Mr. Poulton on Descriptive Histology, Mr. Morgan on Odontography, and Mr. Barclay-Thompson on the Anatomy of the Sauropsida.

In the Physiological Department Prof. Burdon-Sanderson lectures on the Chemical Processes of the Animal Body; at Magdalen Mr. Yule lectures on Practical Physiology.

Prof. Prestwich lectures on the Strata in the Neighbourhood of Oxford, and gives practical instruction in the field on the days following his lectures.

Prof. Gilbert will give an introductory lecture on May 6, on the Sources of the Constituents of Plants—the Soil, the Atmosphere. Dr. Tylor lectures on the Development of Arts and Sciences.

Prof. Pritchard concludes his course on the Planetary Theory, and will give a public lecture on his recent journey to Egypt in order to measure the absorptive power of the atmosphere on the light of the stars.

SCIENTIFIC SERIALS

American Journal of Science, April.—Recent explorations in the Wappinger Valley limestone of Duchess County, New York, by Prof. William B. Dwight. To the paper is appended a plate of the Wappinger Valley fossils.—Description of the Kettle-Holes near Wood's Hall, Massachusetts, with map of the district showing the positions and direction of the larger diameter of the Holes, by Prof. B. F. Koons.—Examination of Mr. Alfred R. Wallace's modification of the physical theory of secular changes of climate (second paper), by Dr. James Croll. Here the question is studied from the physical standpoint, and it is argued that a geographical change in the crust of the earth is not necessary to remove the Antarctic ice.—A contribution to the geology of Rhode Island (continued), by T. Nelson Dale.—On Mesozoic Dicotyledons (Angiosperms), by Lester F. Ward.—On the tourmaline and associated minerals of Auburn, Maine, by George F. Kunz.—On andalusite from Gorham, Maine, by the same author.—On the white garnet from Wakefield, Canada, by the same author.—Horizontal motions of small floating bodies in relation to the validity of the postulates of the theory of capillarity, by John Le Conte.—The principal characters of American Jurassic Dinosaurs; Part vii., the order Theropod (with plates 8 to 14), by Prof. O. C. Marsh.—A new order of extinct Jurassic reptiles (*Macelognatha*), (one illustration, *M. vagans*), by the same author.

THE first article in the *Journal of Botany* for April is a monograph, by Dr. Masters, on the singular "umbrella pine" of Japan, *Sciadopitys verticillata*. The most important points which he brings out are that the true leaves of *Sciadopitys* are the homologues of the true or primordial leaves of *Pinus*; that the so-called "needles" of *Sciadopitys*, although occupying the same relative position as the leaves of *Pinus*, are not necessarily morphologically homologous with them; and that the bracts of the cone of *Sciadopitys* are homologous with the true leaves of that plant, and also with the bracts of Abietineæ generally.

THE most important article in the *Nuovo Giornale Botanico Italiano* for January 1884 is one by Sig. A. Borzi, on a parasitic organism of a very low type which he finds in the ordinary cells of *Spirogyra crassa*, and to which he gives the name *Protochytrium Spirogyræ*. In its systematic position it displays, on the one hand, affinities with the Myxomycetes, on the other hand, with such genera of Chytridiaceæ as *Woronina*, *Rozella*, and *Olpidiopsis*. The entire absence of a cell-nucleus identifies it, according to the author, with Klein's family of Hydromyxaceæ, along with *Monas*, *Vampyrella*, *Monadopsis*, and *Protomyxa*. Its ordinary condition is that of a naked mass of protoplasm, endowed with amœboid movements, and living on the chlorophyllaceous contents of the cells of the host, these plasmodia having the power of coalescing like myxamœbæ; but it also has an encysted state, and in certain conditions propagates itself by the production of uniflagellate zoospores.

Rendiconti del Reale Istituto Lombardo, March 6.—Observations made at Milan on the passage of the atmospheric waves produced by the Krakatoa eruption, by E. G. Schiaparelli.—On a sensible deviation observed in the plumb-line between Milan and Genoa, by E G. Celoria.—On a hitherto neglected sulcus or depression frequently occurring in the frontal bone of the human skull between the boss and the temporal eminence, by Prof. G. Zoja.

March 20.—Obituary notice of the late Quintino Sella, by Prof. T. Taramelli.—Memoir on Antonio Angeloni Barbiani and his literary productions, by E. B. Prina.—Biological notice of *Alosa vulgaris* and *Salmo carpio*, inhabiting the Italian and sub-Alpine lakes, by Prof. P. Pavesi.—On the complete integers of some classes of partially derived equations of any order with two independent variants, by Prof. G. Pennacchietti.—Note on the quantitative determination of alogenous bodies, by P. Ritter-Zähony.—On the two human parasites *Anguillula intestinalis* and *A. stercoralis*, by E. C. Golgi and A. Monti.—Absolute values of the magnetic elements in Milan for the year 1883, by Dr. Ciro Chistoni.

Rivista Scientifico-Industriale, March 15.—Note on Wroblewski's experimental studies on the liquidation of hydrogen.—On the variation in the electric resistance of solid and pure metallic wires according to the temperature, by Prof. Angelo Emo.—On the pretended spontaneous combination of oxygen and hydrogen without increase of temperature effected by the exclusion of light, by L. Ricciardi.—On the migration of *Fuligula rufina* and *Erismatura leucocephala*, Scop., by Dante Roster.

Atti della R. Accademia dei Lincei, March 2.—Report on Alfredo Capelli's monograph on the composition of the groups of substitutions, by S. Battaglini.—Report on Prof. G. Bellonci's memoir on blastopore and the primitive line of the vertebrates, by S. Todaro.—Remarks on a group of curves of the fourth order, by Francesco Brioschi.—An experimental refutation of the hypothesis that every double link between carbon and carbon causes an increase of molecular refraction by a constant quantity, by Rodolfo Nasini.—On the stratification of the serpentine rocks in the Apennines, part i., by Torquato Taramelli.—Note on barometric hypsometry, by Aurelio Lugli.

March 16.—Obituary notice of the late Quintino Sella, by S. Maggiorani.—Meteorological observations at the Observatory of the Campidoglio during the months of January and February.

March 23.—On some unpublished and unknown works of Bartolomeo Marliani, by Enrico Narducci.—A chemical analysis of some brass and bronze objects found at the lacustrine station of Benaco, in Lombardy, by Luigi Pigorini.—Report on the antiquities discovered in various parts of Italy during the month of February 1884, by S. Fiorelli.—On barometric hypsometry, second note, by S. Tacchini.—Absolute values of the magnetic elements in Rome for the year 1883, by S. Tacchini.—On the stratification of the serpentine rocks in the Apennines, part ii., by Torquato Taramelli.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 3.—"Spectroscopic Studies on Gaseous Explosions." By Professors Liveing and Dewar.

Having occasion to observe the spectrum of the flash of a mixture of hydrogen and oxygen fired in a Cavendish eudiometer, the authors were struck by the brightness, not only of the ubiquitous yellow sodium line, but of the blue calcium line and the orange and green bands of lime, as well as of other limes which were not identified. The eudiometer being at first clean and dry, the calcium must be derived either from the glass or from some spray of the water over which the gases with which the eudiometer was filled had been confined. It seemed incredible that the momentary flash should detach and light up lime from the glass, but subsequent observations have pointed to that conclusion. Experiments were subsequently made on the flash of the combining gases inclosed in an iron tube, half an inch in diameter and about three feet long, closed at one end with a plate of quartz, held in its place by a screw-cap and made tight by leaden washers.

The tube was placed so that its axis might be in line with the axis of the collimator of a spectroscope, and the flash observed as it travelled along the tube.

It was seen at once that more lines made their appearance in the iron tube than in the glass vessel, and one conspicuous line in the green was identified in position with the E line of the solar spectrum. Several other lines were identified with lines of iron by comparison with an electric spark between iron electrodes. There could be no doubt that the flash in an iron tube gave several of the spectral lines of iron. The authors supposed that this must be due to particles of oxide shaken off the iron by the explosion, and proceeded to try the effect of introducing various substances in fine powder, and compounds, such as oxalates, which would give fine powders by their decomposition in the heat of the flame. Several interesting observations were made in this way. When some lithium carbonate was introduced, not only were the red, orange, and blue lines of lithium very brilliant, but the green line hardly less so. After the lithium had once been introduced into the tube, the lithium lines continued to make their appearance even after the tube had been repeatedly washed. When the lithium had been freshly put in, the red line was observed to be much expanded, very much broader than the line given by lithium in a Bunsen burner reflected into the slit for comparison. The light was dazzling unless the slit was very narrow; and it was noticed that if the spark by which the gas was fired was at the distant end of the tube, so that the flame travelled along the tube towards the slit, there was a reversal of the red line; a fine dark line was plainly visible in the middle of the band. When the spark was at the end of the tube next the slit, no reversal was, in general, seen. Later observations showed that some other metallic lines might be reversed in this way, and photographs taken of the reversals. These observations with the eye on the reversal of the red lithium line were made with a diffraction grating, and were repeated many times. They show that there are gradations of temperature in the flame, and that the front of the advancing wave of explosion is somewhat cooler than the following part. The combination of the gases is not so instantaneous that the maximum temperature is reached at once. When some magnesia was put into the tube the continuous spectrum was very bright, but the iron lines were still brighter. No line which could be identified as due to magnesium was observed with certainty; there was only a doubtful appearance of *b*. With sodium, potassium, and barium carbonates, only the lines usually seen when salts of those metals are introduced into a flame were noticed; but eye observations of this kind are extremely trying, on account of the suddenness of the flash and the shortness of its duration. Thallium gave the usual green line.

Subsequently the interior of the tube was bored out so as to present a smooth bright surface of iron, and the iron lines which were conspicuous in the flash were noted.

For the purpose of identification the pointer in the eye-piece was first placed on one of the strong iron lines given by the electric discharge between iron electrodes, and then, the discharge being stopped but the field sufficiently illuminated, the eye was fixed steadily on the pointer while the gas in the tube was exploded. In this way it was not difficult to see whether any given line was very bright in the flash. The lines thus identified were those having the wave-lengths about 5455, 5446, 5403, 5396, 5371, 5327, 5269 (E), 5167 (*b*4). These lines were all many times observed in the way described, and as a rule were always present in the flash. Lines with wave-lengths about 5139 and 4352 were seen, and may possibly have been due to iron, and several more lines were seen occasionally, but were not so regularly seen that they could be well identified. The lines λ 4923 and λ 4919 were specially looked for, but neither of them could be seen. A group of blue lines were noticed, and were afterwards identified by photography, a method much less trying than observations by eye. To give intensity to the photographs ten or twelve flashes were usually taken in succession without any shift of the instrument, so as to accumulate their effects in one photograph. For identification the spark between iron electrodes was also photographed, but with a shutter over the lower part of the slit, so that the image of the spark should occupy only the upper part of the field.

Some sixty of the iron lines in the indigo, violet, and ultra violet were thus photographed.

As a rule no iron lines above O make their appearance; in a few plates T is visible, and it is possible that other lines may be obscured by the water spectrum, which always comes out and extends from near *s* to below R. Above T no line at all is visible in any of the photographs, though the spark lines come out strongly enough, and several of the strongest groups of iron lines, both of spark and arc lines, are in the region beyond T.

Other experiments were made with explosions of carbonic oxide and oxygen, and with coal-gas and oxygen. The explosions of these gases were attended with much more continuous spectrum, and the metallic lines were not always as well developed as they vere with hydrogen and oxygen, but on the whole there were as nany metallic lines photographed from the flashes of carbonic xide as from those of hydrogen.

When the iron tube was lined with copper foil, only one copper ine in the visible spectrum, λ 5105, was seen, and in the ultra-iolet two lines, λ 3272 and λ 3245·5. All three lines were very trong, and the two ultra-violet lines were in some cases reversed. These lines were also frequently developed when no copper lining vas in the tube, probably from the brass of the small side ubes.

Copper also gave a line in the indigo, λ 4281 about, decidedly ess refrangible than the copper line, λ 4275, coincident apparently vith the strong edge of one of the bands developed when a copper alt is held in a Bunsen burner.

A lining of copper which had been electro-plated with nickel leveloped only one nickel line, λ 5476, in the visible part of the pectrum, but gave by photography twenty-five lines in the ultra-iolet.

When copper wire electro-plated with cobalt was put into the ube twenty-two cobalt lines in the violet and beyond were hotographed.

No other metal gave anything like the number of lines that vere given by iron, nickel, and cobalt.

A lining of lead gave the lines λ 4058, 3683, and 3639 strongly, nd these lines were frequently developed, though less strongly, vhen there was no lead lining; the metal being without doubt lerived from the leaden washers used to make the ends of the ube air-tight.

A strip of silver gave the lines λ 3381·5 and 3278, and these lnes were sometimes reversed. No trace of the channelled pectrum of silver was developed even when silver oxalate was ut into the tube, and furnished plenty of silver dust after the rst explosion.

A magnesium wire about 2 millims. thick and two-thirds the ength of the tube gave the *b* lines very well; that is to say b_1 and $_2$ were well developed, and b_4 was also seen, but as the iron and nagnesium components of b_4 are very close together, and the ron line had been observed before the introduction of the mag-esium, it was not possible to say with certainty whether or not he magnesium line were present too. No other magnesium line ould be detected. The blue flame line was carefully looked for, ut could not be seen. The photographs showed none of the nagnesium triplets in the ultra-violet, nor any trace of the strong ine λ 2852, which appears in the flame of burning magnesium, nd is yet more conspicuous in the arc when that metal is resent.

Metallic manganese, introduced into the tube in coarse powder, ave the group at wave length about 4029 with much intensity, ut no other manganese line with certainty. In the visible part f the spectrum the channellings in the green due to the oxide vere visible.

A lining of zinc produced no zinc line, and zinc-dust gave only very doubtful photographic impression of the line λ 3342. A trip of cadmium gave no line of that metal either in the visible r in the ultra-violet part of the spectrum.

Tin, aluminium, bismuth, and antimony, also failed to produce line of any of those substances, and so did mercury which was pread over copper foil made to line the tube.

Thallium spread as amalgam over the copper lining gave the nes λ 3775·6, 3528·3 and 3517·8.

Chromium was introduced as ammonium bichromate, which of ourse left the oxide after the first explosion. This gave the chro-ium lines with wave-lengths about 5208, 5205, 5204, 4289, 274·5, 4253·5, very well and persistently, also the lines with vave-lengths about 3605, 3592·5, 3578·5.

Sodium salts (carbonate, chloride) developed the ultra-violet ne λ 3301; and potassium salts give the pair of lines about wave-ngth 3445; but no more refrangible line of either metal was epicted on the photographs. Lithium carbonate gave, besides e lines in the red, orange, green, and blue, the violet line, 4135·5; but no more refrangible line.

Photographs of a flame of mixed coal-gas and oxygen, in which iron wire was burnt, show, as might be expected, the same n lines as are developed in the flash of the detonating gases, d of the same relative intensities. These intensities are not e the same relatively as they are in the arc spectrum. Thus lines λ 3859, 3745, 3737, 3735, and 3719 come out in great ngth, much stronger than the lines λ 3647, 3631, 3618, which remarkably strong in the arc.

German-silver wire, burnt in the flame of coal-gas and oxygen, gave the same nickel lines as were given by nickel in the detonating gases, as well as those of copper and lead.

Copper wire gave, besides the lines λ 3272, 3245·5, a set of bands in the blue, which correspond with those given by copper salts in flames, and are probably due to the oxide.

The greater part of the lines observed in the flames of the exploding gases have been observed by the authors to be reversed when the several metals were introduced into the arc in a crucible of lime or magnesia; which is quite in accord with the supposition that the metals experimented on are volatile, and emit as well as absorb these particular rays, at temperatures lower than that of the arc.

That iron is volatile at a temperature below the fusing point of platinum, which is about 1700° C., has been pointed out by Watts (*Phil. Mag.*, vol. xlv. p. 86), who observed in the flame of a Bessemer converter almost all the green and blue lines of iron which we have seen in the exploding gases, besides one or two lines which we have not observed or identified. Having regard to this volatility of iron, it does not seem so surprising that iron lines should be observed accompanying those of hydrogen to great heights in the sun's atmosphere as that they should not be always seen there.

Copeland (Copernicus, December, 1882) observed in the spectrum of the great comet of 1882 four lines nearly identical with four of the green lines of iron seen in the detonating gas.

It is remarkable that such volatile metals as mercury, zinc, and cadmium should give no lines in the flame of the exploding gases.

The absence of any metallic lines more refrangible than T in the flame of the exploding gases may be in part due to a falling off in the sensibility of the photographic plates for light of shorter wave-lengths; but as the spark lines of iron seem to be quite as strongly depicted on the plates in regions of the spectrum far above T as they are in the regions below, want of sensitiveness in the plates cannot be the only reason for the absence of higher lines, but probably the emissive power of the metals for these lines is feeble at the comparatively low temperature of the flame.

Gouy (*Comp. R.*, 1877, p. 232), using a modification of Bunsen's burner fed with gas mixed with spray of metallic salts, observed at the point of the inner green flame three or four iron lines which have not been observed in the flame of the detonating gas, the lines b_1 and b_2 of magnesium, two cobalt lines in the blue which are not seen in the detonating gas, one line of zinc, and one of cadmium, and the two strong green rays of silver. Can the appearance of these rays under these circumstances imply that the temperature of the inner green cone of a Bunsen burner, when the proportion of air to coal-gas is near the exploding point, is higher than that of the explosion of hydrogen and oxygen?

The interesting theoretical questions which are suggested by the facts recorded in this paper the authors leave for further discussion.

Linnean Society, April 17.—Alfred W. Bennett, M.A., in the chair.—Messrs. R. Lloyd Patterson and Benjamin Lomax were elected Fellows.—Dr. J. Poland exhibited under the microscope a series of preparations, stained by reagents, illustrating the *Bacillus* of anthrax of man. He remarked on the severely fatal character of the malady, not only in this country but on the Continent and certain places abroad. The *Bacillus*-spores were in many instances doubtless conveyed in the dried skins and hides imported from abroad, and under favourable conditions inoculated those handling the dried hides, &c., the germs developing in the usual manner of the low vegetable organisms.—Dr. R. C. A. Prior drew attention to specimens of *Draba aizoides* obtained from Pennard Castle, Swansea, said to be the only locality where this plant grows wild in England.—The ninth contribution to the ornithology of New Guinea, by Mr. R. Bowdler Sharpe, was read, and it dealt with some few birds obtained by Mr. A. Goldie in the Astrolabe Mountains.—A paper was read by the Rev. J. M. Crombie on the algo-lichen-fungal hypothesis. The author gave a brief sketch of the hypothesis as enunciated by Schwendener, Bornet, and others, noticing the various arguments and illustrations which had been adduced in its support. He then discussed the result which had been obtained from experiments in lichen-culture, whether from the spore or by synthesis—observing that in both cases these were confessedly but small, owing to the very great difficulty of cultivating beyond a rudimentary stage except under the same atmospherical conditions in which they grow in nature. Two fatal objections he said might be taken to the theory: '(1) the one having reference to the very peculiar nature of the parasitism it assumed, and the other (2) to the fact that notwithstanding a similarity of appearance there were in reality no true fungal-mycelia nor true algal-colonies in lichens. As to any direct genetic or any indirect parasitical connection between the gonidia of lichens and the hyphal filament, it was further pointed out that none such existed, but that on tracing the evolution of the thallus from the germinating spore, it is seen that the gonidia originate in the cellules of the first parenchymatous tissue formed upon the hypothallus, and that subsequently through the resorption of the lower portion of the cortical stratum they became free, and constituted the thin gonidial stratum. Where seen lying amongst the medullary hyphæ they are often attached to these, not as the result of any copulation, but by means of the lichenin which permeates the whole thallus. The origin of the gonidia and their relation to the rest of the lichen thallus, the author stated in conclusion, thus belonged to the very elements of morphological botany.—There followed a note on a remarkable variation in the leaf of *Banksia marginata* observed by Mr. J. G. Otto Tepper in South Australia; and he questions whether this might not be regarded as the spontaneous production of a new variety or species or the remnant of an extinct form.—Mr. R. A. Rolfe then discoursed on *Hyalocalyx*, a new genus of Turneraceæ from Madagascar. According to Dr. J. Urban (the latest authority) the order consists of five genera and eighty-three species distributed in America from North Carolina and Mexico to the Argentine Republic, and in Africa from Abyssinia to Mozambique and the Cape of Good Hope, while outliers are found in the islands of Zanzibar and Rodriguez. The unique example now added was obtained by Dr. C. Rutenberg on Nossi-bé, a small island on the north-west of Madagascar. Its peculiarities incline Mr. Rolfe to regard it as the type of a new genus with a position between *Mathurina* and *Turnera*; its most remarkable character being its glassy transparent calyx totally destitute of chlorophyll.

Chemical Society, April 17.—Dr. Perkin, F.R.S., president, in the chair.—A ballot was held, and the following gentlemen were elected Fellows:—W. D. Borland, J. C. Bose, W. D. Crumbie, A. F. Dimmock, H. G. Greenish, W. J. Grey, J. Gaskell, J. W. Pratt, A. G. Perkin, W. H. Perkin (jun.), G. H. Wainwright.—The following papers were read:—On the influence of incombustible diluents on the illuminating power of ethylene, by P. F. Frankland. Mixture of ethylene with carbonic anhydride, nitrogen, aqueous vapour, and air, have a lower illuminating power than pure ethylene. Mixtures with oxygen have a greater illuminating power than pure ethylene; carbonic anhydride is the most and air the least prejudicial to the illuminating power.—On trichloropyrogallol, by C. S. S. Webster. The author has prepared mairogallol by the method of Stenhouse and Groves. He finds that the reaction can be separated into two stages, in the first of which trichloropyrogallol is formed. Its reactions are identical with tribromopyrogallol. The author confirms the statements of Stenhouse and Groves in almost every particular.—The synthesis of galena by means of thiocarbamide, by J. Emerson Reynolds. The author has succeeded in coating glass vessels, brass tubes, &c., with a nitrous galenoid coating, by the decomposition of an alkaline solution of lead tartrate with sulphur urea.—On the analysis of Woodall Spa, by W. T. Wright. This spring contains a large amount of bromine (49·7 parts per million) and iodine (5·21 per million); it is much richer in these elements than any other spring in this country.—On the critical temperature of heptane, by T. E. Thorpe and A. W. Rücker. By calculation it is found to be about 281°.

SYDNEY

Linnean Society of New South Wales, February 27.—The following papers were read:—Monograph of the Australian sponges, by R. von Lendenfeld, Ph.D., part 1. This paper is introductory to a monograph upon the Australian sponges, large materials for which have already been accumulated by the author, partly from his own collections, and partly from those in the Museums of Christchurch and Dunedin, New Zealand, and of Adelaide, South Australia. The real investigation of this branch of the Cœlenterata may be said to begin with the work of Grant, 1826; to have risen to a new and much higher level under Schulze, 1875-1881, and to have been continued by Lollas, Keller, Vosmaer, Marshall, the author, and others, with continually increasing success up to the present time. A sufficient account of the bibliography of the Spongida is presented in the paper to enable those interested to find any desired information upon the subject, a matter of no small difficulty at present.—The *Scyphomedusæ* of the southern hemisphere, by R. von Lendenfeld, Ph.D., part 1. The *Scyphomedusæ* or "jelly-fish" appear to be more numerous in the southern than in the northern hemisphere. Of the 210 known species, 104 have already been found in the former, and as the animals of that hemisphere are not nearly so well known as those of the northern, the number of southern species must doubtless be much greater than that mentioned. Only twenty-six of the 104 southern species are Australian, but this apparent poverty of the Medusæ of our shores is due to the limited investigation that has been made. In this paper all the species of this hemisphere are described.—Notices of some new fishes by William Macleay, F.L.S. Four species are here described. Two of them, *Platycephalus longispinis* and *Urolophus bucculentus* were taken in the trawl in deep water outside the Heads of Port Jackson. The third, *Petroscirtes wilsoni*, was found by Mr. J. D. Wilson at the North Shore; and the fourth, *Athirinosoma jamiesoni*, was a small freshwater fish from the Bæmer, one of the head waters of the Brisbane River.—On the improvement effected by the Australian climate, soil, and culture on the Merino sheep, by P. N. Trebeck. In this paper Mr. Trebeck traces the changes and improvement which wool has undergone in Australia since the first introduction of German and Silesian sheep. Samples of the wool of all the periods and flocks alluded to were exhibited. Mr. Trebeck concludes his paper by stating his opinion that the whole of the country on our western watershed was eminently suitable for the Merino sheep, and that we only required the fostering assistance of an intelligent Government to keep in the front ranks of the wool-producing countries of the world.
